TABLE OF CONTENTS

Monday, May 2 10:50 a.m. – 12:30 p.m.

Session: Silicon and CMOS MEMS Resonators
Room: Grand Ballroom C
Session Chair: Sheng-Shiang Li, National Tsing Hua University

Monday, May 2 10:50 a.m. – 12:30 p.m.

Session: Time Transfer and Time Scales
Room: Seacliff Rooms
Session Chair: Samuel Stein, Symmetricom

Monday, May 21:30 p.m.-3:30 p.m.

Session: Fountain Clocks
Room: Grand Ballroom B
Session Chair: Robert Lutwak, Symmetricom

Monday, May 21:30 p.m.-3:30 p.m.

Session: New Material Applications
Room: Grand Ballroom C
Session Chair: Ralf Lucklum, Tech. Univ. of Magdeburg

Monday, May 21:30 p.m.-3:30 p.m.

Session: Phase Noise Measurement and Modeling
Room: Seacliff Rooms
Session Chair: Warren Walls, US Naval Observatory

Monday, May 23:50 p.m. – 5:50 p.m.

Poster Session: Resonators
Room: Pacific Concourse - Area 1
Session Chair: Yoonkee Kim, US Army

Monday, May 2 3:50 p.m. – 5:50 p.m.

Session: Microwave Frequency Standards I
Room: Poster Area 3
Session Chair: Svenja Knappe, NIST

Monday, May 2 3:50 p.m. – 5:50 p.m.

Poster Session: Oscillatorsm Sensors and Transducers I
Room: Pacific Concourse **-** Area 4
Session Chair: Christine Klemenz Rivenbark, Krystal Engineering LLC

Monday, May 2 3:50 p.m. – 5:50 p.m.

Poster Session: Timekeeping, Time and Frequency Transfer, GNSS Applications I
Room: Pacific Concourse - Area 5
Session Chair: Patrizia Tavella, INRIM

Monday, May 2 3:50 p.m. – 5:50 p.m.

Poster Session: Optical Frequency Standards & Applications I
Room: Pacific Concourse **-** Area 6
Session Chair: Pierre Thomann, Universite de Neuchatel

Tuesday, May 3 8:30 a.m. – 11:00 a.m.

Session: Ion Clocks
Room: Grand Ballroom B
Session Chair: Eric Burt, JPL/NASA

Tuesday, May 3 8:30 a.m. – 11:00 a.m.

Session: Novel structures for MEMS Resonators
Room: Grand Ballroom C
Session Chair: Gianluca Piazza, University of Pennsylvania

Tuesday, May 3 8:30 a.m. – 11:00 a.m.

Session: Two Way Optical and Microwave Links
Room: Seacliff Rooms
Session Chair: Mizuhiko Hosokawa, NICT

Tuesday, May 3 1:30 p.m. – 3:30 p.m.

Session: Combs
Room: Grand Ballroom B
Session Chair: Scott Crane, USNO

Tuesday, May 3 1:30 p.m. – 3:30 p.m.

Session: Liquid Sensors
Room: Grand Ballroom C
Session Chair: Fabien Josse, Marquette University

Tuesday, May 3 1:30 p.m. – 3:30 p.m.

Session: Frequency Synthesis & CMOS Oscillators
Room: Seacliff Rooms
Session Chair: Jeremy Everard, University of York

Tuesday, May 3 3:50 p.m. – 5:50 p.m.

Poster Session: Materials and Filters
Room: Pacific Concourse - Area 1
Session Chair: Yoonkee Kim, US Army

Tuesday, May 3 3:50 p.m. – 5:50 p.m.

Poster Session: Oscillators, Synthesizers, Noise & Circuit Techniques II
Room: Pacific Concourse - Area 2
Session Chair: Jeremy Everard, University of York

Tuesday, May 3 3:50 p.m. – 5:50 p.m.

Poster Session: Microwave Frequency Standards II
Room: Pacific Concourse - Area 3
Session Chair: Pierre Thomann, Universite de Neuchatel

Tuesday, May 3 3:50 p.m. – 5:50 p.m.

Poster Session: Timekeeping, Time and Frequency Transfer, GNSS Applications II
Room: Pacific Concourse - Area 5
Session Chair: Patrizia Tavella, INRIM

Tuesday, May 3 3:50 p.m. – 5:50 p.m.

Poster Session: Optical Frequency Standards & Applications II
Room: Pacific Concourse - Area 6
Session Chair: Pierre Thomann, Universite de Neuchatel

Wednesday, May 4 8:30 a.m. – 10:30 a.m.

Session: Optimized and Tunable MEMS Resonators
Room: Grand Ballroom C
Session Chair: Yoonkee Kim, US Army

Wednesday, May 4 8:30 a.m. – 10:30 a.m.

Session: Celebrating Kalman Filter 50th Anniversary
Room: Seacliff Rooms
Session Chair: Demetrios Matsakis, USNO

Wednesday, May 4 **10:50 a.m. – 12:30 p.m.**

Session: Microclocks & Novel Concepts
Room: Grand Ballroom B
Session Chair: John Kitching, NIST

Wednesday, May 4 **10:50 a.m. – 12:30 p.m.**

Session: Quartz Based Resonators
Room: Grand Ballroom C
Session Chair: Ji Wang, Ningbo University

Wednesday, May 4 **10:50 a.m. – 12:30 p.m.**

Session: Algorithms for Clock and Time Scale Estimations
Room: Seacliff Rooms
Session Chair: Ilaria Sesia, INRIM

Wednesday, May 4 **1:50 p.m.-3:50 p.m.**

Session: Lattice Clocks II
Room: Grand Ballroom B
Session Chair: Ekkehard Peik, PTB

Wednesday, May 4 **1:50 p.m.-3:50 p.m.**

Session: Physical Sensors
Room: Grand Ballroom C
Session Chair: Don Malocha, University of Central Florida

Wednesday, May 4 1:50 p.m.-3:50 p.m.

Session: Acoustic Oscillators and Micromechanical Resonators
Room: Seacliff Rooms
Session Chair: Michael Driscoll, Northrop Grumman

Wednesday, May 4 **4:10 p.m.-6:10 p.m.**

Session: Space Clocks & Novel Oscillators
Room: Grand Ballroom B
Session Chair: Louis Marmet, NRC Canada

Wednesday, May 4 **4:10 p.m.-6:10 p.m.**

Session: Mass Sensors
Room: Grand Ballroom C
Session Chair: Leo Reindl, University of Freibourg

Wednesday, May 4 **4:10 p.m.-6:10 p.m.**

Session: Optical Fiber Time and Frequency Transfer
Room: Seacliff Rooms
Session Chair: Jan Johansson, SP

Thursday, May 5 **8:30 a.m.-10:30 a.m.**

Session: Vapor Cell Clocks
Room: Grand Ballroom B
Session Chair: Svenja Knappe, NIST

Thursday, May 5 **8:30 a.m.-10:30 a.m.**

Session: Filters
Room: Grand Ballroom C
Session Chair: Rick Puccio, Quartzdyne

Thursday, May 5 **8:30 a.m.-10:30 a.m.**

Session: Optical Oscillators & Components
Room: Seacliff Rooms
Session Chair: Michael Tobar, University of Western Australia

Thursday, May 5 **10:50 a.m.-12:50 p.m.**

Session: Fundamental Measurement & Sensors
Room: Grand Ballroom B
Session Chair: Giorgio Santarelli, LNE-SYTRE

Thursday, May 5 **10:50 a.m.-12:50 p.m.**

Session: Materials
Room: Grand Ballroom C
Session Chair: Bernard Dulmet, ENS2M

Thursday, May 5 10:50 a.m.-12:50 p.m.

Session: GPS Carrier Phase Time Comparison and Calibration
Room: Seacliff Rooms
Session Chair: Pascale Defraigne, ORB

Welcome from the General Co-Chairs, Prof. Clark T.-C. Nguyen and Dr. Giorgio Santarelli

It is our great pleasure to welcome you to the San Francisco Bay Area and to the Joint Conference of the 65th IEEE International Frequency Control Symposium and 25th European Frequency and Time Forum. This event marks the 5th joint meeting to combine the two leading international technical conferences for research, development, and applications of timing and frequency control.

The 2011 Organizing and Joint Technical Program Committees have strived to provide a stimulating and educational program for all attendees. With a larger than usual number of abstracts to choose from, the conference program easily coalesced to one that encompasses all traditional topics, to include resonators, oscillators, atomic standards, optical frequency standards, timekeeping, and resonant sensors, with a noticeable increase in contributions from MEMS technologists.

On 1 May, the day prior to the meeting, twelve educational and informative Tutorial Sessions are offered. These sessions will cover topics of interest to attendees, and will be presented by internationally recognized experts in their field.

From May 2-5, the conference program includes three parallel sessions of technical presentations and two poster sessions, as well as a panel session on Tuesday morning that is sure to provoke thoughtful discourse among conference participants. Monday and Tuesday evenings offer a Welcome Reception and an Exhibitor's Reception, respectively, giving you ample opportunity to socialize with colleagues and perhaps stimulate that next big idea over a few drinks. Throughout the Symposium an exhibit area of leading frequency control and timekeeping manufacturers will be open and will serve as the site for session breaks, as well as the aforementioned Exhibitor's Reception.

Since the conference venue is situated near the bay at the edge of beautiful downtown San Francisco, it is very close to many of San Francisco's bay front attractions that you may wish to enjoy before or after the conference. Among these attractions are the San Francisco Museum of Modern Art, Pier 39, the Exploratorium, the Aquarium of the Bay, Coit Tower, the Palace of Fine Arts Theatre, the Presidio, and a plethora of world class restaurants. Beyond the bay front lie countless other attractions in the greater San Francisco Bay Area, e.g., the wine country up north, the Golden Gate Bridge, Silicon Valley down south, etc. Needless to say, there is much to do and see at this location, so hopefully you've planned a few extra days before or after the conference in the area.

We hope the Joint Conference will provide you an opportunity to network with colleagues, reconnect or make new friends, and share advancements in the frequency and timing field.

Have a great stay in San Francisco and enjoy the 2011 Joint Conference!

Clark T.-C. Nguyen and Giorgio Santarelli
2011 Joint Conference General Co-Chairs

Welcome from the Joint Program Co-Chairs, Eric Burt and Patrick Gill

It is our pleasure to welcome you to the 2011 Joint IFCS/EFTF. The first joint conference was held in 1999 in Besancon, France with an initial agreement to repeat the joint configuration every 4 years. However, with the success of these joint conferences, in 2007 it was decided to move to a biennial format. 2011 marks the 5th joint conference. With 3 parallel tracks over 4 days covering the entire spectrum of time and frequency topics, the 2011 conference promises to be as technically successful as its predecessors, providing attendees with the latest scientific and engineering results from the international time and frequency community

The field of time and frequency is currently experiencing rapid development in several areas. Pushing the limits of accuracy, optical frequency metrology has emerged as one of the fastest growing sub-disciplines. Developments over the past decade now include optical clocks with accuracy in the eighteenth digit as well as all-optical means of transferring that accuracy both in-house and over trans-national distances via optical fiber and femtosecond combs. The most recent developments in optical frequency metrology will be thoroughly represented at the 2011 conference.

Pushing in the direction of the ultra-small, MEMS technology is poised to revolutionize applications of time and frequency that require low-cost, miniature, ubiquitous sources with high performance. MEMS technology was featured in the 2010 IFCS and a successful panel discussion was held to discuss if and how MEMS technology might replace quartz. In 2011 we will continue to emphasize MEMS technology through sessions devoted to this topic.

In between the two extremes of highly accurate laboratory frequency standards and ultra-miniature devices are small or even chip-scale atomic clocks with impressive performance. With size reduction and increasing performance of such devices, a wide spectrum of applications are arising ranging from clocks in space to sensors that are based on atomic clock technology. With their decreasing mass/power/volume footprint comes the question of whether chip-scale atomic clocks also might someday replace quartz oscillators in certain applications. On Tuesday, May 3, there will be a panel discussion on this topic.

The SI second remains defined in terms of a microwave transition in cesium so that all primary frequency standards are based on this transition. The performance of cesium primary microwave frequency standards is 2 orders of magnitude better than two decades ago. The latest generation of these frequency standards will be discussed in a session devoted to fountain clocks.

In 1960 Prof. Rudolf Kalman described what came to be known as Kalman Filtering. This method of estimating the values of variables in the presence of multiple noise types is now a standard tool in time scale formation. To mark the 50th anniversary of Kalman's work, which occurred last year, we will have an entire session and several tutorials devoted to Kalman Filtering.

The student poster competition has become a tradition at this conference. Started in 2004, the competition has grown steadily each year and the quality of the papers has evolved to be extremely high. In the 2010 IFCS there were over 50 entries. In 2011 there were 76 entries submitted. 24 finalists representing all 6 topical groups of the conference will be on display and judged during the first poster session on Monday, May 2. Winners will be announced during the reception on Monday night.

In addition to the regular technical sessions, we will have a day dedicated to tutorials. There will also be an extensive exhibition with representatives from leading manufacturers and suppliers of frequency control products and equipment from around the world.

We hope that you will have an enjoyable and technically rewarding 2011 conference!

Eric Burt and Patrick Gill
2011 IFCS/EFTF JPC Co-Chairs

Organizing Committee

2011 Joint Conference of the IEEE International Frequency Control Symposium & European Frequency and Time Forum

General Co-Chair

2011 IFCS/EFTF Joint Program Committee

Group 1: Materials, Resonators, & Resonator Circuits

Yoonkee Kim, US Army (Vice Chair)

Jean-Pierre Aubry, Oscilloquartz
Sunil Bhave, Cornell University
Shih Chuang, Statek
Bernard Dulmet, Ecole Nat. Superior of Mech. & Micro (Besancon)
Raymond Filler, US Army
Vladimir Klipov, Sawyer
George Mansfeld, Inst of Radio Engrg
Sheng-Shian Li, Nat. Tsing Hua Univ.
Bernd W. Neubig, Adv. Crystal Products
Moorthi Palaniapan, Nat. Univ. of Singapore
Gianluca Piazza, Univ. of Pennsylvania
Derek (Rick) Puccio, Quartzdyne
Dan Stevens, Vectron
Ji Wang, Ningbo Univ.
Yasuaki Watanabe, Tokyo Metro Univ.
Dana Weinstein, MIT
Yook-Kong Yong, Rutgers University

Group 2: Oscillators, Synthesizers, Noise, & Circuit Techniques

Jeremy Everard, University of York (Vice Chair)

Farrokh Ayazi, Georgia Tech.
Martin Bloch, Frequency Electronics
Rodolphe Boudot, FEMTO-ST
Pierre-Yves Bourgeois, FEMTO-ST
Michael Driscoll, Northrop Grumman
Gary Fedder, CMU
Marvin Frerking, Innovative Tech. Products
Patrick Green, Northrop Grumman

2011 IFCS Awards

IFCS I.I. Rabi Award

This award recognizes outstanding contributions related to the fields of atomic and molecular frequency standards, time scale realization, and time comparison and dissemination.

2011 IFCS I.I. Rabi Award:

Prof. Fritz Riehle, Physikalisch-Technische Budesanstalt (PTB)

Citation: “For outstanding contributions to the field of atomic frequency standards, including pioneering research and development of optical frequency standards and their measurement.”

IFCS W.G. Cady Award

This award recognizes outstanding contributions related to the fields of crystal resonators, frequency control, frequency synthesis, noise measurement and sensor devices.

2011 IFCS W.G. Cady Award:

Prof. Georgy D. Mansfeld, Russian Academy of Sciences

Citation: “For pioneering research in physical acoustoelectronics and acoustics, including acoustic resonance spectroscopy, attenuation mechanisms, piezoelectric properties of thin layers and films, and new acoustic materials.”

IFCS C.B. Sawyer Memorial Award

This award recognizes outstanding contributions in the development, production or characterization of piezoelectric materials of interest to the Symposium Technical Program Committee, or to recognize entrepreneurship or leadership within profit or non profit organizations in the frequency control community (including all parts of the community).

2011 IFCS C.B. Sawyer Memorial Award:

Prof. Achim Wixford, University of Augsburg

Citation: “For the development and successful commercialization of surface acoustic wave driven microfluidic systems.”

2012 IFCS Award Nominations

Nominations are sought for the 2012 IFCS awards. Information is available at the Registration Desk and is also available on the IEEE Frequency Control Conference website at: http://www.ieee-uffc.org/fc

2011 EFTF Awards

EFTF Award

The award, which is open to anyone working in the fields traditionally associated with the European Frequency and Time Forum (EFTF), recognizes exceptional contributions in all fields covered by the EFTF either for fundamental advances or important applications. The significance of contributions includes the degree of initiative and creativity, the quality of work, the degree of success obtained as well as the worldwide scientific impact on the Time and Frequency Community. This award is sponsored by the Société Française des Microtechniques et de Chronométrie. The recipients are selected by the Executive Committee of the EFTF.

2011 EFTF Award:

Dr. James C. Bergquist, NIST Time and Frequency Division

Citation: “For seminal contributions to high-resolution laser spectroscopy and frequency standards for over 30 years.”

EFTF Young Scientist Award:

The EFTF Young Scientist Award is conferred in recognition of a personal contribution that demonstrated a high degree of initiative and creativity and lead to already established or easily foreseeable outstanding advances in the field of time and frequency metrology. A prerequisite is that the work to be taken under consideration has been published in the Proceedings of the European Frequency and Time Forum or the IEEE Frequency Control Symposium. The award honors a person under the age of 40 at the date of the opening session of the 2011 EFTF-IFCS joint conference. The goal is to encourage scientific endeavor and competition and to help young scientists along their career paths. This award is sponsored by the Société Française des Microtechniques et de Chronométrie. The recipients are selected by the Executive Committee of the EFTF.

2011 EFTF Young Scientist Award:

Dr. Tobias Kippenberg, Ecole Polytechnique Fédérale de Lausanne and Max Planck Institute for Quantum Optics

Citation: “For contributions to optical frequency metrology by the demonstration of monolithic micro resonator frequency comb generators.”

EFTF Marcel Ecabert Award:

The Marcel Ecabert Award of the European Frequency and Time Forum (EFTF) is a lifetime award and honors the excellent achievements of the recipient in the field of time and frequency. It is named after the late Marcel Ecabert, founding member of the EFTF and member of its Executive Committee.

2011 EFTF Marcel Ecabert Award:

Dr. Giovanni Busca, KYTIME

Citation: “In recognition of a career successfully devoted to the development of atomic frequency standards, and for his major contributions to the establishment of an industrial infrastructure for ground and space clocks at European level.”

Student Paper Competition Awards

Group 1: Materials, Resonators, & Resonator Circuits

"Mechanically-Coupled CMOS-MEMS Free-Free Beam Resonator Arrays with Two-Port Configuration"
Ming-Huang Li, National Tsing Hua University

Group 2: Oscillators, Synthesizers, Noise, & Circuit Techniques

"Effects of Volume and Frequency Scaling in AlN Contour Mode NEMS Resonators on Oscillator Phase Noise"
Matteo Rinaldi, University of Pennsylvania

Group 3: Microwave Frequency Standards and Applications

"CPT Pump-Probe Measurement of the Cs Clock Transition DC Stark Shift"
Jean-Luc Robyr, University of Fribourg

Group 4: Sensors & Transducers

"SAW-Thin-Film Acoustoelectric Effect in-Situ Observation and Measurement"
Brian Fisher, University of Central Florida

Group 5: Timekeeping, Time and Frequency Transfer, GNSS Applications

"Absolute Calibration of GNSS Time Transfer Systems : NRL and CNES Techniques Comparison"
Amandine Proia, CNES/BIPM

Group 6: Optical Frequency Standards and Applications

"Absolute Frequency Measurement of the 1S-2S Transition in Atomic Hydrogen Using a 900 km Remote Frequency Reference"
Katharina Predehl, Max-Planck-Institue of Quantum Optics

Use of Kalman Filters in Time and Frequency Analysis
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Davis.pdf)
John Davis, National Physical Laboratory

Kalman filters have many applications both in time and frequency and in related topics, for example GNSS analysis.

In this tutorial an overview will be given of the Kalman filter and its relationship to other filters and smoothing algorithms. A detailed description will be given of each element of the Kalman filter, with emphasis on the underlying physical meanings and limited use of mathematics. A step by step description of the filtering process will then be provided.

There are several key applications of Kalman filters within time and frequency analysis. These include clock ensemble algorithms, clock predictors and steering algorithms. The use within the Kalman filter of each of the well-known power law noise processes will be examined. Models of clock and time transfer noise will be discussed in detail, along with the treatment of periodic instabilities and linear frequency drift. Methods of testing Kalman filters using simulated data sets will be demonstrated. Finally the concept of observability, which is of particular importance to clock ensemble algorithms, will be examined.

8:30 a.m. – 10:30 a.m.
Room: Seacliff B

The Leeson Effect, Phase Noise and Frequency Stability in Oscillators
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Rubiola.pdf)
Enrico Rubiola, CNRS FEMTO-ST Institute

Simply stated, an oscillator consists of a loop in which a resonator sets the oscillation frequency and an amplifier compensates for the resonator loss. The oscillation amplitude is set by clipping or other gain-saturation mechanism, usually in the amplifier. When phase noise is introduced in the loop, the oscillator converts it to frequency noise through a process of time-domain integration. The consequence is that the oscillator phase fluctuation diverges in the long run. This phenomenon was originally referred as the “Leeson model” after a short article published by D. B. Leeson [1]. On my side, I prefer the term “Leeson effect” in order to emphasize that it is far more general than a simple model [2].

The first part of this tutorial explains the phase-to-frequency conversion mechanism as a general phenomenon inherent in the feedback, following an heuristic approach based on physical insight. There follow the relationships between the noise of the internal components (sustaining amplifier, resonator, etc.) and the phase noise at the oscillator output, or equivalently the frequency stability.

The second part is the analysis of the phase noise spectra found in the data-sheet of commercial oscillators: dielectric-resonator oscillator (DRO), whispering gallery oscillator (WGO), 5–100 MHz quartz crystal oscillators, opto-electronic oscillator (OEO). The analysis gives information on the most relevant design parameters, like the quality factor Q and the driving power of the resonator, and the flicker noise of the sustaining amplifier.

The last part shows the derivation of the oscillator phase noise formulae from the elementary properties of the resonator. Interestingly, the amplitude non-linearity, necessary for the oscillation amplitude to be stable, splits the resonator relaxation time into two time constants. The approach shown in this last part is general. It applies to all oscillators, including quartz, RLC, microwave cavity, delay-line, laser, etc.

This tutorial updates on the earlier editions, and also on the book [2] by including the AM noise and the impact of AM noise on phase noise [3].

Theory and Analysis of MEMS Resonators
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Kaajakari.pdf)
Ville Kaajakari, VTI Technologies

Microresonators offer promise to integrate bulky analog and RF components on-chip enabling smaller form and reduced system cost. MEMS resonators have been proposed as one-to-one replacements of macroscopic components such as quartz crystals and SAW filters. Microresonator based oscillators have been demonstrated to meet the stringent phase noise requirements of reference oscillators for wireless communication systems, and resonators have been demonstrated to reach frequencies of over 2 GHz. While small may be desirable, scaling down the resonator also has unavoidable physical limits. The
research work of past years allows critical evaluation of these limits and provides tools to analyze feasibility of different microresonator applications.

In this course, we will cover the microresonator basics with the goal of understanding what are the practical applications and limitations of the resonators. We start by modelling of the mechanical resonator with the goal of representing the mechanical resonator as a circuit element (LRC resonator). First, the distributed resonator vibrations are represented with a lumped element. Next, electromechanical coupling mechanisms (capacitive and piezoelectric) are introduced and compared. The theory is expanded to include second order effects such as electrostatic spring softening and nonlinear spring effects. As nonlinear effects effectively set the resonator power handling capacity, the estimation of the nonlinear limit is of fundamental importance for estimating the fundamental limits for miniaturization. Finally, the mechanical resonator and electromechanical transduction models are combined to an electrical equivalent circuit suitable for system design.

In the second part of the tutorial, we compare the model parameters (e.g. motional resistance Rm, electromechanical coupling coefficient kt2) for selected microresonators and commercial devices. These characteristics are compared to application specific criteria.

Fundamentals of Kalman Filtering and Applications to GNSS
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Kaajakari.pdf)
Mohinder Grewal, University of California, Fullerton

This tutorial presents the fundamentals of Kalman filtering with application to GNSS. It addresses the subtleties, problems, and limitations of estimation theory as applied to real world situations encountered in GNSS and navigation, and provides application examples.

10:45 a.m. – 12:45 p.m.
Room: Seacliff B

Phase Noise Measurements
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Nelson.pdf)
Craig Nelson, NIST Boulder

Noise is everywhere. Its ubiquitous nature interferes with or masks desired signals and fundamentally limits all electronic measurements. Noise in the presence of a carrier is experienced as amplitude and phase modulation noise. Modulation noise will be covered from its theory, to its origins and consequences. The effects of signal manipulation such as amplification, frequency translation and multiplication on spectral purity are examined. Practical techniques for measuring AM and PM noise, from the simple to complex will be discussed. Calibration of measurements and common problems and pitfall will also be covered.

Craig Nelson is an electrical engineer at the Time and Frequency Division of the National Institute of Standards and Technology. He received his BSEE from the University of Colorado in Boulder in 1990. After co-founding SpectraDynamics, he joined the staff at the NIST. He has worked on the synthesis and control electronics, as well as software for both the NIST-7 and F1 primary frequency standards. He is presently involved in research and development of ultra-stable synthesizers, low phase noise electronics, and phase noise metrology. Current areas of research include optical oscillators, high-speed pulsed phase noise measurements and phase noise metrology in the 100 GHz range. He has published over 35 papers and teaches classes, tutorials, and workshops at NIST, the IEEE Frequency Control Symposium, and several sponsoring agencies on the practical aspects of high-resolution phase noise metrology.

MEMS Resonators for Frequency Control and Sensing Applications
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Piazza.pdf)
Gianluca Piazza, University of Pennsylvania

This tutorial will review the state-of-the-art in MEMS resonator technology that uses piezoelectric, electrostatic and thermal transduction. Examples of some of the latest micromechanical resonators under development at Universities, National Labs and industry will be provided. Device design, fabrication and performances will be discussed and compared to commercially available resonators such as quartz crystals and surface acoustic wave devices. The utilization of these resonators for frequency control applications such as filtering and high precision signal generation will be presented. In addition, the ability of arraying these devices, fabricating them in large volumes and integrating them with electronics will be emphasized in regards to new opportunities in the area of low power front-ends, channelizers and reconfigurable circuits. Furthermore, the continuous miniaturization and frequency scaling of the MEMS and NEMS resonator technology has enabled the utilization of these devices for the making of very sensitive, portable and low-power sensor arrays. The tutorial will briefly review some examples of chem/bio resonant detectors from academia and industry, and highlight the advantages that MEMS will bring to this space with respect to currently available solutions.

10:45 a.m. – 12:45 p.m.
Room: Seacliff A

Principles of Atomic Clocks
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Lutwak.pdf)
Robert Lutwak - Symmetricom Technology Realization Center

Atomic frequency standards provide the ultimate source of accuracy and stability for all modern communications, navigation, and time-keeping systems. Commercially-available “Industrial” atomic clocks, including cesium beam frequency standards, rubidium oscillators, and hydrogen masers, are based on technology originally developed in the 1950’s. Since that time, technology evolution and field experience have led to a level of performance and reliability that atomic clocks are now deployed throughout critical infrastructure applications.
Recently, for the first time in 50 years, a new type of atomic clock has transitioned from the laboratory into practical application. Chip-Scale Atomic Clocks (CSAC) employ novel techniques for atomic confinement and interrogation, combined with micro-electromechanical systems (MEMS) and modern electronics, to enable atomic timing accuracy in portable battery-powered devices. While CSAC technology is yet relatively immature, already a new family of applications has emerged in handheld communication systems, enhanced personal navigation systems, and remote sensing.
The tutorial will provide an introduction to industrial atomic clocks, focusing on mature technologies: rubidium oscillators, cesium beam frequency standards, and hydrogen masers, as well as the emerging technology of CSAC.

1:45 p.m. – 3:45 p.m.
Room: Seacliff B

Variance Measurements – Practical Use – Statistics – Long Term Prediction
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Vernotte.pdf)
Francois Vernotte, Besancon Observatory

The seminar addresses the estimation of the error bars in the Allan variance, and explains why the upper half-bar in the log-log ADEV plot is bigger than the lower half-bar (while it is a common belief that the lower half-bar is bigger).

Outline
- Practical Allan variance algorithms (with / without overlapping)
- Allan variance versus Allan deviation
- Statistics of the Allan variance and the Allan deviation: chi-squared and Rayleigh distribution
- How to estimate the number of equivalent degrees of freedom (edf) of an Allan variance/deviation measure?
- Probability Density Function and Cumulative Distribution Function of the Allan variance/deviation measures
- Confidence interval over the Allan variance/deviation measures
- Fitting curve over Allan variance measurement
- Link between noise levels and Allan variance response
- Estimation of the noise levels and their uncertainty from the fitting curve
- Extrapolation to very long term time stability
- How to increase the number of edf: the Total variance
- Generalization to the other variances.

1:45 p.m. – 3:45 p.m.
Room: Seacliff C

Nanoscale Electromechanical Resonators and Oscillators
Philip Feng**,** Case Western Reserve University

Nanoscale devices with mechanical degrees of freedom offer compelling characteristics that make them not only interesting tools for fundamental studies, but also intriguing candidates for technological applications. In particular, nanoelectromechanical systems (NEMS) *vibrating* in their *resonant* modes provide promising opportunities and advantages for developing novel transducers and sensors, in the previously inaccessible regimes. In fundamental physics, recently there have been considerable interests and intensive efforts in exploiting such NEMS devices for quantum measurements. In technology development, significant milestones have been achieved using prototypical devices and systems, and rapid progresses are currently being made in resonant sensing; plus other interesting applications are emerging. At the juncture from understanding fundamentals to creating practical technologies, there are great challenges and also enormous opportunities for the *engineering* of NEMS resonators and oscillators.

This tutorial will give an introduction to fundamentals of NEMS and an overview of recent efforts in developing and engineering nanoscale electromechanical resonators and oscillators. After discussing the basic ideas and fundamental aspects of such devices, I shall introduce prototypes of devices enabled by the state-of-the-art nanofabrication techniques, including both top-down and bottom-up approaches. Related and enabling materials, along with their interesting properties and relevant challenges, will also be discussed. I will then discuss device characterization techniques and introduce recent advances in very-high and ultra-high frequency (VHF/UHF) NEMS resonators and oscillators, along with important challenges such as noise and integration. Finally, I will review and discuss some representative areas of applications, latest highlights and new possibilities in this field, and their interesting and promising interactions with a few of today's mainstream technologies.

4:00 p.m. – 6:00 p.m.
Room: Seacliff A

Next-Generation Frequency Standards
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Warrington.pdf)
Bruce Warrington, National Measurement Institute

Optical frequency standards have reached systematic uncertainties of a few parts in 10^17, equivalent to an error of a few seconds accumulated over the lifetime of the universe, and are able to detect time dilation caused by a change in height of less than one metre in the Earth's gravitational potential. Next-generation microwave frequency standards are set to fly aboard the International Space Station, testing relativistic red-shift to a few parts per million and transferring time to ground stations with picosecond-level precision. How are these astonishing feats of ultra-precise measurement achieved? The presentation will cover a short history, some core techniques, and the two main approaches to realising an optical frequency standard: single trapped ions and neutral atoms in optical lattices. Space-borne microwave frequency standards and linear ion traps will also be briefly described, as well
as the challenges in comparing standards across large distances. To conclude, we will
speculate on a redefinition of the SI second, currently defined with reference to cesium,
and on the frontier for the measurement of time and frequency.

4:00 p.m. – 6:00 p.m.
Room: Seacliff B

The Kalman Filter
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/Slides_Galleani.pdf)
Lorenzo Galleani, Politecnico di Torino

The motion of a satellite, the trajectory of an airplane, the position of a boat: all these quantities can be predicted accurately and efficiently with a Kalman filter. Since its introduction half a century ago, the Kalman filter has revolutionized the field of applied optimal estimation. Literally hundreds of applications have been made and the number is still growing. Also atomic timing benefits greatly from the Kalman filter. GPS time, for instance, is generated by the Composite Clock, an algorithm based on the
Kalman filter. In this tutorial we do two things. First, we define the Kalman filter by using a simple example, namely, the motion of a boat. Second, we discuss a few applications of the Kalman filter to atomic timing, including the GPS Composite Clock.

4:00 p.m. – 6:00 p.m.
Room: Seacliff C

Theory and Analysis of Quartz Crystal Resonators
(http://ifcs-eftf2011.org/sites/ifcs-eftf2011.org/files/editor-files/FCSTutorial_2011_Resonator.pdf)
Yook-Kong Yong, Rutgers University
Ji Wang, Ningbo University

Quartz crystal resonators as a key element for frequency control and detection have wide applications in modern electronics. The manufacturing technology of quartz crystal resonators have under gone tremendous changes in last few decades with focused efforts on accuracy, stability, miniaturization and novel applications. These changes required extensive investigations on improving the theory and analytical techniques as represented by improvements in the Mindlin plate equations and the development of finite element analysis aimed at the analysis and design of novel structures of resonators. The critical roles of traditional quartz crystal resonators have been targeted to be replaced by newer technologies such as the surface acoustic wave (SAW) resonators, acoustic wave MEMS, and lately the film bulk acoustic wave resonators (FBAR), but the sophistication of quartz crystal resonator technology itself has demonstrated the continuing and sustainable presence of the traditional quartz resonator with improved performance and refined structure for unique roles in many critical applications.

This tutorial will provide an overview of the needs of future development, design, and research of the quartz resonator technology through an introduction of the material, basic theory, approximate equations, practical methods, and design of the traditional resonator. The lecture will be presented to cover the following: 1) History and trends of quartz crystal resonator technology, 2) Basic theory of wave propagation, 3) Quartz crystal material, 4) Mindlin plate equations, 5) Analytical considerations, 6) Finite element methods.

Panel Discussion

Subject: To What Extent Will Quartz be Squeezed Out By CSAC and MEMS?

Tuesday, May 3rd, 10:30 a.m. – 12:30 p.m.
Grand Ballroom B/C

Panelists:

Chair: John Vig, Consultant, USA
Jean-Pierre Aubry, Oscilloquartz, Switzerland
Martin Bloch, Frequency Electronics, Inc., USA
John Kitching, NIST, USA
Amit Lal, Cornell U., USA
Robert Lutwak, Symmetricom, Inc., USA
Gaetano Mileti, The LTF laboratory - University of Neuchâtel, Switzerland
Clark Nguyen, UC Berkeley, USA

During the past several decades, many billions of quartz crystal oscillators have been produced. The applications have ranged from inexpensive clock oscillators to high stability devices for military and space applications. No technology has been able to seriously compete with quartz - until recently. Now, competition to quartz is emerging. MEMS oscillators are now competing with quartz at the low end, and, recently, the Chip Scale Atomic Clock (CSAC) has become available to compete with some applications at the high end.

At last year's Symposium, a panel of experts, together with an enthusiastic audience, debated the question, "To What Extent Will MEMS Replace Conventional Quartz Resonators?" This year, a panel of experts will continue and extend the debate to the question, "To What Extent Will Quartz Be Squeezed Out by CSAC and MEMS?" The panelists, who include experts in atomic clocks, MEMS, and conventional quartz technologies, will compare the advantages and disadvantages of the three technologies. Brief updates on the state of MEMS oscillator technologies and markets will be provided at the start of the panel discussion.

ACS is the proud producer of Lattice Etch, the only non-aqueous HF solution specifically formulated for the etching (chemical milling and/or polishing) of crystalline quartz available on the market. Lattice Etch provides superior etching performance with consistent and predictable results. Used by leaders in the frequency control market for years to produce high frequency fundamental quartz crystals.

http://adv-chem.com/

AMSystems designs and manufactures thin film processing equipment for the industry, research labs and universities. Our equipment ranges from single wafer R&D modules to production cluster tools. We provide a complete solution for FBAR/SAW technologies, including thin film deposition and thickness uniformity trimming. AMSystems can help build early prototypes utilizing our dedicated equipment.

http://www.amssb.com

Anapico Ltd

Switzerland based Anapico Ltd is a innovative manufacturer of test equipment such as signal source analyzers and low phase noise RF and microwave signal generators. The displayed APPH6000 signal source analyzer measures phase noise down to -190 dBc/Hz.

http://www.anapico.com/

Brandywine Communications is the premier supplier of GPS and time code based precision time and frequency products including wireline and wireless telecommunication networks. Brandywine offers a full suite of Next Generation synchronization, timing and monitoring products to maximize a telecom network's performance and flexibility to the network. Better timing and synchronization means better quality for voice, video and data services.

http://www.brandywinecomm.com/

Brilliant Instruments

Time interval analyzers with 3 ps resolution and 4 million measurements per second in modular instrument formats.

EndRun TECHNOLOGIES

"Smarter Timing Solutions"

EndRun Technologies is the only provider of indirect-GPS disciplined oscillators. Designed and manufactured in California, EndRun synchronizes time and frequency systems using GPS or indirect-GPS (indoor antenna with IS-95 CDMA). A wide variety of products are available spanning from GPS fiber optic links, GPS inline pre-amplifiers, NTP time servers, IEEE-1588 grandmaster clocks, primary time & frequency references and distribution. The gem of the product line includes the ultra-low-noise oscillator that provides the most precise and stable GPS-derived frequency reference in the world. Guaranteed.

http://www.endruntechnologies.com/

Frequency Electronics, Inc. is a world leader in the design, development and manufacture of high precision timing, frequency control and synchronization products for space and terrestrial applications. Frequency Electronics' products are used in commercial, government and military systems, including satellite payloads, missiles, UAVs, aircraft, GPS, secure radios, SCADA, energy exploration and wireline and wireless communication networks.

http://www.freqelec.com/

GuideTech is a leading provider of precision test and measurement instruments for scientific laboratories, development and volume manufacturing applications based on its patented "Continuous Timing Interval Analyzer" (CTIA) technology. GuideTech's multi-channel timing test systems substantially improve test throughput of Automated Test Equipment (ATE) systems through fast measurement rates, greater accuracy, increased parallelism, and through critical high-speed timing test coverage. The Company sells its PC-based timing instruments since 1988 into the scientific lab market to customers such as NIST, NASA, CERN, US Naval Observatory, Northrop, Rolls Royce and other respected science organizations worldwide. GuideTech's PC products and test systems are available in ISA, PCI, PCIe, PXI, and PXIe. With very strong R&D, the company is scheduled to launch 9 new products in 2011.

http://www.guidetech.com

Jackson Labs Technologies, Inc. designs and manufactures Precision Timing and Frequency References including ground-breaking Chip Scale Atomic Oscillators (CSACs) and ultra-miniature GPS Disciplined Oscillators. Our smallest product is less than 1 inch square and consumes less than 0.5W, and our highest performance product is slightly larger than a pack of cigarettes, and is based on a Cesium Vapor Atomic Reference for ultra-fast warm-up, very low power, and very good holdover performance.

http://www.jackson-labs.com/

Noise XT is a high spectral purity instrumentation provider offering Phase and Amplitude Noise Test Systems. Our products measure Absolute, Residual, Added noise on CW and Pulsed signals with offsets up to 500MHz and on input signals up to 140GHz. Our new product DCNTS exhibits the lowest noise floor of the industry with down-to -195dBc/Hz performance. It is the only complete dual phase noise test set with cross-correlation feature. Its unique signal processing software allows very fast high performance measurements.

http://noisext.com/

Pascall Electronics Ltd based on the Isle of Wight in England (UK) is a leading supplier of RF & Microwave components, subsystems and custom power supplies for aerospace, defence, marine and civil markets. Pascall has special expertise in providing industry leading ultra low noise oscillators and frequency generators solutions covering VHF to X-band. Such devices are particularly suited for radar, communication and high end test systems

http://www.pascall.co.uk/

Piktime Systems Ltd specializes in: *time transfer solutions for time scales purpose, *high precision measurements of frequency and time, *distribution of time signals and reference frequency. Our core product is time transfer system TTS-4 which allows comparison of time scales and clocks on long distance. TTS-4 receiver is capable to carry observations on all available frequencies for GPS, GLONASS and GALILEO. Our product offers high precision along with comfortable and stable operation. Piktime Systems Ltd closely co-operates with The Astrogeodynamical Observatory (AOS) of the Space Research Centre.

http://www.piktime.com/

Roth & Rau MicroSystems is a leading supplier of plasma and ion beam processing systems for the semiconductor, MEMS, and sensor industries. Our “IonScan” frequency trimming systems are widely used in SAW, BAW, and FBAR manufacturing for yield maximization. We also offer a full range of precision thin film deposition and etching systems for a broad range of processes, including Reactive Ion Etching (RIE), Plasma Enhanced Chemical Vapor Deposition (PECVD), Ion Beam Etching (IBE) and Ion Beam Sputter Deposition (IBSD), using our own in-house developed plasma and ion beam sources.

http://www.roth-rau.de/konzern/microsystems/de/index.php

Sansei-Showa Co., Ltd produces production and test equipment for the Quartz Crystal and Semiconductor industry.

http://www.sanseishowa.com/

"Industry leader of test and manufacturing equipment for the frequency control industry." We make measurement, temperature test, frequency adjustment, sorting and various other production equipment for the frequency control industry.

http://saunders-assoc.com

Spectracom is a leading provider of time and frequency technology. Our application-specific products are designed for synchronization and timing of networks, systems and devices; calibration and test of precise frequency instruments, and measurement of frequency signals. Products include sync tester/analyzers, GPS simulators, time and frequency analyzers/counters, secure master clock synchronization systems, and more.

http://www.spectracomcorp.com/

SpectraDynamics, Inc. is a leading supplier of Time and Frequency Products with exceptionally low noise and high stability. Our main product lines are Time and Frequency Distribution Amplifiers, Frequency Synthesizers and Noise Measurement Systems. SpectraDynamics, Inc. is proud to serve the Time and Frequency community around the world.

http://www.spectradynamics.com/

Spectratime is a world's leader in high-performance crystal, rubidium, maser and integrated GPS/GNSS reference clocks and related test instruments, by offering smart, cost-effective and high-quality products for the telecom, defense, broadcasting, instrumentation, and space industries.

http://www.spectratime.com/

Symmetricom's precision frequency standards deliver exceptional performance and unsurpassed accuracy, stability and reliability in the most challenging of environments. Our hydrogen, cesium and rubidium standards and quartz oscillators have supported more military communications, satellite ground stations, metrology laboratories and test & measurement applications than any other precision frequency references in the world.

http://www.symmetricom.com/

T4Science is a world's leader in high-performance hydrogen maser clocks, by offering smart, cost-effective and high-quality products and total support services for the multiple scientific and GNSS space industries.

http://www.t4science.com/

XECO, Inc. is a manufacturer of quartz inverted mesa blanks offering many styles and sizes of blanks both electroded and non-electroded from frequencies of 20 to over 600 MHz fundamentals. For unique applications requiring special electrode patterns or mesa shapes, XECO can produce blanks to your specifications with minimal tooling fees. XECO exclusively uses swept quartz and a unique photolithographic process to produce blanks and can offer the highest quality blank available on the market from an independent supplier.

http://www.xeco.net/

Technology-leader Zurich Instruments (ZI) designs and manufactures high performance dynamic signal analysis instruments for advanced scientific research and leading industrial applications. ZI products include lock-in amplifiers, phase-locked loops, instruments for electrical impedance spectroscopy, and application specific pre-amplifiers. Headquartered in Zurich, Switzerland, ZI was established in 2008. ZI customers are scientists and engineers in leading research labs and organizations worldwide.

Quantum Information Processing and Atomic Clocks*

D. J. Wineland, NIST, Boulder, CO

Abstract:
For approximately the last fifteen years, the subject of quantum information processing (QIP) has occupied the efforts of many laboratories, leading to logic gate implementations and demonstrations of basic protocols for universal quantum computation. The potential strength of quantum computing derives in part from the exponentially-increasing size of state space with the number of bits - when such "qubits" exist in superposition states. Primary drivers for this work include the potential realization of efficient factoring (P. Shor) and unstructured searches (L. Grover), however these applications are probably at least decades away. In the near term, simple elements of QIP can be applied to simulation of interesting quantum systems or to metrology. For atomic clocks, simple logic gate protocols have been used to realize "quantum logic spectroscopy" which has led to an Al+ optical clock with systematic uncertainty less than $1x10^{-17}$ (T. Rosenband et al.). Particular entangled states created with QIP techniques can provide improved clock stability in certain circumstances. Extensions of these techniques may also have more general spectroscopic applications.

* NIST work supported by ONR, AFOSR, IARPA, NSA, DARPA, and the NIST Quantum Information Program.

Bio:
DAVID WINELAND received a bachelor's degree from Berkeley in 1965 and his Ph.D. from Harvard in 1970, under Norman Ramsey. After a postdoctoral appointment at the University of Washington, under Hans Dehmelt, he joined NBS (now NIST), where he is the leader of the Ion-Storage Group in the Time and Frequency Division at Boulder. The group's research has focused on laser cooling and spectroscopy of trapped atomic ions with applications to atomic clocks, quantum-limited metrology, and quantum state control.

Parallel Oral Session Schedule

Monday, May 2 10:50 a.m. - 12:30 p.m.			
	Grand Ballroom B	**Grand Ballroom C**	**Seacliff Rooms**
	A1L-A - Lattice Clocks I	**A1L-B - Silicon and CMOS MEMS Resonators**	**A1L-B - Time Transfer and Time Scales**

Trapping induced frequency shifts by comparison of two Sr optical lattice clocks at the 10^{-17} level

Abstract— We present a comprehensive study of the frequency shifts associated with the lattice potential in Sr lattice clocks. By comparing two such clocks with a frequency stability better than 5.10^{-17} after one hour of averaging time, and varying the lattice depth up to U_0 = 900 E_r with E_r being the recoil energy, we evaluate lattice related shifts with an unprecedented accuracy.

Three different types of frequency shifts induced by the lattice have been identified as potential limitations to the accuracy of optical lattice clocks [1]. The first one is related to the non scalar feature of the atom-lattice interaction, which results from the atomic hyperfine structure [1,2]. It induces a small vector and tensor component in the confinement potential. In addition to the intensity dependence, this makes the light shift slightly dependent on the lattice polarization and geometry. We report the first observation of these effects in a Sr lattice clock and measure them with percent accuracy. We also show that the tensor effect can be used to operate a clock with ^{87}Sr in an optimal 3D lattice.

The second effect, Hyperpolarizability, refers to a shift due to higher order coupling [1]. The frequency shift scales as U_0^2 and therefore cannot be compensated for by a change of the lattice frequency. A first experimental study showed that this effect was small enough to not alter Sr clock accuracy at the 10^{-18} level for U_0=10 Er [3]. We improve on this limit by almost two orders of magnitude.

Finally, a subtle effect of higher order multipolar terms has recently been predicted [4]. Dipole magnetic (M1) and quadrupole electric (E2) interactions indeed lead to a shift of the internal atomic energy levels that is linear in lattice laser intensity. However, their spatial dependence in a lattice formed by the interference of several traveling waves does not match the one of the main dipole electric term. This in turn leads to a change of the oscillation frequency in the lattice potential wells and thereby of the spacing of the atomic external energy levels. This effect is expected to differ for both clock states. The net M1/E2 frequency shift of the clock frequency scales as $U_0^{1/2}$ and again cannot be compensated for by tuning the lattice frequency. In Ref. it is argued that this effect could be as large as 10^{-16} for U_0 = 50 E_r,! We perform the first experimental study of the M1/E2 effect showing that it is controllable to within 10^{-17} even for U_0 as large as 700 E_r.

***Abstract*—We report results for improving the stability and uncertainty of the NIST ^{171}Yb lattice clock. The stability improvements derive from a significant reduction of the optical Dick effect, while the uncertainty improvements focus on improved understanding and constraint of the cold collision shift.**

I. Introduction

Optical lattice clocks have potential for achieving time and frequency measurement at unprecedented levels of accuracy and stability. However, to date these young systems are far from reaching this potential. Here, we describe efforts to mitigate effects which, left unresolved, pose significant obstacles to achieving these levels of performance. To improve the clock stability, we reduce the optical Dick effect. To improve the eventual accuracy of this system, we probe cold collisions between the lattice-confined atoms.

II. Reducing the optical Dick effect

The fundamental limit to the instability of an atomic frequency standard is given by the quantum projection noise (QPN). For an optical atomic clock that probes a large ensemble of quantum absorbers, the QPN limit can be quite low. For example, for a Yb or Sr lattice clock with 10^5 atoms, a 1 Hz transition linewidth, and a cycle time of $T_c = 1$ second, the QPN instability limit is below 10^{-17} at 1 s. However, while such clocks have resolved optical transition linewidths approaching 1 Hz, the instability of these systems is much higher than indicated above. Instead, the fractional frequency instability is such that it would require significantly more than 10^4 seconds to reach the 10^{-17} level. This is because these systems are usually limited by the Dick effect [1], i.e. as the atoms are periodically interrogated by the local oscillator (LO) with a period of T_c and for a probe duration of T_p, the frequency noise of the LO is downsampled onto the transition spectrum and contaminates the clock stability. In this way, the frequency noise, the probe time T_p, and the cycle time T_c all influence the magnitude and downconverted Fourier frequency of the aliased noise and thus the stability degradation. The previous operating conditions for our Yb lattice clock were $T_p = 0.08$ s and $T_c > 0.5$ s. With a frequency noise of 0.5 Hz/$\sqrt{\text{Hz}}$ at a Fourier frequency of 1 Hz, this led to a Dick-limited instability of 1-2 $\times 10^{-15}$ at 1 s.

In order to reduce this limitation, several improvements could be made: reducing the LO frequency noise that is aliased, achieving a higher duty cycle with longer probe times or reduced dead time [2], or choosing a form of spectroscopy which is less sensitive to the aliasing process (e.g. short-pulse Ramsey spectroscopy). All of these are useful from a practical perspective. However, by improving the LO laser coherence and stability, we can achieve both reduction of the LO frequency noise and longer probe times. In order to improve the LO stability, the level of Brownian thermal noise in the optical cavities used for laser stabilization must be reduced. When stabilizing a laser to an optical cavity, the thermal-noise limited laser instability dominated by the cavity mirrors [3] is given by:

$$\sigma_{therm} = \sqrt{\ln 2 \frac{4k_bT}{\pi^{3/2}} \frac{1-\sigma^2}{Ew_0L^2} \left(\phi_{sub} + \phi_{coat} \frac{2}{\sqrt{\pi}} \frac{1-2\sigma}{1-\sigma} \frac{d}{w_0} \right)} \quad (1)$$

Here, σ, E and ϕ_{sub} are Poisson's ratio, Young's modulus and the mechanical loss for the mirror substrate, and ϕ_{coat} and d denote the mechanical loss and thickness of the thin-film reflective coating. w_0 is the laser beam size on the mirror, T is the mirror temperature (K), k_B is Boltzmann's constant and L is the cavity length. In order to improve laser stabilization by reducing the thermal noise, we designed a cavity with length $L = 29$ cm, fused silica substrates with low mechanical loss ($\phi_{sub} \approx 10^{-6}$) and a somewhat large beam size using mirrors with a somewhat longer radius of curvature ($R = 1$ m). For these parameters, the thermal-noise-limited fractional frequency instability is 1.4×10^{-16}.

To reduce acceleration-induced cavity length changes, the optical cavity sits horizontally on four symmetrically placed Viton hemispheres [4], [5]. The precise support position is optimized to reduce the vertical acceleration sensitivity. Figure 1 shows the vertical acceleration sensitivity as a function of support position, indicating both finite-element simulation results as well as experimentally measured sensitivities. Simulation results are also shown for cavity acceleration sensitivity offset from the cavity optical axis. The measured sensitivity reaches as low as 7 kHz/(ms^{-2}) at the laser wavelength of 578 nm. The experimental measurement also includes weak, incidental acceleration in the horizontal dimensions. During

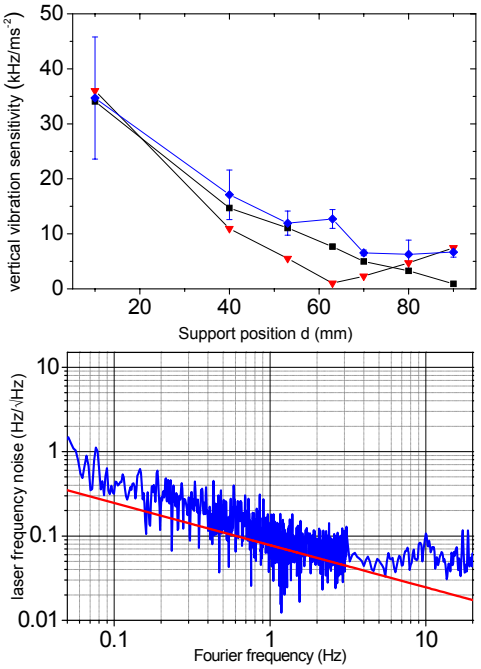

Fig. 1. top: Vertical acceleration sensitivity of the optical cavity. Experimental measurement (blue diamonds), simulation results (red triangles), simulation results for 250 μm removed from the cavity optical axis (black squares). The support position, d, is measured from where the cavity taper begins. bottom: Measured frequency noise spectrum for the laser locked to the fully-isolated cavity. The solid red line gives the theoretical prediction of the Brownian thermal noise.

normal operation, the reference cavities sat on vibration isolators.

While the use of fused silica mirrors helps reduce Brownian thermal-mechanical noise, it makes the cavity more susceptible to thermal expansion. However, a balance between the thermal expansion of the cavity components can be achieved, and we have been able to demonstrate operation of these cavities at the zero crossing of the coefficient of thermal expansion. This is done at a temperature conveniently just above ambient [6].

By comparing two independent cavity systems, we measured the frequency noise spectrum of the cavity-stabilized laser as shown in Figure 1. The red line is the thermal noise limit for each reference cavity. Up to several Hz, the laser frequency noise is close to the thermal noise limit. This low level of frequency noise in turn reduces the aliased noise contributing to the Dick effect. Furthermore, the reduced frequency noise spectrum yields laser coherence times which allow us to extend our clock probe time up to 1 second. For a more conservative operating condition of $T_p = 0.3$ s, the Dick instability is at $1.5 \times 10^{-16}/\sqrt{\tau}$, for measurement time τ. This constitutes an order of magnitude improvement over our previous Dick limit, and enables a significant improvement of the clock stability. By using the narrow atomic transition as a frequency discriminator, we have made measurements consistent with a clock instability at the $5 \times 10^{-16}/\sqrt{\tau}$ fractional frequency level [6].

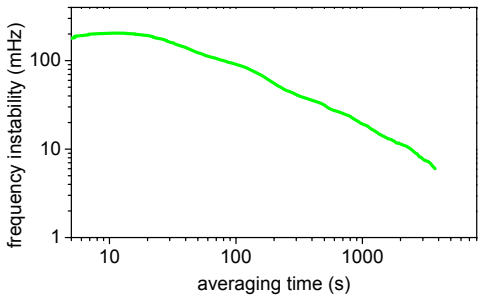

Fig. 2. Frequency instability from measurement of the cold collision shift, when the shift is cancelled to zero (see text).

III. Cold collision shift

While the presence of many atoms in the optical lattice is desirable for low clock instability due to quantum projection noise, another consequence of large atom number is high number density which can lead to significant interactions between the atoms. These interactions can shift the clock transition frequency and in so doing can potentially compromise the absolute uncertainty of the optical standard. Non-zero interactions in a ^{171}Yb optical lattice clock were first observed using one-pulse Rabi spectroscopy [7]. More recently, we have studied the resulting cold collision shift of the clock transition using two-pulse Ramsey spectroscopy, for atoms confined both in a one- and two-dimensional optical lattice. The choice of Ramsey spectroscopy was driven by simplification: the interactions yielding the collision shift occur primarily during the Ramsey dark time, when the atomic population is not simultaneously being driven by the probing laser field. By studying the collision shift as a function of excitation fraction, sample inhomogeneity, and Ramsey dark time, we have determined that the collisions responsible for the shift are dominated by p-wave interactions between a ground and excited state atom pair [8].

We have been able to identify regimes where the cold collision shift can be canceled, which is metrologically interesting for clock operation. One such case is given by controlling the excitation fraction just above 50%, where the shift on each clock state is the same. By operating at these conditions, the collision shift was measured to be consistent with zero at or below the 10^{-17} fractional frequency level. Figure 2 highlights such a measurement, showing the frequency instability of the measured collision shift. This data is taken by stabilizing the probe laser to interleaved samples of high and low atomic density, and measuring the frequency shift between the two cases. Due to the clock stability improvements described in section II, we are able to measure the shift at the 10^{-17} level with only several thousand seconds of measurement time. This measurement emphasizes the potential of the Yb lattice clock for very high measurement stability, as well as high accuracy through control of the cold collision shift.

Hybrid MEMS Resonators and Oscillators

Sunil A. Bhave

Abstract— **With quality factors (Q) often-exceeding 10,000, vibrating micromechanical resonators have emerged as leading candidates for on-chip versions of high-Q resonators used in wireless communications systems. However, as in the case for transistors, extending the frequency of MEMS resonators generally entails scaling of resonator dimensions. Unfortunately, smaller size often coincides with lower-power handling capability and increased motional impedance. In this paper we introduce novel transduction techniques which can improve the motional impedance of MEMS resonators by 1000× over traditional 'air-gap' transduced resonators, present latest results on narrow-bandwidth parametric filters for frequency-agile radio receivers, and discuss performance scaling of NEMS resonators to X-band frequencies.**

I. Introduction

Maturity in micro-electro-mechanical systems (MEMS) fabrication technology has opened the opportunity to design high quality factor (Q) mechanically-coupled micromechanical structures capable of implementing ultra-low-power frequency-domain signal processing functions. We endeavor to demonstrate new and high-impact micro-electro-mechanical circuits using such mechanically-linked networks. In the OxideMEMS Lab we have invented new mechanical designs and efficient transducers to manufacture MEMS resonators with high resonance frequency, low motional impedance, strong transducer coupling coefficient, low bias drift and large tuning range. We characterized and cataloged these resonators, developed and verified butterworth van-dyke (BVD) resonator models, investigated their coupling mechanisms to demonstrate channel-select filters, and explored inter-domain coupling to design merged resonant body transistors.

II. Dielectrically Transduced Resonators

Modern wireless transceivers are designed under a mandate to minimize the use of off-chip passive devices. However, the increasingly-crowded radio spectrum and the impending arrival of next generation 7-band cellular phone and the joint task force radio system (JTRS) has necessitated front-end filters capable of eliminating both out-of-band and out-of-channel interferers. Such channel-select filters will also relax the dynamic range requirements of the LNA and the phase noise requirements of the local oscillators, leading to a 10× reduction in power consumption of direct-conversion radio receivers.

Building of initial pioneering work at Berkeley and Delft, we demonstrated solid-dielectric transduced thickness shear mode MEMS resonators with 807 MHz center frequency, motional impedance $R_X < 100\Omega$ and Q's > 7,000 [1]. We have developed 'orthogonal frequency tuning' technique for independently changing the series and parallel resonant frequencies of dielectrically transduced thickness shear mode resonators. Using this technique our channel-select filter array is capable of dynamically tuning center frequency and filter bandwidth, thereby reducing capacitive loading at the filter input. This enables reception of multiple waveforms, and leads to substantial reduction in the number of filters in next-generation frequency-agile transceivers [2].

The thickness shear mode resonators have high Q and low R_X. However, their second-order dependence on CAD-defined dimensions severely limits the frequency design space. Contour-mode resonators can be designed across a much wider frequency range but have minimal tuning capability [3]. We have invented, designed and demonstrated a digital tuning technique for a filter consisting of mechanically coupled contour-mode resonators. By altering the polarization voltage applied to each resonator in the array we can digitally change the filter center frequency and alter the bandwidth from 1.4 MHz to 700 kHz (Figure 1) [4]. Unlike the analog voltage tunable shear-mode filters, the digitally-tunable filters are significantly less sensitive to variations and noise on the DC polarization voltage. We also proposed and demonstrated a 2D filter arraying technique to make the filters less susceptible to process variations [5]. We worked with Professor Tom Kenny's group at Stanford and developed an epi-silicon encapsulation process for vacuum packaging our resonators and filters in milli-Torr, clean micro-environment (Figure 2) [6].

Dielectric-transduction enables us to design high-Q, low impedance resonators and filters. However, dielectric transducers have very small bandwidth (< 0.2%), preventing them from being used for wide bandwidth IF filters. Aluminum Nitride (AlN) has been used to fabricate IF filters with 2% band-width, however these are fixed-frequency filters. We collaborated with Army Research Labs and co-developed voltage tunable ferroelectric contour-mode resonators and filters using lead zirconate titanate (PZT)-on-Silicon technology [7]. We have demonstrated resonators with 5% center frequency tuning and impedance < 100Ω. At MEMS 2009 we demonstrated the first monolithic, frequency

agile, channel-select filter bank integrating RF MEMS PZT switches with PZT-on-Silicon contour-mode filters (Fig 3) [8].

III. Aqueous Transduction

The frequencies of contour mode resonators are defined by CAD-defined lateral dimensions and can cover frequencies from 40 MHz – 2.4 GHz. But unlike shear mode resonators, the frequency expressions for contour modes and flexural vibration modes do not directly couple. It is therefore more difficult to perform orthogonal frequency tuning of contour mode resonators. BioMEMS groups have recently demonstrated that by using an LO signal that is faster than the response time of a polar fluid, it is possible to prevent electrode polarization and double-layer formation, enabling electrostatic transduction in liquid media. To determine whether the same approach enhances the performance of contour-mode RF MEMS resonators, we used an air-gap poly-SiGe disk resonator and submerged it under a water droplet. However, immersing the resonator in water caused excessive mass-loading and Q losses resulting from viscous drag. To eliminate mass-loading and viscosity effects of the water-droplet on the resonator, we coated the resonators with a hydrophobic, non-conformal self-assemble monolayer (SAM). We rolled a water droplet over the resonator such that it had enough time to wick the nano-gaps, but greatly reduced the chance of water seeping under the resonator. We were surprised to measure Q > 3,000 and motional impedance R_X < 4.2 kΩ, reduced from 510 kΩ with air-gap transduction. Replacing air in the sub-micron transducer gap with DI water enhanced the electrostatic spring by > 50× and extended the tuning range to 3%, the highest tuning-range reported for contour-mode resonators [9] (Figure 4).

IV. Internal Dielectric Transduction

Placing the dielectric or ferroelectric transducer on top of the resonator avoids the dielectric from hindering the contour-mode resonator vibration. However, such transducers suffer from two inefficiencies – the Poisson's effect and improper placement of the dielectric above regions of minimal strain. Both affect the effective coupling coefficient, and fractional bandwidth of the resonator. In the OxideMEMS lab we developed the concept of internal dielectric transduction, in which dielectric transducers are incorporated directly into the resonator body. With dielectric films positioned at points of maximum strain in the resonator, this transduction improves in efficiency with increasing frequency, enabling resonator scaling to previously unattainable frequencies. Using internal dielectric transduction in longitudinal-mode resonators, we have demonstrated a frequency-quality factor (f.Q) product of 5.1×10^{13} [10].

We measured these resonators by capacitively driving and sensing acoustic vibrations in the device. However, capacitive detection often requires 3-port scalar mixer measurement, complicating monolithic integration of the resonators with CMOS circuits. The internal dielectric bulk-mode resonators can be utilized in a 2-port configuration with capacitive drive and piezo-resistive detection, in which carrier mobility is dynamically modulated by elastic waves in the resonator. We demonstrated piezo-resistive sensing of silicon-based dielectrically transduced resonators with 1.6% frequency tuning and control of piezo-resistive trans-conductance gm by varying the current flowing through the device [11]. Furthermore at Transducers'09, we demonstrated selective excitation of targeted harmonics in poly-silicon dielectrically transduced bar resonators by varying dielectric position in the resonator body (Figure 5). We also showed frequency scaling behavior, with improved transduction efficiency at higher frequency. RF resonators up to 6.2 GHz were demonstrated, with f·Q products up to 3.1×10^{13} [12]. The high Qs measured in these resonators indicates the ability to scale resonators to high frequency without compromising f·Q product.

The initial calculations for optimizing internal dielectric transduction assumed the silicon and dielectric transducers had similar acoustic velocity and Young's modulus. Recently, we refined and published a complete theoretical treatment without such assumptions and provided correction factors for optimally designing the internal dielectric transduced resonators [13].

V. Resonant Body Transistor

The Resonant Body Transistor is a NEMS resonator integrating a sense transistor directly into the resonator body, geometrically similar to a suspended (HF undercut and released) split-gate FinFET, as shown in Figure 6. The region in light grey in Figure 6 represents the active region of the resonator, while the dark grey region is highly doped. The active region near the drive electrode is biased into accumulation (red), so that a large capacitive force acts across the thin dielectric film (yellow), driving longitudinal resonant motion in the body. A gate voltage is applied to the opposing electrode, generating an inversion channel (blue) which results in a DC drain current. At resonance, elastic waves formed in the resonator modulate the drain current both by physically changing the gate capacitance and by piezo-resistive modulation of carrier mobility. The internally amplified RBT has significantly lower output impedance than capacitive detection mechanisms, simplifying impedance matching with active circuits.

The RBT was designed and fabricated at CNF. Using internal dielectric transduction for driving the resonator into acoustic resonance, the RBT uses a field-effect transistor embedded into the resonator to detect resonance. We demonstrated an 11.7 GHz RBT with a Q > 1,800 in vacuum (Figure 6) [14]. This is by far the highest frequency ever measured in silicon. Moreover, due to its use of internal dielectric transduction, the RBT promises to scale favorably to 60GHz.

***Abstract*—MEMS based timing devices have been proposed as an alternative to Quartz systems for certain applications. Through using an oven-controlled system it is possible to stabilize the frequency response of such a MEMS system over a large ambient temperature range. This work presents a BAW MEMS resonator in poly-SiGe which achieves significantly lower power consumption for frequency stabilization over temperature through Joule heating than for a similar system in SOI, while showing promising phase noise performance in an oscillator setup. Since the poly-SiGe resonator can be processed on top of standard CMOS, this enables the possibility of full integration of an Oven-Controlled MEMS Oscillator.**

I. INTRODUCTION

Silicon-based resonators provide an attractive alternative to replace conventional frequency control and timing devices that are based on high quality factor (*Q*) resonators such as quartz crystal, piezoelectric ceramic and surface acoustic wave (SAW) [1,2]. The bar-type bulk-acoustic (BAW) poly-SiGe resonators exemplify this by offering the possibility to integrate MEMS and CMOS in a "MEMS-last" approach [3,4]. Optimizing the quality factor Q is crucial, as it is a critical figure of merit for resonators and has a large impact both on the motional resistance and on the phase noise for circuits employing these resonators.

A further important consideration for timing devices is the frequency stability over temperature (typically ±10ppm down to ±0.1ppm over temperature range -40°C to +80°C). Due to the relatively large frequency drift of MEMS devices over temperature (in the order of tens of ppm/°C) in comparison to quartz, a compensation scheme is required to stabilize frequency over temperature. Several frequency-correcting mechanisms can be employed, typically steered by an ambient temperature sensor. A well-known solution is to embed the MEMS oscillator in a fractional PLL, whose fractional frequency control word is steered by a temperature sensor [5]. In such a system, the PLL provides a clock output, stable over temperature. However the output is polluted with fractional-PLL noise. Moreover, the feed-forward temperature compensation requires multipoint calibration for ppm-level stability over a wide temperature range, and requires a high-resolution, sufficiently linear temperature sensor.

A second possibility involves keeping the resonator at a fixed temperature by placing the device in a micro-oven [6]. This approach is followed in this work, creating an Oven-Controlled MEMS Oscillator (OCMO), which potentially yields good clock stability over ambient temperature. The target temperature for the resonator should be set above the specified ambient temperature range, for example at 95°C. Hence, a power-efficient micro-oven is needed that can keep the resonator at 95°C. A bar-type BAW resonator system is presented that proposes to heat the resonator, keeping it at a constant temperature above the maximum operating range and therefore minimizing the effect of ambient temperature changes on the resonance frequency. This design is made possible through the use of T-type supports which allow for Joule heating through the supports, while simultaneously optimizing the design in terms of anchor losses to the substrate, therefore maximizing the Q [7]. The T-type design is rigid in the direction of actuation, allowing the relatively high bias voltages needed to lower the motional resistance and ease the design of an oscillator system.

In this paper such an oscillator system is demonstrated using commercially available off-the-shelf components (COTS), showing sufficient phase noise performance for many applications, with the promise of full integration of the poly-SiGE resonator with CMOS to produce an Oven-Controlled MEMS Oscillator (OCMO). Furthermore we show that the lower thermal conductivity of poly-SiGe compared to SOI provides a significant advantage in the amount of power needed to heat the resonator for similar devices manufactured in both technologies.

This work is organized as follows: Section II introduces the poly-SiGe technology, Section III describes the resonator design using T-shaped supports, while section IV discusses the implementation and of an oscillator based on the SiGe resonator using COTS. We demonstrate the proposed poly-SiGe OCMO is thus adequate for analog performance and for temperature stabilization through Joule heating.

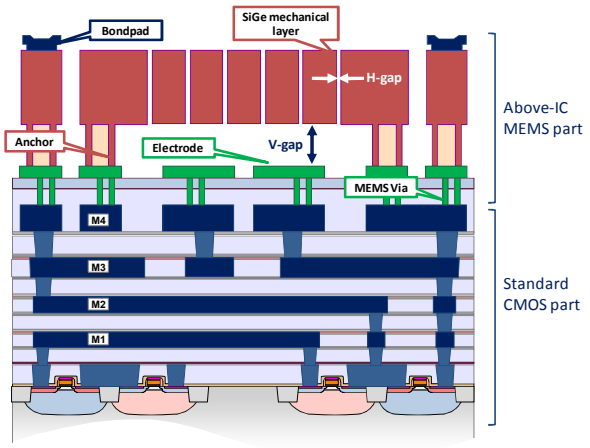

Figure 1, Cross-section layer build-up of the SiGe MEMS above-IC

II. POLY-SIGE MEMS TECHNOLOGY

Poly-SiGe IMEC MEMS technology allows for the fabrication of MEMS devices directly above a planarized CMOS wafer, on top of the metal interconnection lines, as described in [3,8]. This integration approach enables cost and area reduction as several CMOS functionalities, such as sustaining amplifier and temperature-compensation, can be placed just below the resonator. Ultimately, other functionalities such as a real time clock, gyros, accelerometers or pressure sensors can be integrated on the same die. For explanatory purposes, Figure 1 illustrates the cross-section of a resonator above the complete CMOS process. In this work, however, the MEMS device is defined on top of a simple AlCu interconnection that mimics the top metal of a CMOS backend stack. A SiC layer is deposited to protect the CMOS metallization during the vHF MEMS release process [3]. Vias are opened into this layer to realize the connection with the IC. A chemical vapor deposited (CVD) SiGe layer fills in the vias and form simultaneously the electrode. After electrode patterning, the wafer is planarized to ensure optimal definition of the 3µm high density plasma (HDP) oxide sacrificial gap. Anchors are defined in the oxide layer and then filled during the deposition of the SiGe MEMS structural layer by a combination of CVD and plasma-enhanced CVD (PECVD) processes [9].

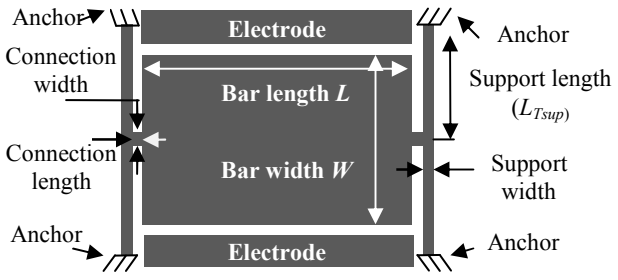

Figure 2, Schematic top view of a bar-type BAW resonator with "acoustically long" T supports. [7]

III. BAR RESONATOR DESIGN

The bar-type BAW resonators studied in this paper consist of right parallelepipeds suspended in free space by means of T-supports, *e.g.*, as in Figure 2. Figure 3 shows a SEM image of such a bar-type resonator as realized in imec's poly-SiGe MEMS platform [3,8]. The bar vibrates along its width in an extensional mode. A bar targeting a resonance frequency f_{res} is designed with a bar width W close to $\lambda_{long}/2$, where λ_{long} is the acoustic longitudinal wavelength at f_{res}. The resonance frequency, for the first width extensional mode, is approximately given by:

$$f_{res} \approx \frac{1}{2W}\sqrt{\frac{E}{\rho}} \qquad (1)$$

where E and ρ denote the Young's modulus and specific mass of the resonator material, respectively. In this work an E of 120 GPa, ρ of 4575 kg/m^3 and W of 110 µm result in a resonance frequency of 24MHz. The other design parameters are presented in Table 1. The bar resonator is electro-statically actuated via two electrodes separated from the resonator by transduction gaps (250 nm in this work), e.g., as shown in Fig. 2.

A. T-type support

The T-type support comprises of a support placed parallel to the side of the resonator connecting to the resonator at the symmetry line with a short, narrow connection. Figure 4 contains SEM images of a manufactured resonator with a

Table: Design parameters considered in this work.

Variable	Symbol	Value
Design Frequency (SiGe)	f_{res}	24 MHz /48 MHz
Bar Width	W	110µm /55µm
Bar Length	L	220µm/110µm
Support Width	W_{sup}	1 µm
Support Length	L_{sup}	Design dependent
Transduction Gap	d_{gap}	250 nm
Connection Width	$W_{connect}$	2 µm
Connection Length	$L_{connect}$	2 µm

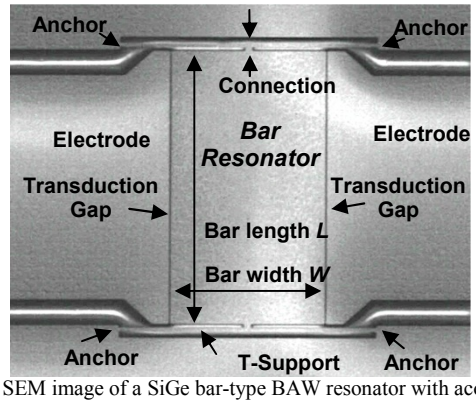

Figure 3, SEM image of a SiGe bar-type BAW resonator with acoustically long T-type supports. Design parameters are as in Table 1 for a 48MHz device, with a support length of 38µm.

T-type support. A λ/4 transformer technique can be applied to obtain an optimum support length $L_{Tsup,opt}$ to minimize energy losses to the anchors, with $L_{Tsup,opt}$ given by:

$$L_{Tsup,opt} \approx \frac{2i\lambda_{flex}}{4} + \frac{L_{cl-cl,1}}{2}, \qquad i = 0,1,2,3... \tag{4}$$

where for a given clamped-clamped beam, the flexural wavelength λ_{flex} is given by:

$$\lambda_{flex} = \lim_{n\to\infty} \left(L_{(n+2)} - L_n \right) \tag{6}$$

where $L_{(n+2)}$ and L_n are the lengths of beams with respectively $(n+2)^{th}$ and n^{th} flexural harmonics occurring at the frequency f_{res} [7]. We can compute λ_{flex} with eq. (6), after which $L_{Tsup,opt}$ is obtained from eq. (4). $L_{cl-cl,1}$ is the length of a clamped-clamped beam with first flexural resonance frequency equal to f_{res}, approximated by [7]:

$$L_{cl-cl,1} \approx \sqrt{\frac{1.028 W_{sup} \sqrt{E/\rho}}{f_{res}}} \tag{5}$$

Figure 5 demonstrates the benefits of using this technique. It shows the measured Q values against support length for a bar type resonator with design frequency at 48 MHz, along with simulations of the Q factor due to anchor losses. It can be seen that maxima for the Q values do indeed exist at multiples of $\lambda_{flex}/2$ given a certain offset as described by eq. (4). Therefore the Q factor can be optimized for longer support lengths, allowing us to design supports with higher thermal isolation between the resonator and the anchor.

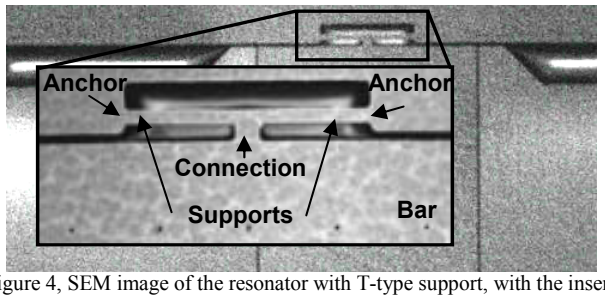

Figure 4, SEM image of the resonator with T-type support, with the insert showing a closer view of the support itself.

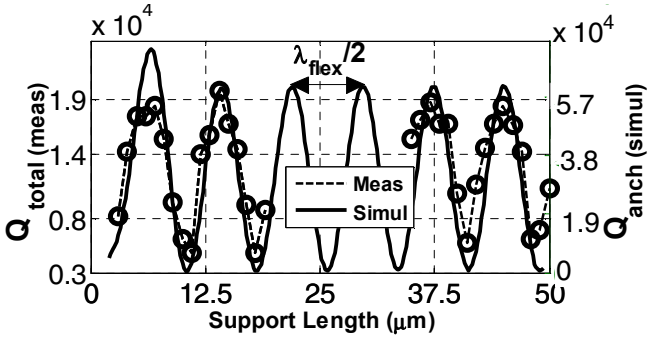

Figure 5, Measurement of Q and COMSOL simulation of the anchor loss Q_{anch} versus support length for a T-support, with $\lambda_{flex}/2$ shown to be 7.5μm. Devices were designed to operate at 48 MHz.

IV. Oven-Controlled MEMS Oscillator

An Oven-Controlled MEMS Oscillator (OCMO) potentially yields good clock stability over ambient temperature. The target temperature for the resonator should be set above the specified ambient temperature range, for example at 95˚C. Hence, a power-efficient micro-oven is needed that can keep the resonator at 95˚C.

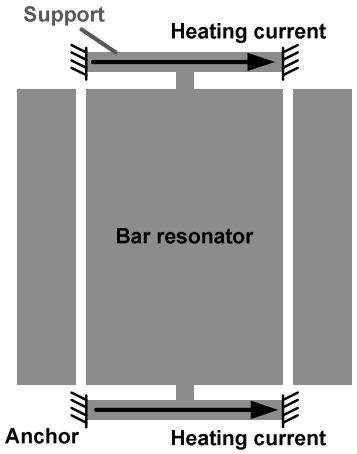

Figure 6, Schematic layout of the resonator, top view, showing the current used for Joule heating to keep the resonator at a fixed temperature.

A. Resonator design for use in OCMO

We use the T-type support described in the previous section for the BAW type bar resonator targeted at 24 MHz. This T-type support design provides several advantages for an OCMO design. Firstly the design is very stable in the direction of actuation, which allows the application of large bias voltages [7]. The supports also provide both a thermal resistance for Joule heating, as well as thermal isolation between the bar and the substrate. Figure 6 demonstrates how the current for Joule heating flows through the supports. Since the resonator is intended to operate in a vacuum packaged environment, the predominant thermal losses occur through the anchors which are connected to the substrate. The thermal isolation provided by the support length is therefore

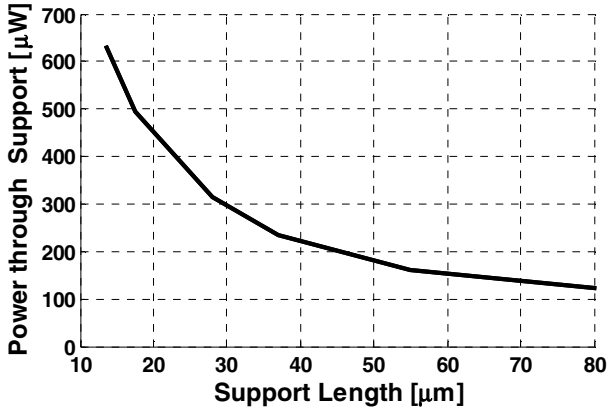

Figure 7, Simulated power required to heat SiGe resonator (with design parameters as in Table 1 for 24MHz and support length 38μm) to a temperature of 95˚C degrees with ambient at -40˚C.

crucial in determining the amount of power needed to keep the resonator at a fixed temperature. In Fig. 7 FEM simulation results can be seen showing that a minimum support length of 35µm is required (with support width at 1µm) to keep the heating power under 250µW. Using eq. (4) the support was designed to have a width and length of 1µm and 38µm respectively, maximizing the quality factor while meeting the required length specification provided by the thermal limitations.

B. Oscilator using COTS components

To demonstrate the feasibility of the system, a 24MHz oscillator has been built around the SiGe resonator using COTS components. Figure 8 shows a diagram depicting the system and contains an amplifier, a tunable phase shifter, a band-pass filter, a 20 dB coupler, a programmable attenuator and a limiter. The resonator is probed on wafer inside a vacuum chamber. Figure 9 depicts the measured phase noise of the 24MHz oscillator. For reference, the phase noise of the same setup using a commercial 26MHz quartz crystal is also shown. Both achieve the GSM specifications (referred to 24MHz and also indicated on Figure 9) at lower offset frequencies. At higher offset frequencies, the SiGe oscillator exhibits a higher noise floor. This is partly due the larger amount of gain required due to the relatively larger motional resistance of SiGe resonator as opposed to the crystal. However the SiGe performance is also limited by the 50Ω external loop components and is expected to improve through full CMOS co-integration of the sustaining amplifier. Indeed, a trans-impedance amplifier can be designed with far lower input-referred noise than an off-the-shelf 50Ω amplifier. Also, the tunable attenuator used to control the amount of gain in the system is one source of noise that can be removed when using a custom designed amplifier with the correct gain specifications. When considering the performance achieved despite the limitations of the probing setup and the COTS components used in this design, it can be seen that the technology shows potential to achieve GSM phase noise performance.

C. Power consumption for heating in SiGe and SOI

The OCMO micro-oven functionality is implemented by heating the resonator through use of Joule heating. Currents are applied through the T-type supports as demonstrated in Figure 6. The amount of power required to reach 95˚C is of crucial importance to the feasibility of the system. Poly-SiGe has a thermal conductivity that is more than 40 times lower than silicon (2.8 W/mK and 120 W/mK for SiGe and Silicon respectively), providing a distinct advantage in this implementation. Since the device is intended for packaged vacuum operation the majority of the thermal losses occur through the supports to the substrate. For the SiGe resonator, the thermal resistance of the T-type support is much larger than for the SOI support, which results in large power savings. The measured power required to heat the resonator to the targeted 95˚C is shown in Figure 7 for SiGe and SOI resonators with the same physical dimensions. The SiGe system needs far 40 times less power (<250µW at -40°C ambient) than an SOI implementation would need (> 10mW at -40°C ambient). In reality the generation of heater currents requires more power than that dissipated in the supports, resulting in a larger effective heater power. These SOI numbers compare to the work in [6]. A drawback for the implementation in SiGe is the lower quality factor of the poly-crystaline structures compared to the crystalline SOI.

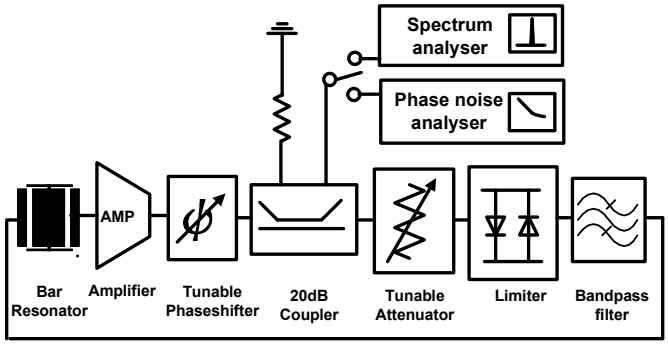

Figure 8, Oscillator setup using COTS sustaining amplifier

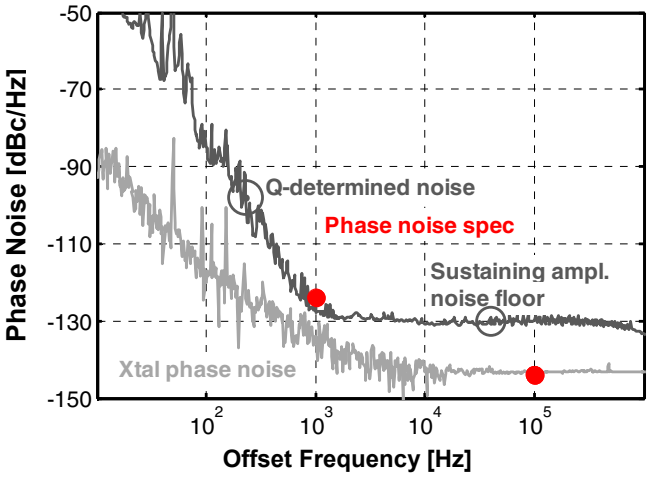

Figure 9, Measured phase noise of the SiGe MEMS oscillator using a COTS sustaining amplifier loop. For reference, the measured phase noise of a 26MHz XTAL oscillator using the same COTS setup. Also depicted is the phase noise specification for GSM.

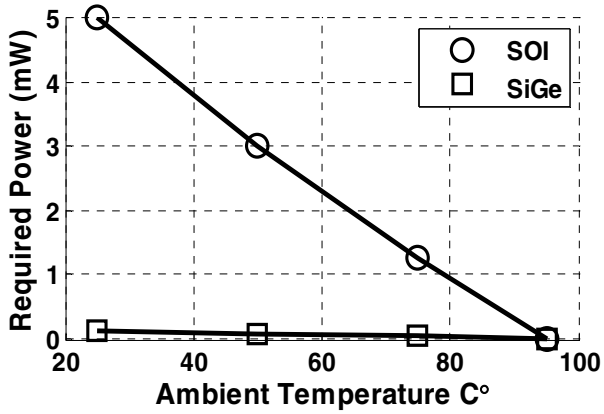

Figure 10, Measurements showing the required heater power applied through support legs of 38µm to maintain resonator temperature at 95˚C with varying ambient temperature for SOI and SiGe resonators with identical configurations.

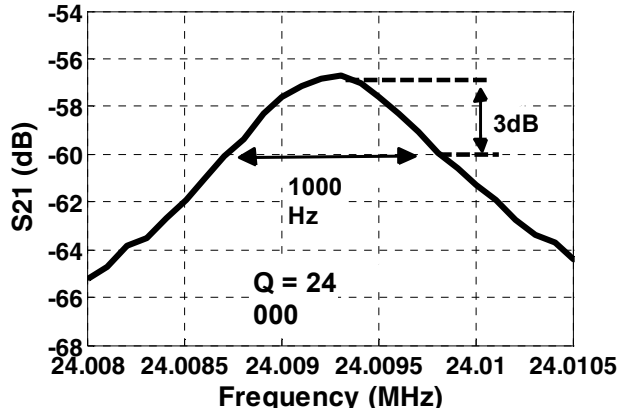

Figure 11, Measured S_{21} of a poly-SiGe resonator with length and width 220 and 110μm respectively. The quality factor is shown to be 24000.

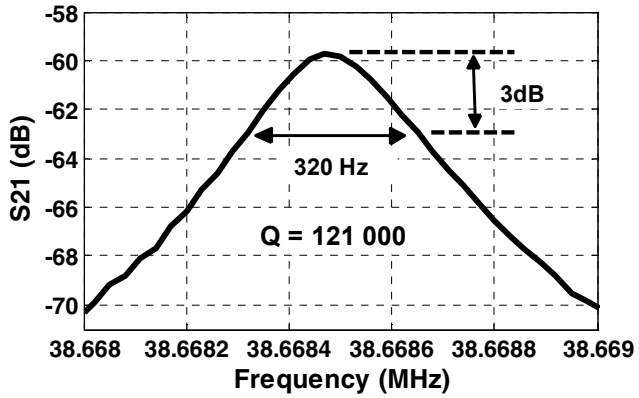

Figure 12, Measured S_{21} of a SOI resonator with length and width 220 and 110μm respectively. The quality factor is shown to be 121000.

Figure 11 and Figure 12 display the measured S_{21} of a SiGe and SOI resonator respectively, showing a quality factor of 24,000 for SiGe (at 24MHz) and 121,000 for SOI device (at 38.7MHz). The higher Q for SOI indicates that SOI resonators have an advantage with respect to SOI for achieving low phase noise in a timing device. However, as we have shown, the system with the SiGe does show potential to meet the GSM specification, indicating that SiGe is *good enough*. On the other hand, the 40 times higher power consumption of a micro-oven in SOI (in excess of 10mW) is prohibitive for a TCXO replacement, making SiGe a more suitable technology in which to implement an OCMO.

V. CONCLUSIONS

We demonstrate an oscillator using a bar-type BAW MEMS resonator that shows promising phase noise performance. The resonator is designed using T-shaped supports, optimizing the Q while providing sufficient thermal isolation to the substrate. The SiGe resonator requires significantly less power to heat than a similar device in SOI. Furthermore, the SiGe platform allows the resonator to be processed on top of CMOS, enabling a fully integrated OCMO system.

***Abstract*—Integrated CMOS-MEMS free-free beam resonator arrays operated in a standard two-port electrical configuration simultaneously with low motional impedance and high power handling capability centered at 10.5 MHz have been demonstrated by the combination of pull-in gap reduction mechanism and mechanically-coupled array design. The mechanical links (i.e., coupling elements) using short stubs connect each constituent resonator of an array to its adjacent ones at the *high-velocity* vibrating locations to accentuate the desired mode and reject all other spurious modes. A single second-mode free-free beam resonator with quality factor Q > 2,200 and motional impedance R_m < 150 kΩ has been utilized to achieve mechanically-coupled resonator arrays in this work. In array design, a 9-resonator array has been experimentally characterized to have around 10X performance improvement on motional impedance and power handling as compared with that of a single resonator. In addition, two-port electrical configuration is much preferred due to its low feedthrough nature and high design flexibilities for future oscillator and filter implementation rather than its one-port counterpart.**

I. Introduction

Vibrating off-chip mechanical tank components such as quartz crystals and SAW resonators are widely used in wireless transceivers and electronic systems for precision timing and filtering applications. In particular, quartz crystal oscillator, a classical timing reference device, has been used in consumer electronics for more than fifty years because of its exceptional Q and excellent thermal stability. In recent years, electrostatic silicon-based resonators are very promising in terms of their low motional impedance, high Q, small volume, satisfactory power handling capability, and IC compatible processes, paving a way of realizing miniature MEMS oscillators [1]. However, commercialized MEMS oscillators currently available in the timing market are still using two-chip stacking with wire-bonding connections, therefore against the ultimate miniaturization and integration [2][3].

In contrast, CMOS-MEMS based high-Q resonators become a promising candidate for realizing monolithic integration of resonators and circuits [4]. In our previous work, a deep-submicron gap fundamental-mode free-free beam resonator centered at 11.5 MHz was designed and fabricated by utilizing a foundry CMOS-MEMS platform with motional impedance down to 112 kΩ and Q's greater than 1,500 under dc-bias voltage of 60V [5]. However, the previously-designed beam resonator is limited by one-port electrical configuration due to its fundamental vibrating mode shape; therefore, the monolithic CMOS-MEMS oscillator implementation will become very difficult. Moreover, the large dc bias voltage (often greater than 50V) is required to attain acceptable motional impedance for a single resonator due to its insufficient transduction area. In addition, the power handling capability is also restricted by the tiny device size of such a "single" resonator.

To overcome the aforementioned issues without affecting Q, in this work, second-mode free-free beam resonator arrays combined with pull-in mechanism for gap reduction are designed to replace the previous fundamental free-free beam resonator version. The major advantages of resonator array design mainly comes from (i) the large transduction area to effectively reduce the required dc-bias voltage while maintaining reasonable motional impedance and (ii) higher power handling capability compared to that of the single resonator since the maximum handling power is proportional to the effective stiffness of the resonator. Furthermore, the

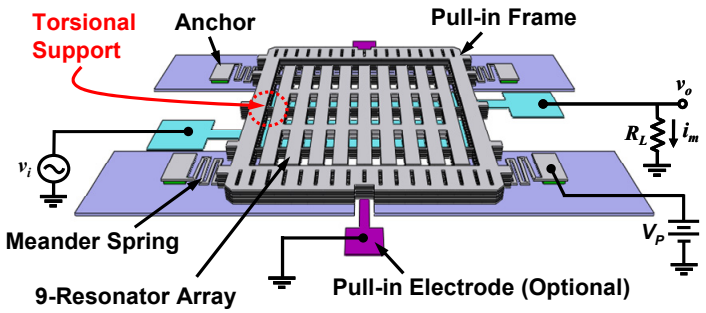

Fig. 1: Perspective view schematic of a 2nd-mode free-free beam resonator array consists of 9 identical resonators in a standard two-port electrical configuration.

This work was supported by National Science Council (NSC) of Taiwan. Travel was supported by IEEE-IFCS. This work was granted the best student paper award at 2011 Joint Conference of the IEEE International Frequency Control Symposium and European Frequency and Time Forum, San Francisco, USA.

two-port electrical configuration proposed in this work not only alleviates the electrical feedthrough between the input and output ports but also separates the signal and dc-bias ports, hence making monolithic CMOS-MEMS oscillator implementation possible. A comprehensive study of CMOS-MEMS resonator arrays is provided in this work to address issues on motional impedance and power handling capability.

II. Array Design and Gap Reduction Mechanism

The perspective view of a deep-submicron gap free-free beam resonator array is shown in Fig. 1 with a typical two-port biasing and excitation configuration. Two parallel electrodes are placed underneath the resonator array with an original gap of around 1μm before pull-in operation for gap reduction. One end of the torsional supporting beams is connected to the outer pull-in frame while the other end is attached to the nodal points of the resonator array to minimize the acoustic loss, hence attaining high Q. As also shown in Fig. 1, the pull-in frame is suspended by four meander springs. Since these meander springs have very low stiffness (i.e., very low pull-in voltage), the optional pull-in electrodes in Fig. 1 can be shorted to ground in a normal operation.

The mechanical resonance frequency of a single free-free beam resonator is determined by its material properties, including equivalent Young's Modulus E and density ρ, and geometric parameters, including beam thickness h_r and length L_r. The vibrating mode shape of a second-mode free-free beam is shown in Fig. 2(a); the corresponding resonance frequency of the beam can be derived using Euler-Bernoulli beam theory, given by

$$f_o = 2.833\sqrt{\frac{E}{\rho}}\frac{h_r}{L_r^2}. \qquad (1)$$

Note that the electrical stiffness is neglected in (1) for simplicity.

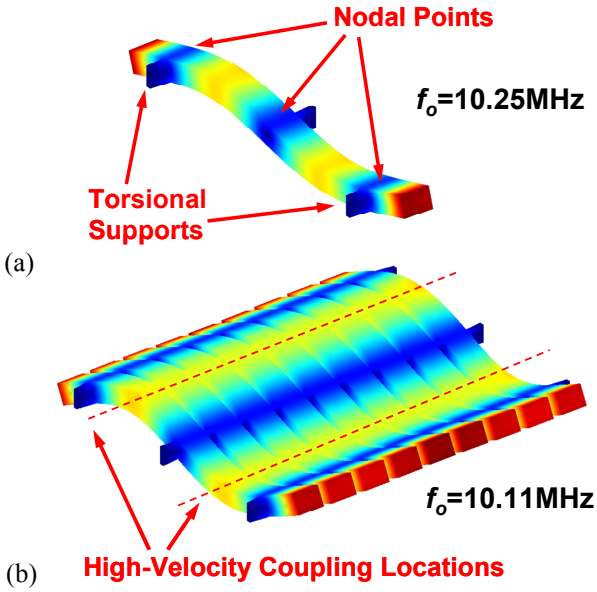

Fig. 2: Finite element simulated mode shapes for (a) a single free-free beam resonator and (b) a 9-free-free beam resonator array. The supporting beams are placed at the nodal locations of both the free-free beam resonator and array to reduce the anchor loss, hence improving the quality factor.

To achieve the mechanically-coupled resonator array, the identical resonators are placed nearby, and each constituent resonator is connected to the adjacent ones by mechanical coupling links, as described in [6]. The resonance frequency of an arrayed resonator is very similar to that of a single resonator if all of the constituent resonators of the array are operated in phase, as shown in Fig. 2(b). However, in general such a multiple degree-of-freedom mechanical system would generate plenty of spurious modes near the desired mode in contrast to single resonance behavior, thereby preventing the implementation of subsequent filter and oscillator applications. To eliminate the spurious modes [7][8], stiff mechanical coupling elements (half-wavelength couplers or short stubs at high-velocity vibrating locations) can be used to effectively push the spurious modes away from the desired frequency; electrical phasing design also helps to select only one vibrating mode and reject all the others. The use of high-velocity coupling and electrical phasing design in this work selects the in-phase vibrating mode of a resonator array as shown in Fig. 2(b) while eliminating all other unwanted modes.

For a capacitively-transduced resonator, the motional impedance R_m and maximum handling power $P_{o\max}$ are governed by the following equations

$$R_m = \frac{k_{re}d_o^4}{\omega_o Q V_P^2 \varepsilon_o^2 A_e^2} \qquad (2)$$

$$P_{o\max} = \frac{\omega_o k_{re}}{Q} X_{\max}^2 \qquad (3)$$

where d_o, k_{re}, ω_o, Q and A_e are electrode-to-resonator gap spacing, equivalent stiffness, radian resonance frequency, quality factor, and electrode-to-resonator overlap area, respectively, and where V_P and ε_o are the dc-polarization voltage and free-space permittivity, respectively. In (3), the parameter $X_{\max}$ denotes the maximum vibration amplitude of the resonator. To reduce the motional impedance R_m and increase the maximum power handling capability $P_{o\max}$ of a resonator, mechanically-coupled array design concept is adopted here to effectively increase both the equivalent stiffness k_{re} and transduction area A_e, hence lowering R_m and

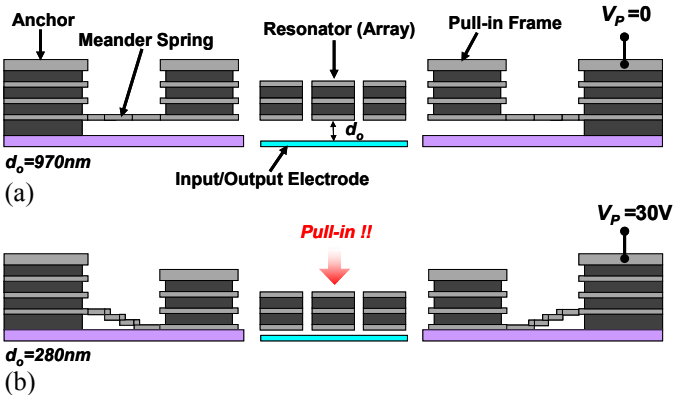

Fig. 3: Cross-section view schematics of the CMOS-MEMS resonator array illustrating resonator status (a) before and (b) after a dc-bias voltage is applied into the resonator structure.

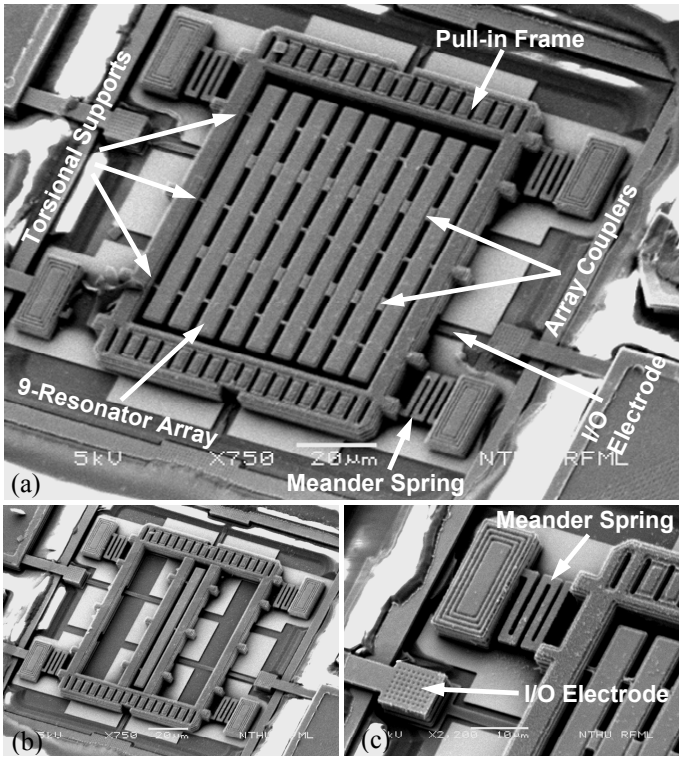

Fig. 4: (a) Global view of a 9-resonator array where the constituent resonator components are located at the center of the pull-in frame. (b) Fabricated single free-free beam resonator using the same pull-in frame. (c) Meander-spring zoomed view of the 9-resonator array.

increasing P_{omax}. To further reduce the motional impedance, the pull-in gap reduction mechanism to enable deep-submicron gaps is an efficient approach to minimize R_m. Fig. 3(a) and (b) present the gap-reduction operation of the resonator array with status (a) before pull-in operation where dc-bias V_P is 0V and (b) after pull-in gap reduction where dc-bias V_P is 30V. The final gap of around 280nm is set by altitude difference of the two polysilicon layers in the 0.35μm CMOS process.

III. Fabrication Process

The free-free beam resonator arrays were fabricated by using a generalized 0.35μm 2P4M CMOS-MEMS platform provided by TSMC followed by a maskless wet-release process [4]. A commercial silicon-dioxide etchant with very high selectivity between metal and oxide was used to perform the maskless oxide release process without the help of critical point dryer. After wet release process, the surrounded sacrificial oxide was removed, leaving the resonator structures together with their pull-in frames suspended above the input/output (I/O) electrodes and pull-in stoppers by the use of the soft meander springs.

Fig. 4(a) presents a global SEM view of a fabricated CMOS-MEMS second-mode free-free beam resonator array containing 9 identical resonators. The array couplers (at high-velocity vibrating locations) and I/O electrodes are also indicated. In this work, a single resonator was also fabricated for comparison with a SEM view shown in Fig. 4(b). The meander-spring zoomed view is also shown in Fig. 4(c). Note

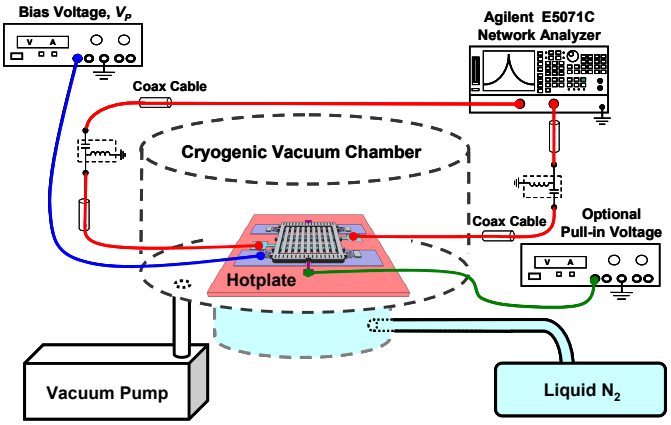

Fig. 5: Two-port measurement setup for a free-free beam resonator array in a cryogenic vacuum probe station.

that this single resonator only has three torsional supports for minimizing the anchor loss while the resonator array in Fig. 4(a) possesses six torsional supports for persevering enough polarization voltage V_P to avoid device breakdown.

IV. Experimental Results

As mentioned above, a typical two-port biasing and excitation configuration is used to characterize the fabricated CMOS-MEMS resonator and array. As shown in Fig. 5, the fabricated resonator was placed in a cryogenic vacuum probe station to measure its capacitive transduction characteristics under a vacuum level of 100μTorr. Since the meander springs of the pull-in frame are of low stiffness, the optional pull-in voltage port shown in Fig. 5 is connected to ground throughout the following measurement results. To operate the device, a dc-bias voltage V_P is applied into the resonator to perform pull-in, as a result producing a deep-submicron electrode-to-resonator gap of around 280nm. Then a small ac signal v_i is applied onto the input electrode. Such a small ac signal v_i together with the dc-bias voltage V_P would generate electrostatic force to drive the resonator into resonance as frequency of v_i matches the resonance frequency of the beam structure, hence sourcing out a motional current i_m to the output electrode. The motional current then goes back to the network analyzer, showing a high-Q frequency response due

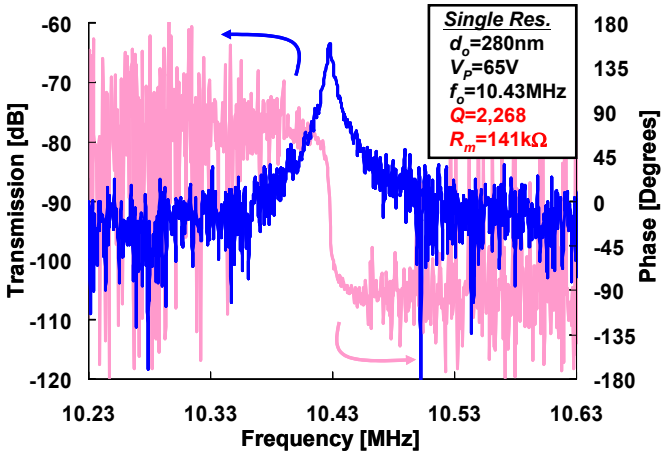

Fig. 6: The measured frequency spectrum of a single resonator under a bias voltage of 65V in a vacuum environment.

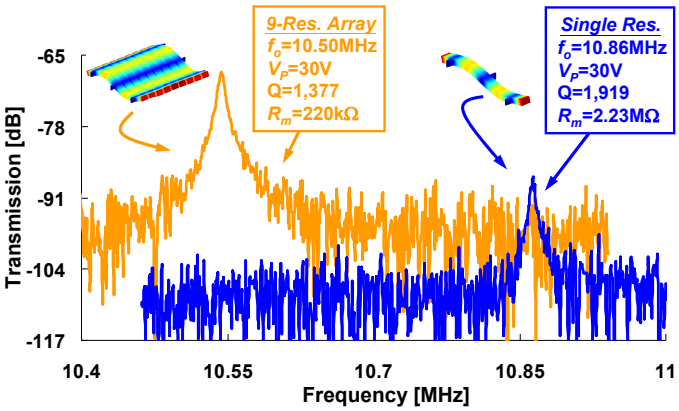

Fig. 7: The measured frequency spectra of single resonator and multi-resonator array under the same bias voltage of 30V in vacuum environment.

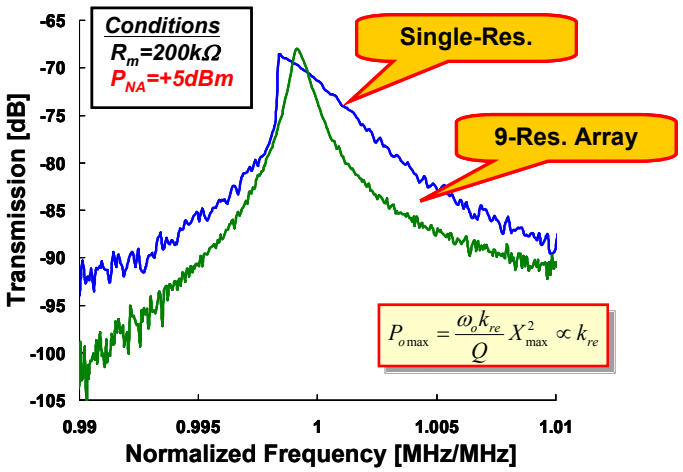

Fig. 8: Comparison of single resonator and 9-resonator array under the same motional impedance and input power level.

to the mechanical vibration.

Fig. 6 presents the measured transmission amplitude and phase plots for a single second-mode free-free beam resonator centered at 10.43 MHz under a dc-bias voltage of 65V in vacuum. The motional impedance of the resonator is less than 150 kΩ with quality factor greater than 2,200, comparable to that of the fundamental mode free-free beam resonators (one-port electrical configuration) fabricated by using the same CMOS-MEMS process [5]. To characterize the performance of the resonator array, Fig. 7 presents measured frequency characteristics of the fabricated single free-free beam resonator and the nine mechanically-coupled resonator array tested under the same bias voltage V_P of 30V and 100μTorr vacuum environment. Obviously, the resonator array exhibits lower motional impedance than that of the single resonator as expected. In theoretical calculation, the motional impedance reduction ratio is proportional to the number (9 in this work) of constituent resonators used in an array. In Fig. 7, motional impedances of 2.23 MΩ and 220 kΩ for single resonator and 9-resonator array, respectively, were measured, showing the reduction ratio is around 10.1 which is in good agreement with the ideal ratio of 9. The discrepancy of R_m reduction ratio mainly comes from the contribution of additional transduction areas between short stubs and I/O electrodes in an array.

To characterize the relative enhancement of the power handling capability for the mechanically-coupled resonator array, single resonator and 9-resonator array were tested under the same transmission conditions, i.e., the same motional impedance and input power level. As shown in Fig. 8, these two resonators with similar motional impedance R_m and quality factor Q were operated under the same driving condition of P_{NA} = 5dBm, showing different measured transmission spectra. P_{NA} denotes the power directly from the network analyzer in Fig. 5. In such a power level, the single resonator was driven into the Duffing nonlinear regime while the 9-resonator array was still far away from its bifurcation point, showing significant power handling improvement using mechanically-coupled array approach.

V. Conclusion

In this work, two-port CMOS-MEMS free-free beam resonator arrays combined with pull-in gap reduction mechanism to enable deep-submicron electrode-to-resonator gap spacing have been successfully demonstrated with preferred electrical configuration (i.e., two-port operation) and much lower dc-bias voltage (only 30V versus more than 60V used in previous single beam resonator) for attaining satisfactory motional impedance. In addition, the power handling capability of the mechanically-coupled resonator array is significant improved, hence paving a way for realizing low phase noise monolithic CMOS-MEMS oscillators in the future.

***Abstract*—Bulk dilation modes in rectangular plates of particular orientations in single crystal silicon are found to have distinct advantages over to those in isotropic materials. Finite element modeling using an anisotropic model reveals plates aligned to the ‹110› direction in (100) silicon have modes which offer excellent capacitive coupling and good isolation to the supports. Low impedance and high *Q* are predicted for select geometries. Experimental results are included, showing a 100-MHz resonator having an unloaded *Q* of 90,000, which demonstrate an *f*-*Q* product of ~1×10^{13}.**

I. Introduction

Micromechanical resonators [1] are a promising alternative to traditional macro-scale frequency control devices. Silicon is an attractive material since it is well characterized, it has deterministic material properties, and it offers low acoustic loss.

Electrostatic micromechanical resonators, also known as capacitive resonators, are attractive for a number of reasons. Since metallization is not necessary on the resonating structure, the resonator can be monolithic in the strictest sense. Very high quality factors, no built-in stress, and excellent long-term stability are possible in silicon capacitor resonators.

The characteristic motional resistance R_1 in early demonstrations of capacitive resonators was 10 kΩ to 1 MΩ. It is desirable for resonators, especially those at higher frequencies, to have lower R_1. Reducing R_1 (*i.e.*, increasing output current from an input voltage) involves increasing electrode area, improving electromechanical coupling, and optimizing the mode shape of the resonator.

High *Q* reduces the close-to-carrier phase noise. Ensuring high *Q* requires minimizing the magnitude of the loss mechanisms. It is necessary to minimize both the intrinsic and extrinsic loss mechanisms. The design-dependent extrinsic losses are reduced through mode isolation (from other modes) and designing for mode shapes which limit energy leakage into the surrounding medium.

Good linearity is also desired in the resonator for a low noise floor. The linearity limit of a resonator is determined by material properties and physical dimensions. It is evident that a large resonator is desirable.

A silicon plate resonator with a large lateral dimension is introduced to satisfy the requirements for low R_1, high *Q*, and good linearity. See Figure 1. As the lateral dimension is increased, it is known that wavelike properties commonly appear in the observed modes. The modes for some isotropic plates are shown in Figure 2.

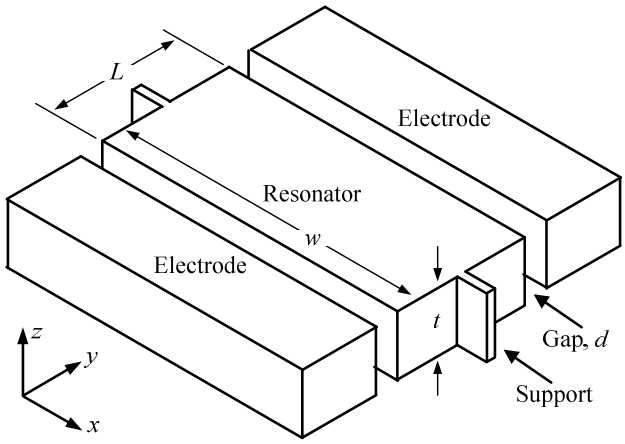

Figure 1. Perspective view of a capacitive plate resonator with two supports and two fixed electrodes.

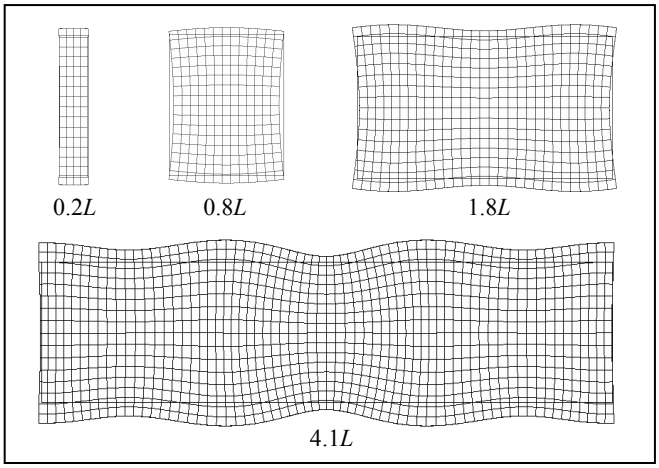

Figure 2. Typical mode shapes in narrow, wide, and very wide rectangular plates in isotropic materials (ν=0.28).

The objective of this work includes: 1) characterizing the dilation modes of rectangular plates in isotropic and anisotropic materials and 2) understanding whether plate modes can be optimized for the metrics of interest. Finite element analysis is performed in ANSYS using SOLID186 elements and isotropic and anisotropic material models.

II. Bulk Dilation Modes

A brief discussion of bulk dilation modes in capacitive resonators follows. The natural frequencies are

$$f_n = \frac{n v_a}{2L}, \tag{1}$$

where n is the mode number, v_a is the acoustic velocity and L is the length of the resonator. The motional resistance of a capacitive bulk dilation mode resonator may be simplified to

$$R_1 = \frac{k_r \pi \sqrt{E_i \rho_m} d^4}{2Q\varepsilon^2 V_P{}^2 A}, \tag{2}$$

where k_r is the relative dynamic stiffness, E_i is the elastic modulus in the i direction, ρ_m is the mass density, d is the gap size, ε is the permittivity of the gap, V_P is the polarization voltage, and A is the overlap area of the electrodes. It is evident that increasing A reduces R_1 – more current is available when the transduction area is increased. Reducing k_r also reduces R_1. An interesting observation is that R_1 is not directly dependent on frequency. Contrary to the trend in prior art, higher frequency resonators do not necessarily have higher R_1.

k_r is a comparison between the dynamic stiffness k_n and the stiffness of a slender ideal 1-dimensional resonator.

$$k_r = \frac{k_n}{k_{n,1D}} \tag{3}$$

It is strongly dependant on the mode shape. One goal of this work is to understand the effect of increasing A on k_r.

The dynamic stiffness k_n for each mode is found from the energy in the mode W and the average of the displacement of the resonator electrode surface normal to the fixed electrode u_y. For a low k_n (and consequently low k_r), all the energy in the mode is preferably attributed to u_y.

$$k_n = \frac{2W}{\overline{u_y}^2} \tag{4}$$

III. Isotropic Plates

The analysis begins by extending the findings on bulk dilation modes of isotropic plates summarized in [2]. In a plate with a small width w (*e.g.*, 0.2L), the mode is entirely uniform along the ends. See Figure 2. As w is increased to 0.8L, some non-uniformity is observed. Lateral motion at the support location exists. For a plate with a width of 1.8L, the most prominent mode is a third mode along the x direction. For a width of 4.1L, the most prominent mode is a seventh-order mode along x. Although the frequencies of these modes are very similar, the latter three modes are in three different modal families.

Focusing on the seventh-order modal family of an isotropic material with a Poisson ratio v of 0.28, observe the attributes of the mode as the width is increased. See Figure 3. For w=3.5L, there are out-of-phase regions which cause charge cancellation. The mode in this geometry has poor coupling and a large k_r. For w=4.1L, the displacement is somewhat uniform. With this geometry, the u_x motion at the support is minimal. For w=4.3L, the displacement is most uniform. This is the optimal plate geometry for coupling and the k_r is 1.2. Further increasing w to 4.8L leads to a more wavelike mode with substantial u_x motion at the support. In these thin isotropic plates, the optimal coupling and optimal support isolation occur for different values of w.

The solutions for isotropic plates having widths of [0,10]L, thickness t of L/5, and v = 0.28 are summarized in Figure 4. k_r and normalized u_x (to the average u_y) are plotted. The minima for k_r, for w>2L, are approximately 1.2. There are geometries in which the support u_x is small. However, u_x is quite sensitive to the width.

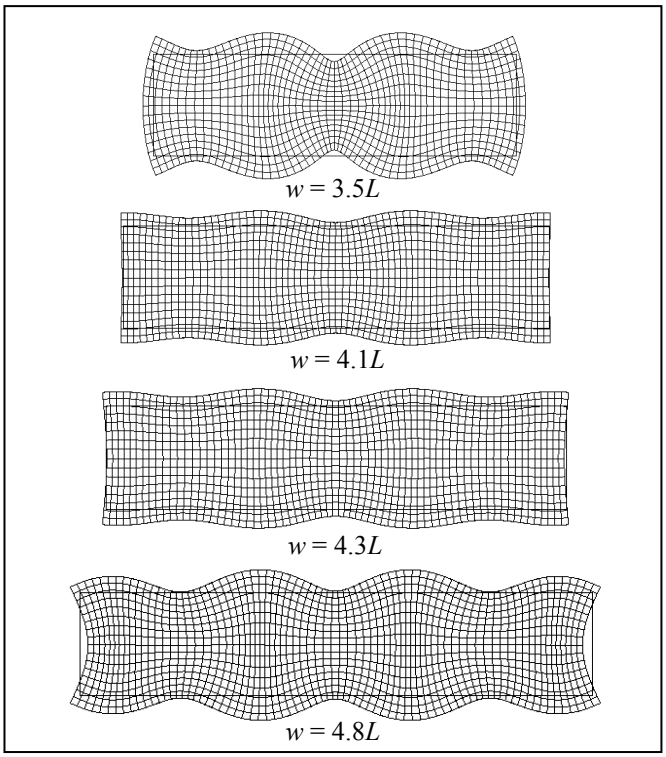

Figure 3. Variation of mode shape within a modal family for width of 3.5L, 4.1L, 4.3L, and 4.8L (isotropic, v=0.28).

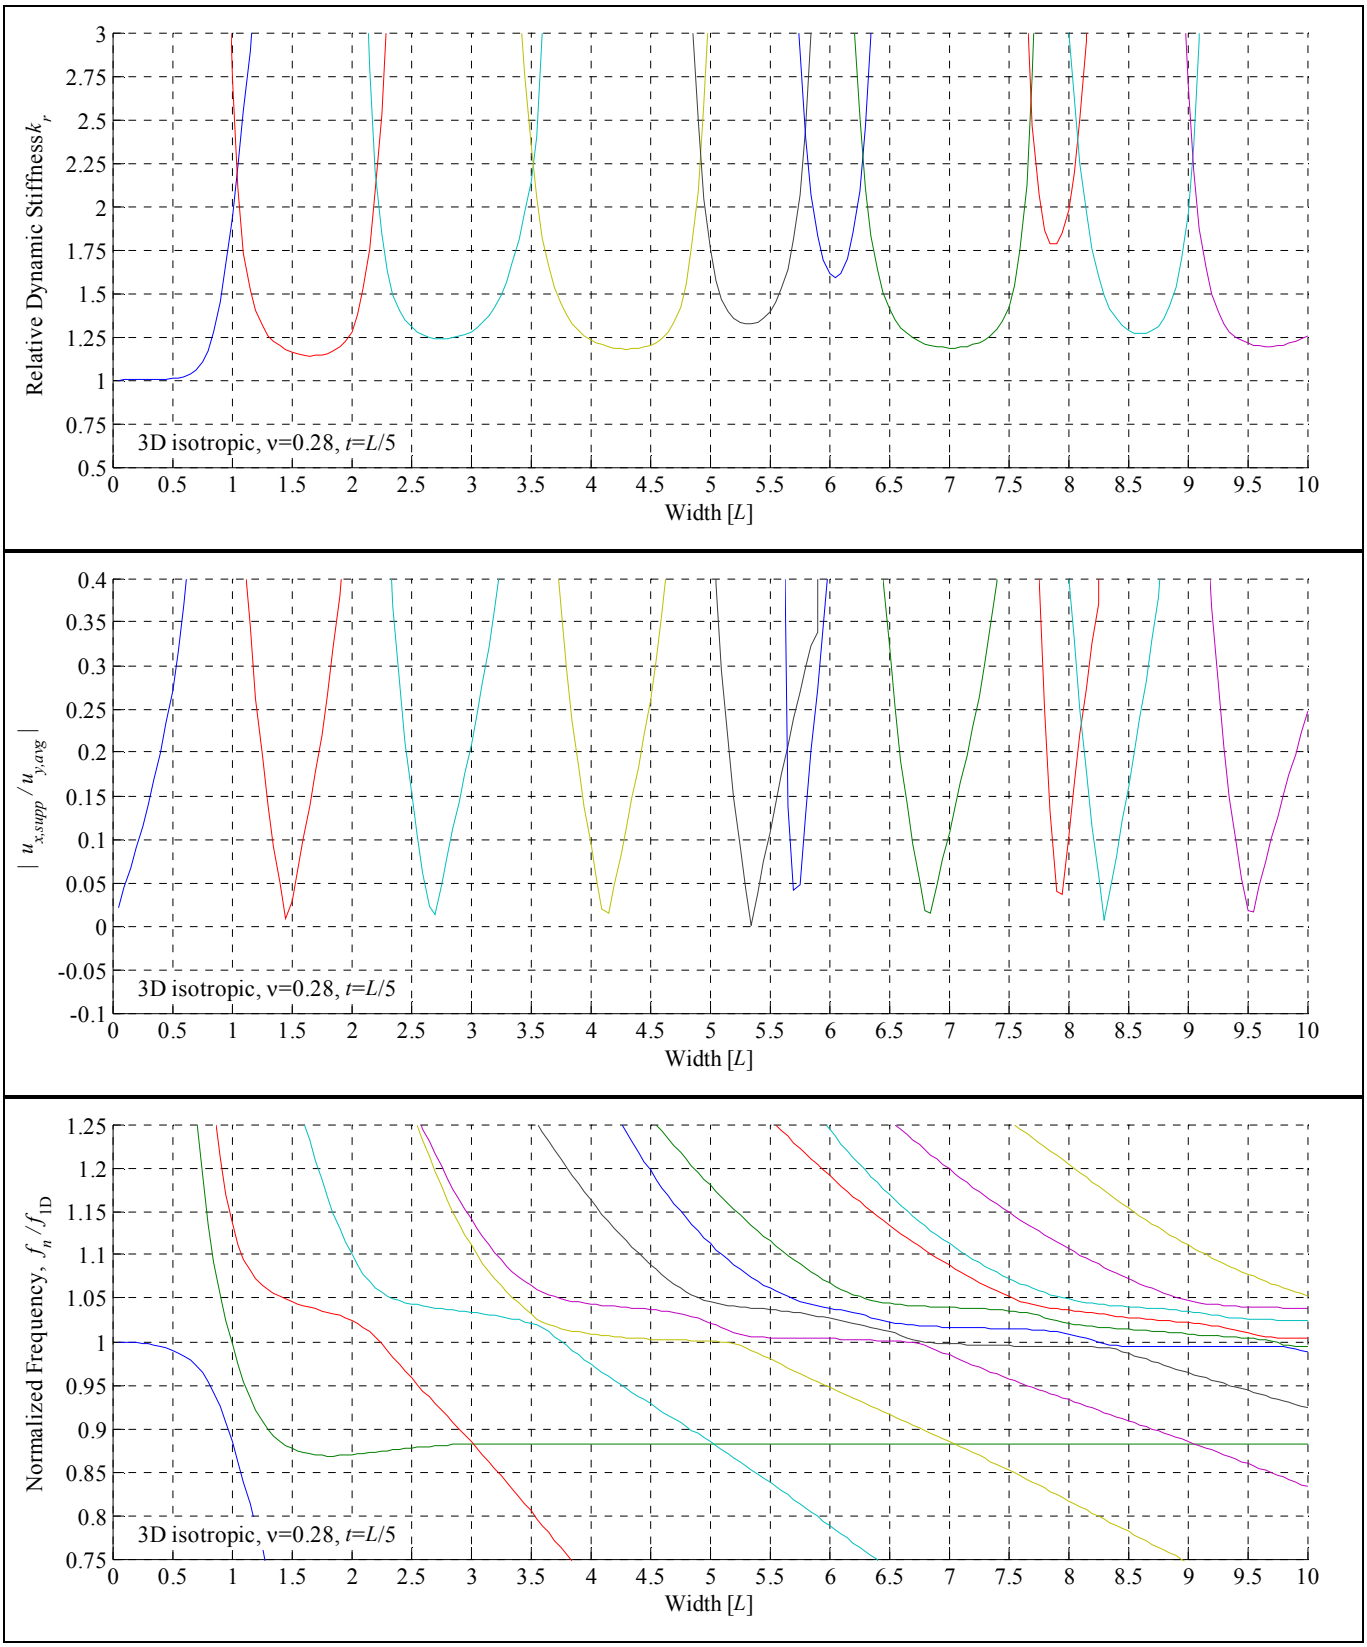

Figure 4. Relative dynamic stiffness, normalized support motion, and normalized frequency in isotropic plates with ν=0.28 and a thickness of L/5.

IV. Anisotropic Plates

The analysis for anisotropic plates is performed similarly. A very interesting observation is that uniform modes are observed in plates aligned to the ‹110› direction in (100) silicon. A thorough analysis was completed for plates with t equal to $L/5$ and $L/2$. The mode shape for $L/5$-thick plates with w=[3.4,4.1]L are very uniform (Figure 5). For w=3.7L, the mode has the smallest u_x response at the support. The k_r and normalized support u_x are shown in Figure 6.

There are several advantages for these anisotropic plates. First, k_r is ~1 for a large variety of widths. Next, u_x is smaller compared to isotropic plate modes. The u_x minima coincide with the k_r minima. Also, u_x has low sensitivity to w.

Increasing the thickness to $L/2$ reveals further advantages. See Figure 7. Compared to $L/5$ plates, the range of widths for which $k_r \approx 1$ is broader. The u_x also have lower sensitivity to w. The most beneficial attribute is that the transduction area is increased without increasing die size.

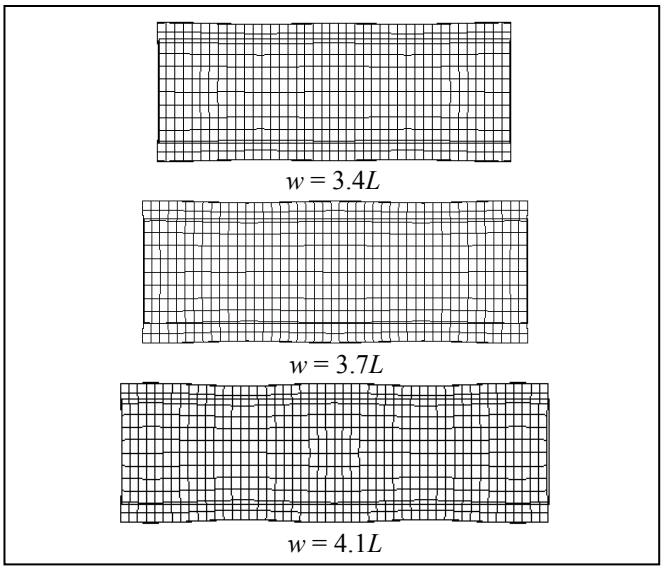

Figure 5. Variation of mode shape within a modal family for width of 3.4L, 3.7L, and 4.1L (anisotropic, t=L/5).

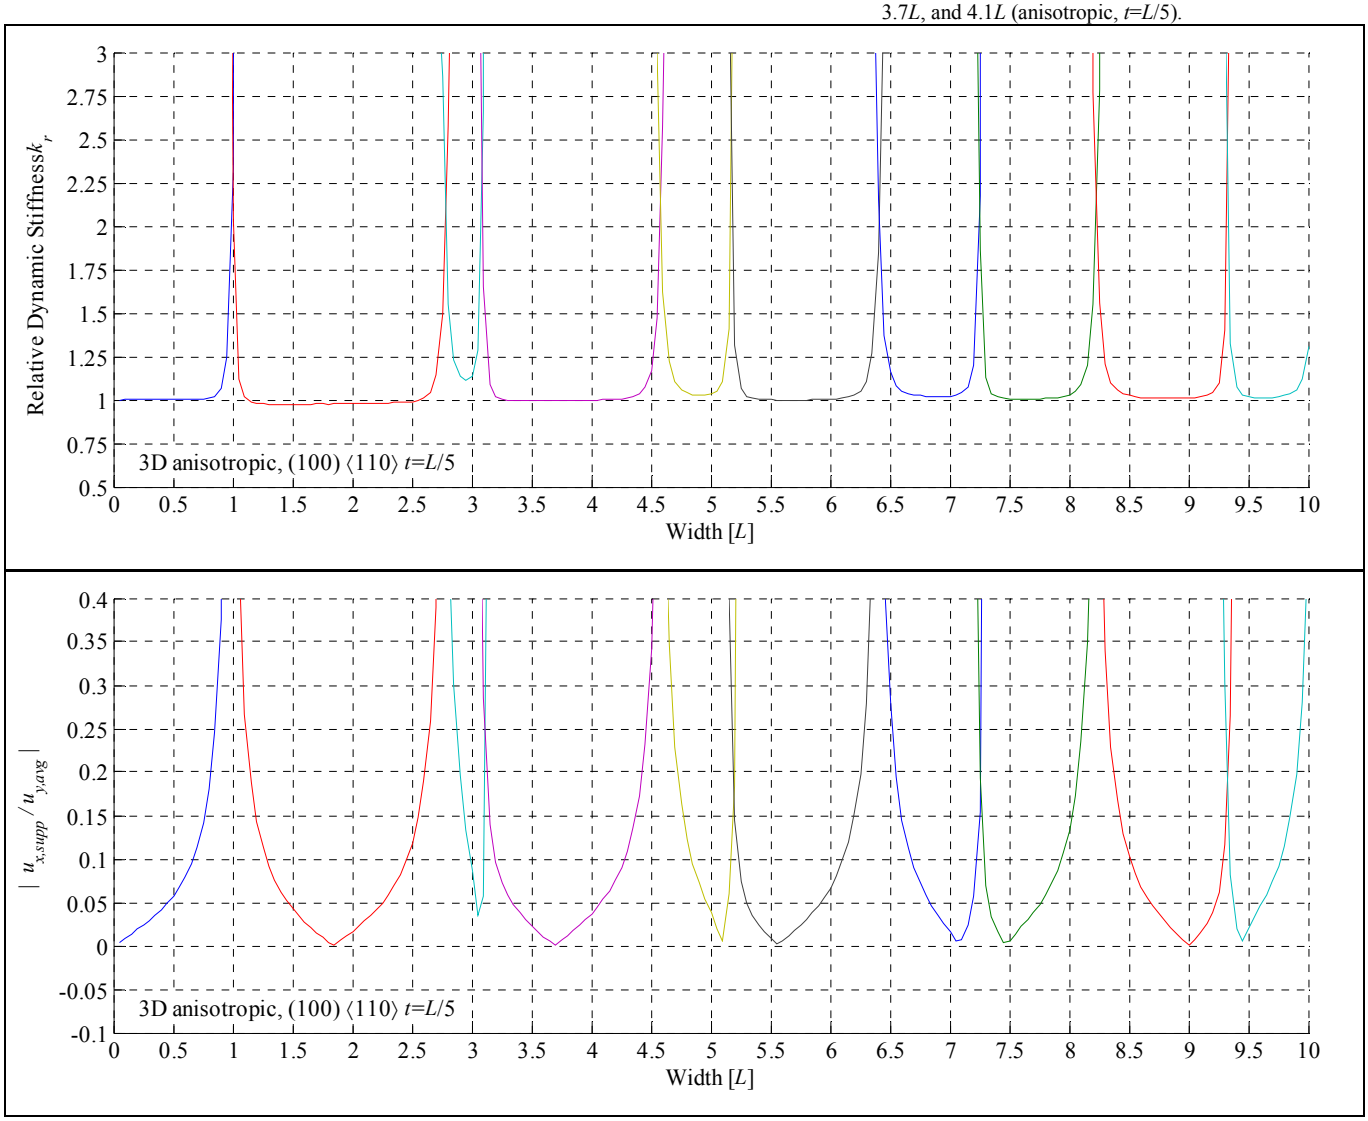

Figure 6. Relative dynamic stiffness and normalized support motion in anisotropic plates aligned to ‹110› in (100) silicon having a thickness of $L/5$.

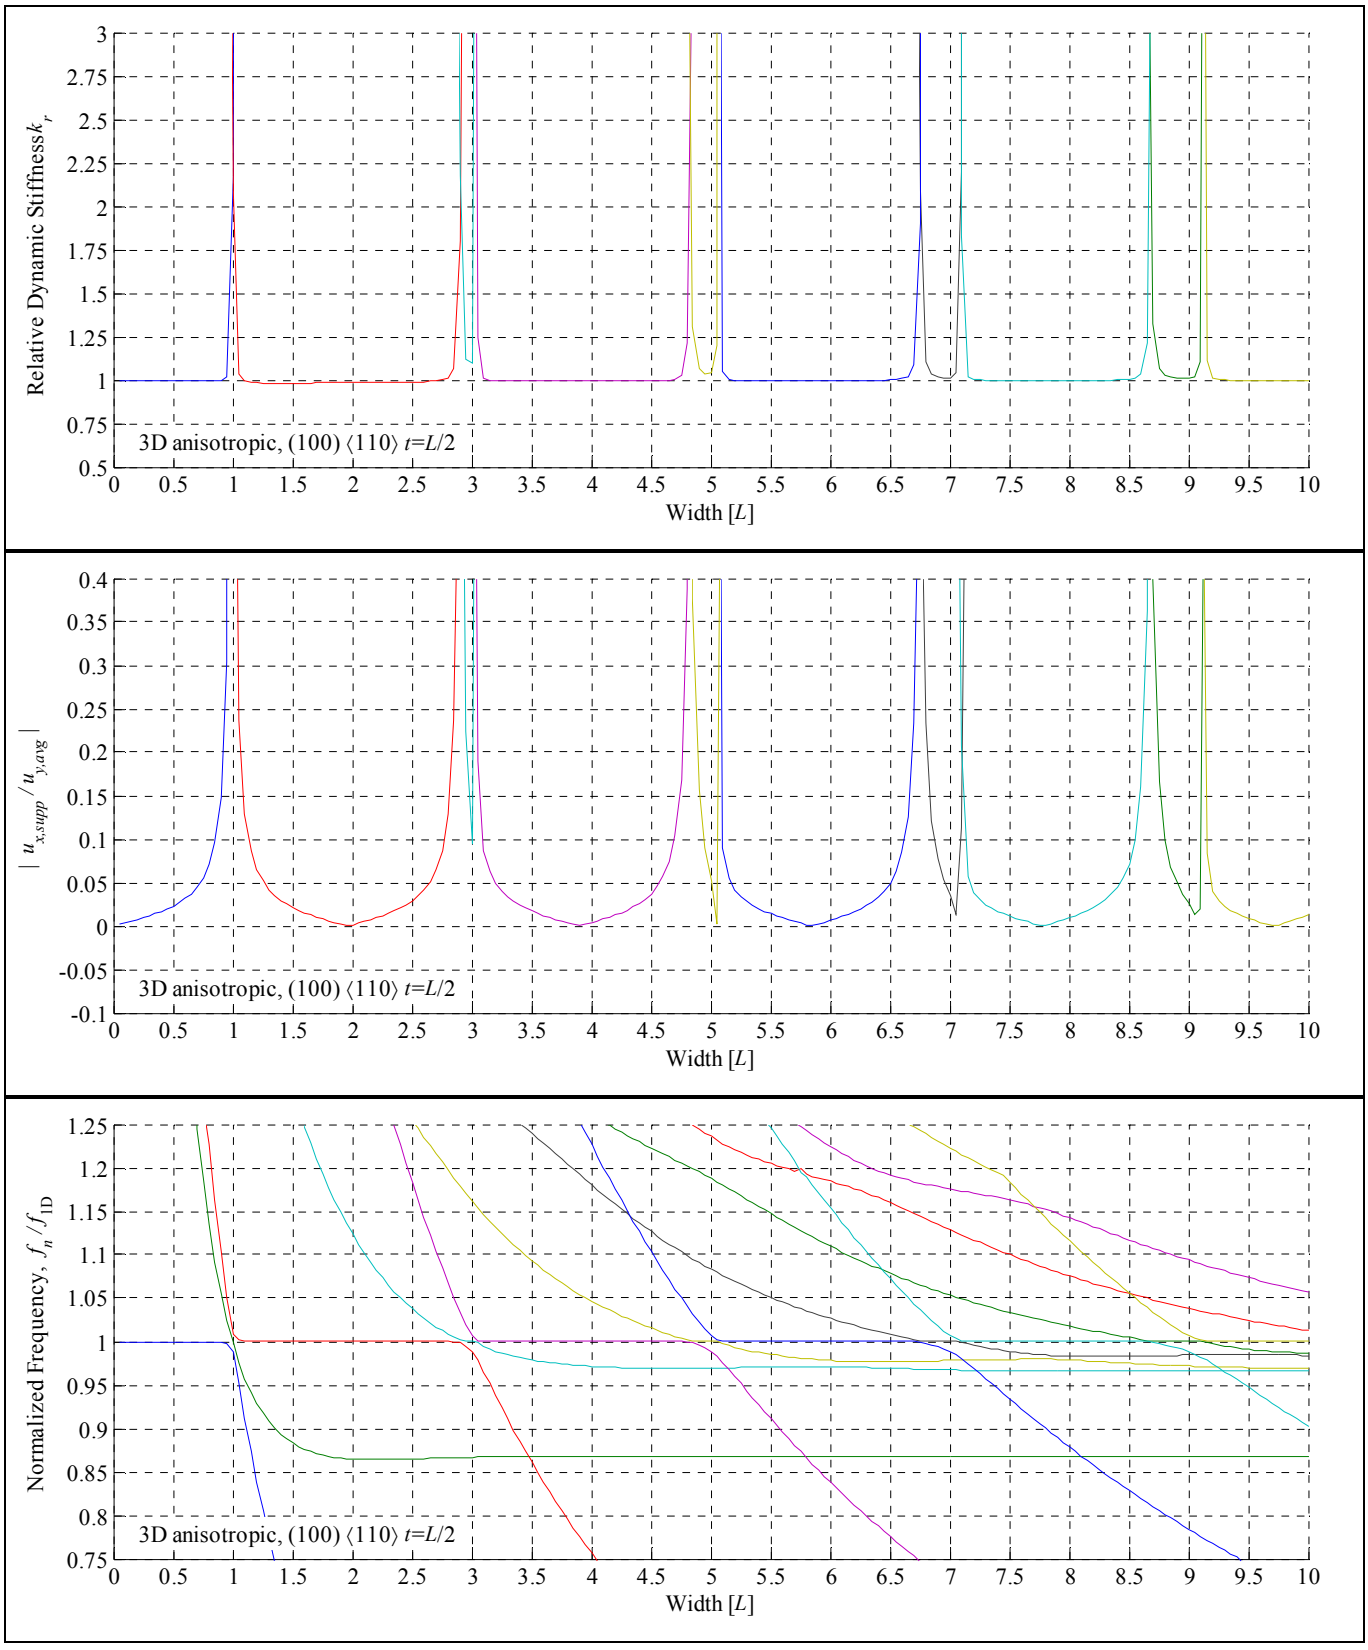

Figure 7. Relative dynamic stiffness, normalized support motion, and normalized frequency in anisotropic plates aligned to ‹110› in (100) silicon having a thickness of L/2.

Periodicity is evident from the results. Widths of even multiples of L provide small motion at the supports and good coupling. The optimal widths for minimizing support loss are 2.0L, 3.9L, 5.8L, 7.7L, and 9.7L.

V. Experimentation

Resonators with L=40μm and t=L/2 were fabricated using the HARPSS-on-SOI process [3]. A resonator with a width of 9.7L and 225-nm gaps is shown in Figure 8. The resonance frequency of this resonator was measured to be 103 MHz along with a quality factor of 90000. See Figure 9. The optimized design enabled the f-Q product of ~1×10^{13}.

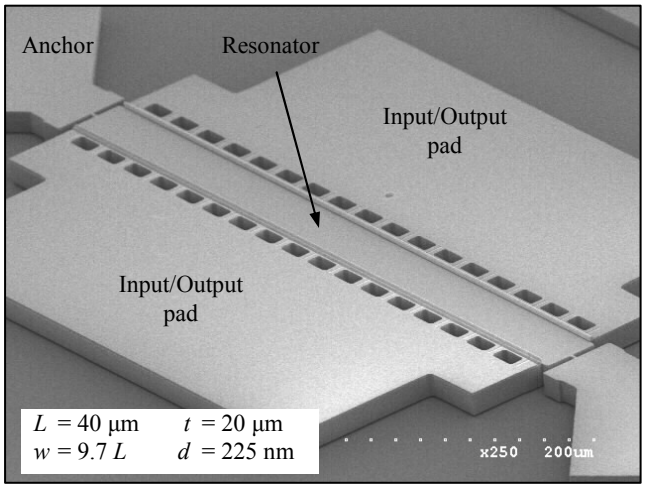

Figure 8. Scanning electron micrograph of a resonator fabricated using the HARPSS-on-SOI process.

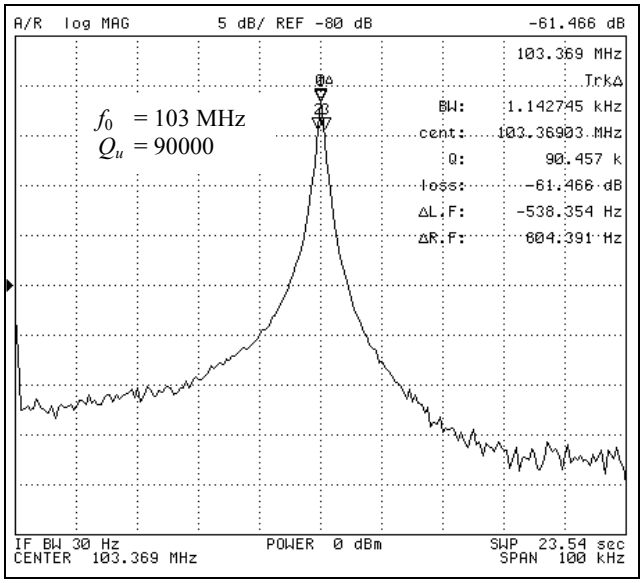

Figure 9. Transmission frequency response of the resonator showing an unloaded Q of 90000 at a frequency of 103 MHz.

Conclusions

Bulk dilation modes of plates aligned to the ‹110› direction in (100) silicon were found to have improved attributes over plates in isotropic materials. In anisotropic plates, the relative dynamic stiffness is unity for many geometries. For a broad range of widths, a 1-dimensional assumption applies. The thorough exercise also revealed specific widths at which the motion of the support location is minimal. This enabled a 100-MHz resonator to demonstrate an f-Q product of 1×10^{13}. Future work includes characterizing modes in plates with larger thickness.

***Abstract*—Atomic Clock Ensemble in Space (ACES) is a mission using high-performance clocks and links to test fundamental laws of physics in space. The ACES microwave link (MWL) will make the ACES clock signal available to ground laboratories equipped with atomic clocks. The ACES MWL will allow space-to-ground and ground-to-ground comparisons of atomic frequency standards. The MWL comprises the Flight Segment (FS) as part of the ACES payload as well as a distributed set of Ground Terminals (GT), collocated with the ground atomic clocks. MWL is a two-way, two-frequency link transmitting a carrier signal modulated by a PN code, both phase coherent with the local clocks. MWL is designed to reach a time resolution (TDEV) of 0.3 ps in less than 300 s of integration time. In addition to the MWL, operating in microwave domain, ELT is an optical link based on the exchange of laser pulses detected and time stamped in MWL in the local time scale in space and on ground.**

The engineering model of the MWL FS and the first prototypes of the MWL GT will be used for end-to-end testing of the MWL performance. The end-to-end test is using a set-up, where the MWL FS and GT are connected by cables through a test equipment that allows the full simulation of the signal dynamics during an overflight of the ISS over a MWL GT. The MWL design and test results of the individual elements will be briefly reported. The results of the end-to-end test will be presented and perspectives for clock comparisons with ACES discussed.

I. INTRODUCTION

ACES is a distributed system designed to disseminate a high stability and accuracy clock signal [1,2]. It consists of a space payload generating the ACES atomic frequency reference and a network of ground terminals connected to high-performance atomic clocks on ground.

Transported on the International Space Station (ISS) by the Japanese transfer vehicle HTV in the 2014-2015 timeframe, the ACES payload will be installed at the external payload facility of the Columbus module, using the space station robotic arm.

The ACES payload (Fig. 1) accommodates two atomic clocks: PHARAO (acronym of "Projet d'Horloge Atomique par Refroidissement d'Atomes en Orbit"), a primary frequency standard based on samples of laser cooled caesium atoms, and SHM (acronym of "Space Hydrogen Maser"), an active hydrogen maser for space applications. The performances of the two clocks are combined to generate an on-board timescale with the short-term stability of SHM and the long-term stability and accuracy of the PHARAO clock. The on-board comparison of PHARAO and SHM and the distribution of the ACES clock signal are ensured by the Frequency Comparison and Distribution Package (FCDP), while all data handling processes are controlled by the eXternal PayLoad Computer (XPLC). A GNSS receiver installed on the ACES payload and connected to the on-board time scale will provide orbit determination of the ACES clocks. One of the main objectives of the ACES mission consists in maintaining a stable and accurate on-board timescale that will be used to perform space-to-ground as well as ground-to-ground comparisons of atomic frequency standards. The ACES clock signal will be compared to ground clocks using two separate links: a time and frequency transfer link in the microwave domain (MWL) and an optical link (ELT). These comparisons will enable fundamental physics tests and applications in different areas of research.

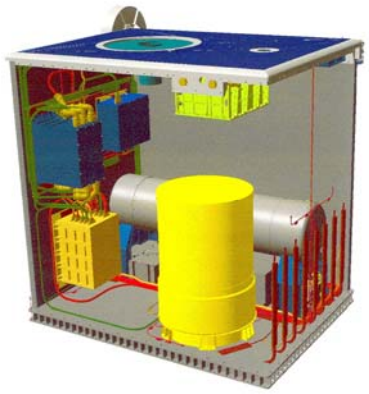

Figure 1. ACES Payload Design. Front: SHM; back: PHARAO, side panels removed for better visibility.

The planned mission duration is 18 months. During the first two weeks, the functionality of the clocks and of MWL will be tested. Then, a period of 6 months will be devoted to

The work presented is performed under ESA contract 16242/02/NL/JS.

the characterization and performance evaluation of the clocks. During this phase, a clock signal with frequency inaccuracy in the 10^{-15} range will be available to ground users. Under microgravity conditions, it will be possible to tune the linewidth of the atomic resonance of PHARAO by two orders of magnitude, down to sub-Hz values (from 11 Hz to 110 mHz). After the clocks optimization, performances in the 10^{-16} range both for frequency instability and inaccuracy are expected. In the second part of the mission (12 months, possibly extended up to 30 months), the on-board clocks will be compared to a number of atomic clocks on ground operating both in the microwave and optical domain.

ACES will perform worldwide comparisons of advanced clocks operating on different atoms or molecules reaching a frequency resolution in the 10^{-17} regime. These measurements will test general relativity and seek for new interactions beyond the Standard Model.

The ACES mission is developed by ESA with ASTRIUM as prime contractor. PHARAO is funded and developed by CNES as contribution to the ACES mission.

The ACES Mission is presently in phase C/D. All instruments and subsystems are in an advanced state of development with engineering models delivered and flight models manufacturing started. The ACES Payload and Ground Segment Critical Design Reviews (CDR) have been successfully passed in 2009 and 2010, respectively.

Development is now proceeding towards a delivery of the ACES payload flight model in 2013. ACES is designed for a mission duration of 1.5 years with the possibility for extension to a minimum of 3 years.

II. ACES Scientific Objectives

ACES will conduct the first experiments with cold atoms under microgravity conditions equivalent to a freely falling laboratory; it will perform fundamental physics tests to high resolution, and develop applications in different areas of research.

A. New Generation of Microwave Clocks for Space

A new generation of space clocks reaching frequency instability and inaccuracy of few parts in 10^{16} will be validated by ACES. PHARAO will combine laser cooling techniques and microgravity conditions to significantly increase the interaction time and consequently reduce the linewidth of the clock transition. Improved stability and better control of systematic effects will be demonstrated in the space environment. PHARAO will have a fractional frequency instability of $1 \cdot 10^{-13} \cdot \tau^{-1/2}$, where τ is the integration time expressed in seconds, and an inaccuracy of few parts in 10^{16}. The reliability offered by active H-masers will be made available for space applications by SHM. SHM will demonstrate a fractional frequency instability of $1.5 \cdot 10^{-15}$ after only 10000 seconds of integration time. Two servo-loops will lock together the clock signals of PHARAO and SHM generating an on-board time scale, combining the short-term stability of the H-maser with the long-term stability and accuracy of the caesium clock (Fig. 2).

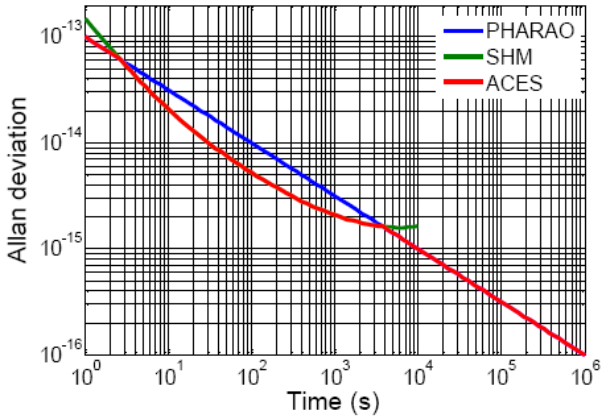

Figure 2. Fractional frequency instability specified for the PHARAO, SHM, and ACES clock signals in space

The ACES clock signal will be distributed via a dedicated Microwave Link (MWL). Frequency transfer with time deviation better than 0.3 ps at 300 s, 7 ps at 1 day, and 23 ps at 10 days of integration time will be demonstrated (Fig. 3). These performances, surpassing existing techniques (TWSTFT and GPS) by one to two orders of magnitude, will enable common view and non-common view comparisons of ground clocks with 10^{-17} frequency resolution after a few days of integration time. Thanks to the recent development of optical frequency combs [3,4], which significantly simplify the link between optical and microwave frequencies, ACES will be able to take full advantage of the progress of optical clocks [5,6], today reaching instability and inaccuracy levels of a few parts in 10^{17}.

ACES will also deliver a global atomic time scale with 10^{-16} accuracy, it will allow clock synchronization at an uncertainty level of a few hundreds of ps, and contribute to international atomic time scales (TAI, UTC…).

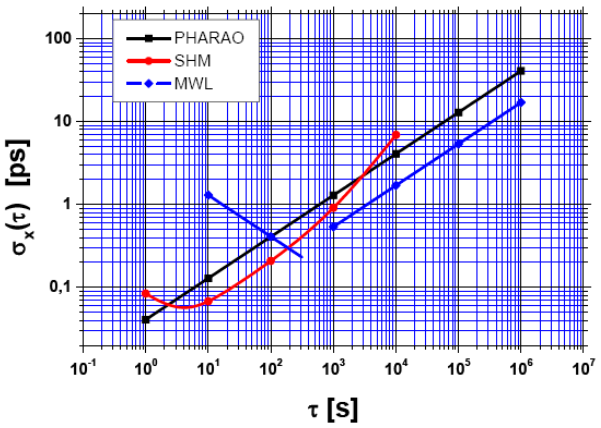

Figure 3. Time instability specified for PHARAO, SHM, and MWL.

B. Fundamental Physics Tests with ACES

According to Einstein's theory of general relativity, identical clocks placed in different gravitational fields experience a frequency shift that, in the frame of the PPN

approximation, depends on the difference between the Newtonian potentials at the clocks positions. The comparison between the ACES on-board clocks and ground-based atomic clocks will measure the frequency variation due to the gravitational red-shift with a 35-fold improvement on previous experiments [7], testing Einstein's prediction at the 2 ppm uncertainty level.

Time variations of fundamental constants can be measured by comparing clocks based on different transitions or different atomic species [8]. Indeed, any transition energy can be expressed in terms of the fine structure constant α and the two dimensionless constants m_q/Λ_{QCD} and m_e/Λ_{QCD}, depending on the quark mass m_q, the electron mass m_e, and the QCD mass scale Λ_{QCD} [9,10]. ACES will perform crossed comparisons of ground clocks both in the microwave and in the optical domain with a frequency resolution of $1\cdot10^{-17}$ in a few days of integration time. These comparisons will impose strong and unambiguous constraints on time variations of fundamental constants reaching an uncertainty of $1\cdot10^{-17}$/year in case of a 1-year mission duration, down to $3\cdot10^{-18}$/year after three years.

The foundations of special relativity lie on the hypothesis of Local Lorentz Invariance (LLI). According to this principle, the outcome of any local test experiment is independent of the velocity of the freely falling apparatus. In 1997, LLI tests based on the measurement of the round-trip speed of light have been performed by comparing clocks on-board GPS satellites to ground hydrogen masers [11]. In such experiments, LLI violations would appear as variations of the speed of light c with the direction and the relative velocity of the clocks. ACES will perform a similar experiment by measuring relative variations of the speed of light at the 10^{-10} uncertainty level.

C. Applications

ACES will also demonstrate a new technique, called "relativistic geodesy", to map the Earth gravitational potential. This technique uses a precision measurement of the Einstein's gravitational red-shift between two clocks to determine the corresponding difference in the local gravitational potentials. The possibility of performing comparisons of ground clocks at the 10^{-17} frequency uncertainty level will allow ACES to resolve geopotential differences at 10 cm.

A dedicated GNSS receiver on-board the ACES payload will ensure orbit determination, important for comparing clocks and performing fundamental physics tests. In addition, the GNSS subsystem will be connected to the ACES clock signal, opening the possibility to use the GNSS network for clock comparisons or remote sensing applications (GNSS radio-occultation and reflectometry).

In addition to the ACES MWL, the European Laser Timing (ELT) link will allow clock comparisons, time transfer, and ranging experiments in the optical domain. The combination of ELT and MWL will provide a bench to test two different time transfer and ranging techniques, also opening the door to studies of atmospheric propagation delays.

III. MWL Status

The ACES clock signal distributed by FCDP is finally transmitted to ground stations by the ACES microwave link. The proposed MWL concept is an upgraded version of the Vessot two-way technique used for the GP-A experiment in 1976 [7] and the PRARE geodesy instrument. The system operates continuously with a carrier frequency in the Ku-band. The high carrier frequencies of the up and down links (13.5 GHz and 14.7 GHz respectively) allow for a noticeable reduction of the ionospheric delay. A third frequency in the S-band (2.2 GHz) is used to determine the Total Electron Content (TEC) and correct for the ionospere time delay. A PN-code modulation (100 Mchip/s) of the carrier removes the phase ambiguity between successive comparison sessions separated by large dead times. The system is designed for multiple access capability, allowing up to 4 simultaneous ground users distinguished by the different PN-codes and Doppler shifts.

A. MWL Flight Segment

The engineering model of the flight segment electronic unit (Fig. 4) has been completed and tested.

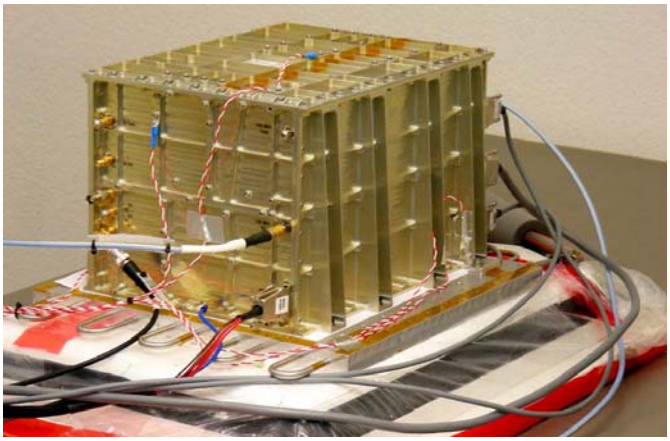

Figure 4. MWL Flight Segment engineering model under test.

MWL long-term stability is ensured by the continuous calibration of the receiver channels provided by a built-in test-loop translator. For shorter durations (< 300 s), time stability is driven by the noise performance of the Ku transmitter and receiver and of the DLL (Delay-Locked Loop) boards. The 100 MHz chip rate has already enabled a time stability better than 2 ps to be achieved with code measurements. Carrier phase stability is shown in Fig. 5, where time deviations down to 80 fs at about 100 s are reported. For longer durations, time deviation remains well below the 1 ps level even in the worst conditions of signal to noise density ratio (C/N), corresponding to very low elevation angles of the ISS over a ground terminal. The thermal sensitivity of the system has been measured and used to calibrate MWL phase comparison data against temperature variations. The sensitivity to a series of key parameters such as clock input power, received signal C/N, supply voltage, Doppler, Doppler rate, etc. has been measured. The susceptibility of the system to narrowband and broadband interference, as well as to multipath effects has been characterized.

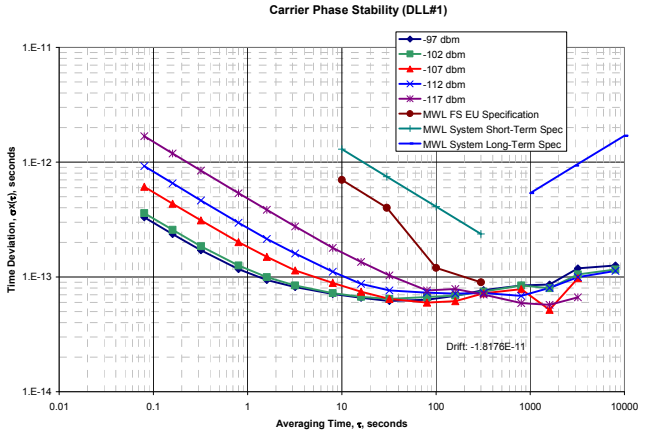

Figure 5. MWL Flight Segment stability of the carrier phase, expressed in time deviation, for different carrier-to-noise power density ratios. Measurement are compared to MWL system requirements and derived MWL FS contributions.

The engineering model of the flight segment S-band and Ku-band antennas (fig. 6) have been completed and tested. The antennas exhibit a extremely flat phase pattern over the complete field of view covering 140°.

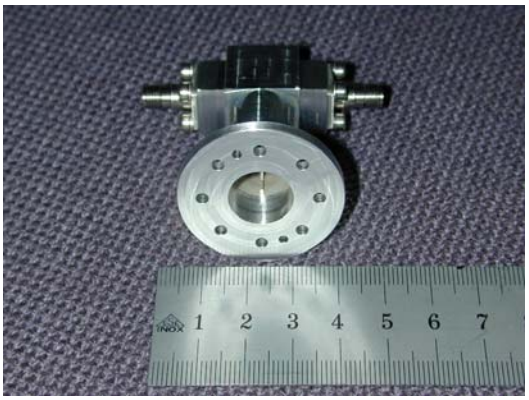

Figure 6. Engineering Model of the MWL Flight Segment Ku-Band antenna.

B. MWL Ground Terminal

The MWL ground terminal electronics is similar to the MWL flight hardware, symmetry being important in a two-way system to reduce instrumental errors. The ACES MWL Ground Terminal (MWL GT) is a microwave station interfacing the local clock on ground to the ACES payload allowing space-to-ground clock comparisons. To reduce phase instabilities due to the tracking motion, the electronic unit of the MWL GT has been rigidly attached to the antenna unit. The Ku-band signal is delivered to the antenna feeder via a waveguide, a high stability RF cable is used for the S-band. The antenna is a 60 cm offset reflector with a dual-band feed system automatically pointed in azimuth and elevation by a steering mechanism. A computer controls the steering unit based on ISS orbit prediction files, collects telemetry and science data both from the local clock and the MWL GT electronics, and interfaces directly with the ACES Users Support and Operation Center (USOC). The system is housed below a protective radome cupola (fig. 8), which also allows to stabilize the temperature of the enclosed volume by an air conditioning system, part of a separate service pallet. The MWL ground terminal is presently being assembled (fig. 7). After dedicated tests on the ground terminal, a MWL system level test will be conducted. The test will be performed using dedicated test equipment that will allow reproducing the signal dynamics both in terms of amplitude and frequency (Doppler) variations.

Figure 7. MWL Ground Terminal under assembly (top: steering unit with antenna and electronics unit, middle, bottom: electronics unit front panel, backplane).

Figure 8. MWL Ground Terminal protective radome

The MWL ground terminals will be collocated with the ground atomic clocks operated by metrology institutes and research laboratories. The hosting site will provide the clock signal to the MWL ground terminal (table 1) ensuring ground clock synchronisation to UTC to 0.5 μs (100 ps after 10 days for at least two of the ground clocks).

The MWL ground terminal comprises the radome pallet including antenna, electronics unit, steering unit and radome and the service pallet including control computer, steering unit controller, power supply (and UPS), and water chiller to thermally stabilise the MWL electronics unit. All these elements are accommodated in an air-conditioned outside cabinet. A dedicated air-conditioning system will maintain and stabilise the temperature inside the radome.

The total weight of system is 270 kg for the radome pallet and 380 kg for the service pallet and air-conditioning system. Power supply demand include about 6 kW for all electronics, thermal chiller and cabinet cooling with an additional 3-5 kW for the radome thermal control, capable to operate the MWL GT in a large range of ambient environments from -30 °C to +45 °C.

TABLE I. CHARACTERISTICS OF THE MWL GROUND TERMINAL TO LOCAL GROUND CLOCK INTERFACE.

Signal	**Characteristics**
Receiver characteristics	Single ended, AC coupled, no galvanic isolation w.r.t. chassis ground
Nominal frequency	100 MHz ± $1 \cdot 10^{-7}$
Waveform	Sine
Input level	6 dBm ± 2 dB
Spurious of input signals	Harmonic: ≤ 69 dBc No harmonic: ≤ 69 dBc in a bandwidth of 100 kHz around the carrier
Nominal input impedance	50 Ω
VSWR	≤ 1.20
S11 stability	≤ $1.5 \cdot 10^{-3}$ pp/day
Connector	3.5 mm female

Signal	PPS
Slope	Rising slope
Trigger level	0-4 V (programmable)
Impedance	50 Ω
Connector	3.5 mm female

C. MWL Data Analysis

MWL provides time-tagged code and carrier phase measurements on the two Ku-band signals (up and down-link) and on the S-band down-link signal. Housekeeping and telemetry data, collected both at the ACES payload and on ground, provide additional calibration parameters (temperature, RF power, etc.) to be applied to MWL raw measurements. ACES scientific products are generated by analyzing MWL raw data, together with additional information, in particular ISS orbitography, parameters for the troposphere model, etc. Data analysis algorithms will be able to deal with the intrinsic noise of the measurements, possible events such as temporary signal loss, etc. and will provide results at the expected performance levels even in adverse conditions. Algorithms include a DRVID (Di erenced Range Versus Integrated Doppler)-based multipath detection. Ionospheric delay calculation will be performed zusing the Ku- and S-band downlink signals, possibly using again DRVID in addition.

For this purpose, a complete model describing the space-to-ground comparison of clocks via MWL has been developed. The model includes relativistic corrections up to third order in *v/c*, which are still non negligible for reaching a frequency uncertainty level well below $1 \cdot 10^{-16}$. Algorithms to measure and control the instabilities introduced by atmospheric propagation delays (ionosphere and troposphere) are included in the code, as well as algorithms for the correct identification of phase ambiguities and cycle slips. The code has been tested on raw MWL data having the same noise behaviour measured during of MWL EM tests and processed by an independent program which also models atmospheric propagation delays and link-related signal attenuation. The results presented in [12,13] show a good agreement with the ACES system requirements.

Based on this work, algorithms are presently developed and implemented in the ACES ground segment infrastructure to operationally exploit the MWL measurement and to generate the ACES data products available to the scientific community.

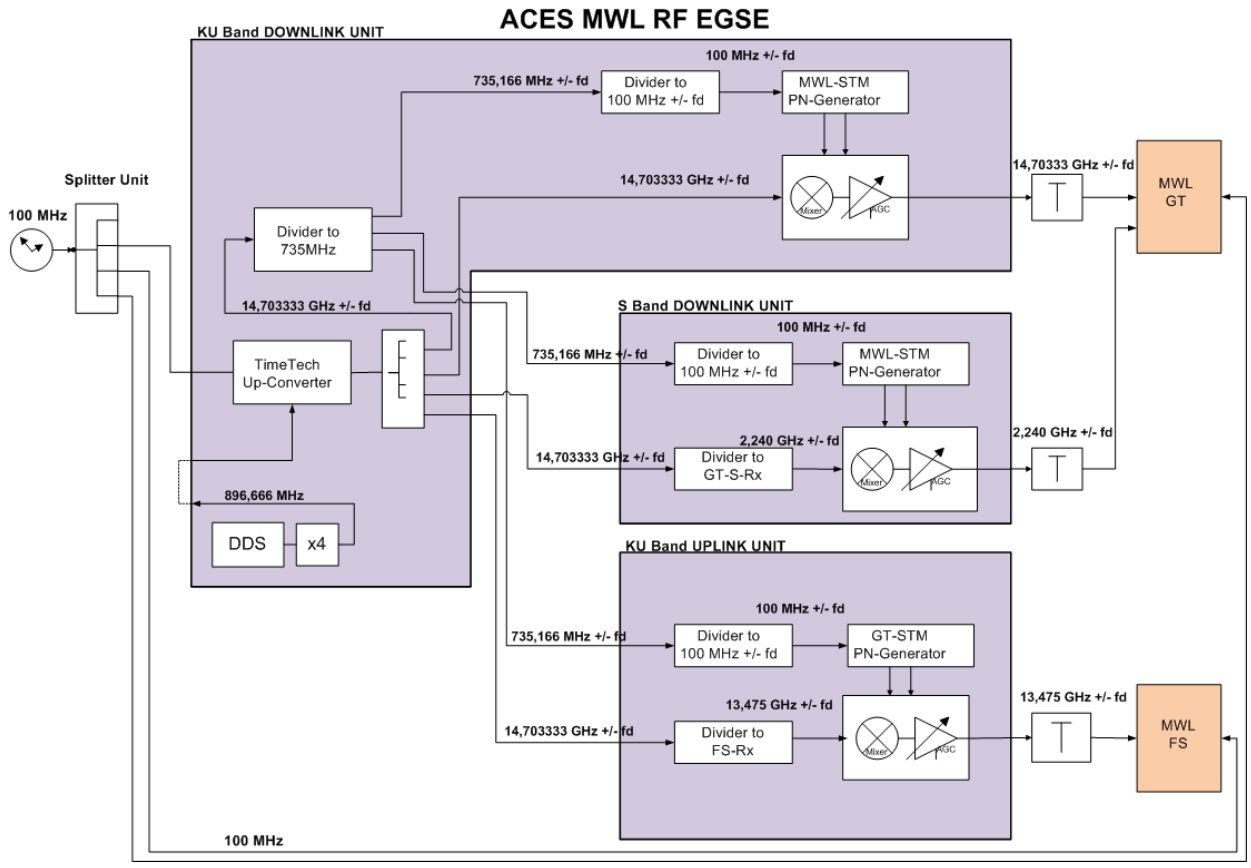

Figure 9. MWL end-to-end test RF EGSE providing full Doppler simulation.

IV. MWL Test Results

A. MWL Test Program

The MWL system is thoroughly tested in incremental steps. The MWL FS and MWL GT electronic units are measured against a dedicated EGSE as well as using their internal test loop translators to determine intrinsic stability. The sensitivity against variations in the environment (temperature, supply voltage, clock signal level, etc.) is independently measured and sensitivity coefficients are validated using realistic variation patterns. The antennas are characterised for gain as well as for their individual phase pattern, allowing to apply corrections in post-processing depending on line-of-sight angles.

Following stand-alone tests, the system is validated in an end-to-end test comprising MWL FS and MWL GT electronic units connected by cables through a signal simulator RF EGSE (fig. 10).

Within the end-to-end test the system stability with Doppler, Doppler rate and variations in signal amplitude is verified. Delay calibration between uplink and downlink is demonstrated in the end-to-end test.

Figure 10. MWL end-to-end test set-up (MWL FS on the right, MWL GT electronics on the left, RF EGSE in the two center racks)

B. MWL End-To-End Test Configuration

The MWL end-to-end test is presently conducted using the MWL FS electronics unit Engineering Model and the MWL GT electronics unit of the first item being build. Both items under test are connected by cable including appropriate and variable attenuation to offset the free-space range. An RF

EGSE simulates Doppler, generated in a DDS and applied coherently on the PN code and carrier signals (fig 9).

The end-to-end test configuration supports both, common clock and dual clock measurements. The common clock configuration will be used to test the MWL intrinsic stability, where the dual clock measurement resembles the operations set-up during the mission; results obtained in this configuration will be compared to measurements performed externally between the two reference clock using a separate phase comparator.

The end-to-end test includes static tests without Doppler and signal amplitude variations followed by Doppler tests. It concludes with a test including the full signal dynamics for a typical ISS passage over a MWL GT.

In the end-to-end test configuration, the differential delay calibration of uplink versus downlink is demonstrated. Delay calibration is performed by comparing the ground clock PPS to a PPS generated internally to the MWL GT.

The end-to-end test data evaluation makes use of extensive data post-processing developed specifically for the test and being a part of the algorithms under development for the ACES mission data exploitation itself.

C. MWL End-to-End Test Results

First results have been obtained from the end-to-end test (fig 11) with constant Doppler.

The figure shows the MWL end-to-end carrier phase stability, expressed in time deviation. The upper curve represents the measurement in the MWL FS of the MWL GT received carrier phase against the local reference signal; measured with DLL2. The lower curve represents the measurement in the MWL GT of the MWL FS received carrier phase against the local reference; measured with DLL1. Results are based on raw data, i.e. before establishing the lambda configuration and applying the two-way formula.

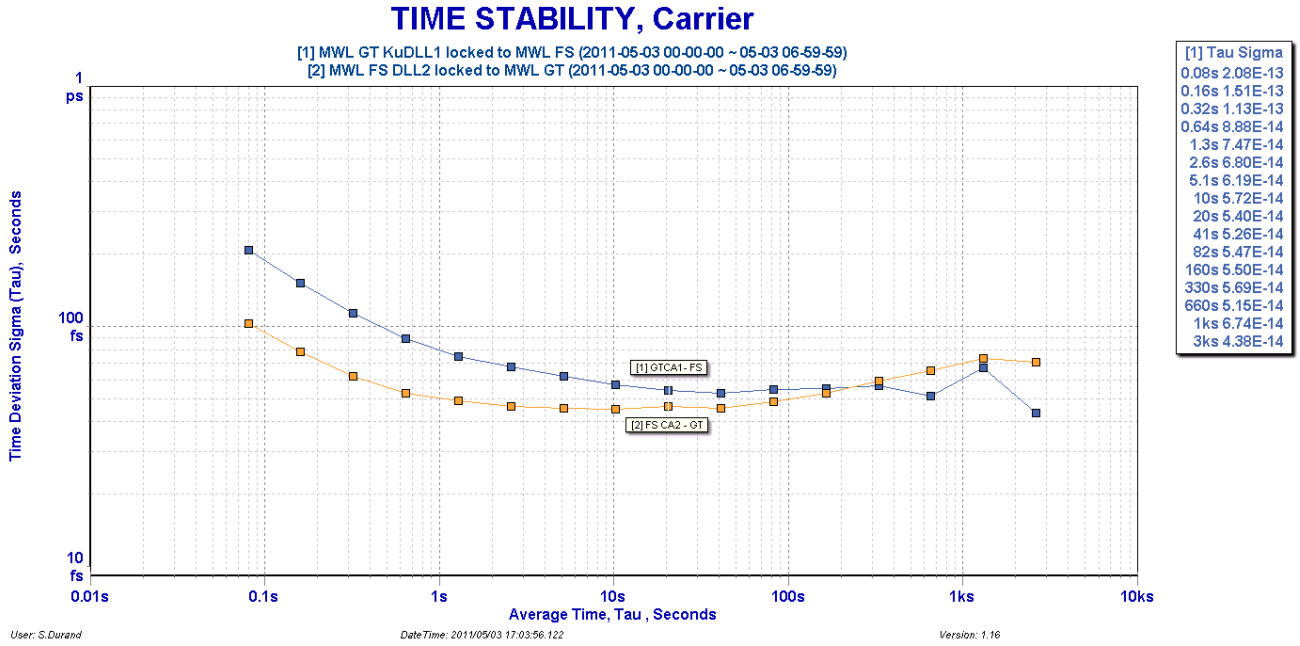

Figure 11. MWL end-to-end test results (carrier phase stability with constant Doppler measured in the MWL FS (blue curve) and in the MWL GT (orange curve)

The system performance reaches stability in the order of 50-60 fs, which is well within the specification requesting 240 fs. The MWL system remains stable up to several hundred seconds of integration time, performance at integration time larger than 1 thousand seconds is dominated by thermal noise in the EGSE.

Remarkably, the system performance is already reached with the code measurements at 300 seconds of integration time (fig 12).

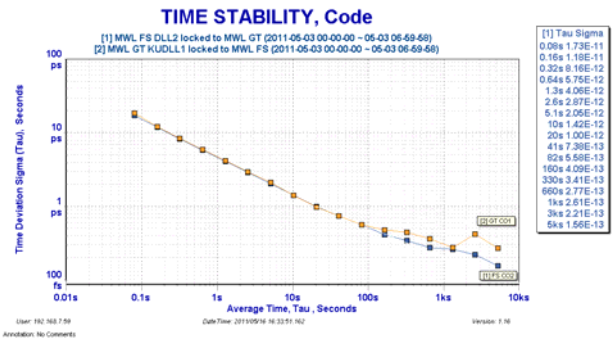

Figure 12. MWL end-to-end test results (code phase stability with constant Doppler measured in the MWL FS (upper curve) and in the MWL GT (lower curve)

The code phase is primarily used to resolve carrier phase ambiguities, the performance is well suited to obtain this goal.

V. OUTLOOK

The MWL end-to-end test is planned to be completed by June 2011. Based on a successful demonstration of performance, the MWL FS flight model will be build and manufacturing of the full set of MWL Ground Terminals will be released.

***Abstract*— The GNSS main technique currently used for accurate time and frequency transfer is the so-called "geodetic time transfer", based on a consistent modeling of dual-frequency code and carrier-phase measurements. This technique enables frequency transfer with an uncertainty of 0.1 nanoseconds thanks to the very low noise level of the carrier phase measurements, but the accuracy of time transfer can only reach the level of a couple of nanoseconds in the best cases, due to the noise and multipath of the GPS and GLONASS codes. However, in the near future Galileo will offer one promising signal, namely the broadband signal E5, with an ultimate low range noise in the cm range and with the lowest multipath error impact observed before. This paper investigates the use of this precise code for accurate time transfer.**

I. INTRODUCTION

Measurements from Global Navigation Satellite Systems (GNSS) are used since the eighties to perform precise and accurate Time and Frequency Transfer (TFT) [1-2]. Nowadays, the main technique used for TFT is the so-called "geodetic time transfer", based on the joint analysis of GPS (and GLONASS) dual-frequency code and carrier-phase measurements. It is widely recognized for its high frequency stability (see for instance [3-5]), thanks to the very low noise level of the carrier phases, enabling time transfer with an uncertainty of 0.1 ns (nanoseconds), when ignoring the uncertainty of the instrumental hardware delays calibration. This calibration value can be determined with an uncertainty at the level of about 1 ns for GPS links, as it has been shown in recent experiments [6-7]. However, the time transfer accuracy is also limited by the colored signature of the code noise, affecting the medium-term stability of the solution and inducing possible discontinuities at the day boundaries [8-10]. Therefore, the accuracy of time transfer given by this technique can only reach the level of a couple of nanoseconds in the best cases.

On the other hand, the European Galileo system is currently under development, and will be interoperable with GPS and GLONASS. Galileo signal is on the air since December 2005, when the first experimental Galileo satellite GIOVE-A was launched. Presently, there are two experimental Galileo satellites in operation, GIOVE-A and GIOVE-B, and the first four operational Galileo satellites (building the Galileo In-Orbit Validation (IOV) constellation) are due for launch in 2011. GIOVE satellites transmit the ranging signals using all the code modulations currently foreseen for the future Galileo, and provide therefore a foretaste of their performance in real-life applications. Due to the use of a higher PRN chip rate of 10.23 MHz and two subcarriers spaced at 30.69 MHz resulting in a 51 MHz wide signal bandwidth, the ranging signals of Galileo provide significant improvement of the (long) multipath performance as compared to current GPS/GLONASS. In 2008, some studies with GIOVE-A data evidenced that the E5AltBOC code demonstrates the highest multipath suppression as compared to other signals and very low magnitude of average multipath errors, down to the values about 20 cm [11]. Previous research done by the authors of this paper [12] showed that this very precise GNSS pseudorange is very promising for improving time transfer applications.

The purpose of this article is to develop accurate methods for time transfer with Galileo E5AltBOC (E5 hereafter). In section 2 we revise the current GNSS main time transfer technique; section 3 presents the noise level of the E5 code using the experimental GIOVE satellites observations and investigates the possible approaches to use it for time transfer; the fourth section presents some results from tests with Galileo simulated data, and the last section is dedicated to the conclusions of this work and perspectives for the future.

II. STATE OF THE ART

The current geodetic time transfer method is based on a consistent analysis of ionosphere-free combinations for the code and carrier-phase measurements on L1 and L2 bands, that is,

$$P_3 = \alpha_f \cdot P_1 - \beta_f \cdot P_2,$$
$$L_3 = \alpha_f \cdot L_1 - \beta_f \cdot L_2,$$

978-1-61284-110-6/11/$26.00 ©2011 IEEE

with

$$\alpha_f = \frac{f_1^2}{f_1^2 - f_2^2} \approx 2.545, \quad \beta_f = \frac{f2}{f_1^2 - f_2^2} \approx 1.545,$$

which are finally given by

$$\begin{aligned} P_3 &= \| x_{rec} - x^{sat} \| - c\Delta t_{rec} + c\Delta t^{sat} + Trop + \delta_3^P + \varepsilon_3^P, \\ L_3 &= \| x_{rec} - x^{sat} \| - c\Delta t_{rec} + c\Delta t^{sat} + Trop + \lambda_3 N_3 + \delta_3^\phi + \varepsilon_3^\phi, \end{aligned} \quad (1)$$

where x_{rec} is the receiver position, x^{sat} is the satellite position, c is the vacuum speed of light, Δt_{rec} is the receiver synchronization clock error, Δt^{sat} is the satellite synchronization clock error, *Trop* is the tropospheric delay, λ_3 is the wavelength of the carrier-phase combination, N_3 is the integer phase ambiguity of L3, δ_3^P contains the receiver hardware delays for the P3 code, δ_3^ϕ is the initial phase delay of the phase combination, ε_3^P is the pseudorange noise and multipath, and ε_3^ϕ is the ionosphere-free carrier-phase noise.

The carrier phases themselves allow to give a precise signal evolution, at the subnanosecond level, as already mentioned, but they need to be combined with code data, due to the fact that they contain an unknown initial ambiguity (integer number of cycles, see (1)) which must be solved. The P3 code is used for this task, determining then the absolute receiver clock offset. The noise of the ionosphere-free P3 combination is given by the expression

$$\sigma_{P_3} = \sqrt{2.545^2 \cdot \sigma_{P_1}^2 + 1.545^2 \cdot \sigma_{P_2}^2} \approx 3 \cdot \sigma_{P_1}.$$

The ionosphere-free combination therefore amplifies the pseudorange noise and multipath with respect to the individual code measurements. As a consequence, the accuracy of the time transfer solution is at the level of up to a couple of nanoseconds.

The most important parameter for time transfer is Δt_{rec}, i.e. the receiver clock synchronization error with respect to the reference of the satellite clocks. When the receiver frequency is driven by or synchronized with an external atomic clock frequency, Δt_{rec} gives indeed access to this external clock. The solution for Δt_{rec} is obtained from a least-squares fitting of the code P3 and carrier phase L3 observations. Using a Precise Point Positioning (PPP) approach [14-15], it is possible to determine at the same time the Δt_{rec}, the station position, the tropospheric zenith delay *Trop*, and the float carrier phase ambiguities (λ_3 N_3+ δ_3^ϕ); the satellite positions and clocks are provided by external products, e.g. the IGS products. Note that δ_3^P will be absorbed in the clock solution Δt_{rec}, and should be corrected for using external calibration parameters (receiver, antenna and cable delays).

III. USING THE GALILEO E5ALTBOC PSEUDORANGE FOR TIME TRANSFER

A. E5 observation equation

The observation equation for E5 is quite similar to the observation equation for P3, with an additional term containing the ionospheric delay at frequency E5:

$$E_5 = \| x_{rec} - x^{sat} \| - c\Delta t_{rec} + c\Delta t^{sat} + Iono_5 + Trop + \delta_5^P + \varepsilon_5^P, \quad (2)$$

where δ_5^P contains the receiver hardware delays for this frequency and ε_5^P is the pseudorange noise and multipath.

In order to obtain the receiver clock error, Δt_{rec}, all the other contributions to the E5 code must be corrected. As explained before, the satellite positions and clocks can be provided by external products. The troposphere zenith delay can be either obtained from external products (if such products exist for the station where the clock is located), or estimated as explained before for PPP. The ionospheric delay is the main limitation and requires being determined at the highest possible precision level. Different ways can be used to correct for the ionospheric delay. Combining the E5 code with another code in order to perform an ionosphere-free solution, as done with the GPS/GLONASS P3, will cause the loss of the properties of this very precise code, due to the noise of the second pseudorange used for the combination. This will thus offer no advantage with respect to the present geodetic time transfer approach. Alternative approaches exist and are presented in the next section.

B. Ionosphere correction of the E5 pseudorange measurement

1) Ionosphere correction for single-frequency receivers

Having only single-frequency measurements at our disposal requires external products for the ionosphere correction. It is therefore necessary to use maps providing the Total Electron Content (TEC) as a function of the latitude and longitude, in order to get the ionospheric delay for each signal path. Using global TEC maps proposed in the IONEX format, as for example those provided by the IGS analysis center CODE [16], however only corrects for the long wavelength and long term variations (above 2 hours) of the TEC. It was demonstrated with GPS that this is not sufficient for time and frequency transfer: the ionosphere-free combination P3 improves time transfer by a factor of 2 with respect to using P1 code corrected with the CODE TEC maps, for intercontinental baselines [17].

On the other hand, regional ionosphere maps, currently under development (as for instance the ones produced by the US National Oceanic and Atmospheric Administration (NOAA)), offer a better spatial and temporal resolution with respect to the global maps, as they are built with more dense networks. They could then provide a more precise correction for the ionospheric delay on pseudoranges; this will be tested in the future.

Another approach to correct the ionosphere could be to estimate this effect by means of an appropriate model from the Code-minus-Carrier (CMC) observable. The latter is obtained from the difference between the E5 code and carrier-phase measurements, and retains only the ionosphere correction and the carrier-phase inherent ambiguity term. Indeed, the L5 carrier-phase observation equation reads:

$$L_5 = \| x_{rec} - x^{sat} \| - c\Delta t_{rec} + c\Delta t^{sat} - Iono_5 + Trop + \\ + \lambda_5 N_5 + \delta_5^{\phi} + \varepsilon_5^{\phi}. \quad (3)$$

Note that the ionosphere contribution $Iono_5$ contains here only the first order (i.e. in $1/f^2$ where f is the frequency), which affects the code and carrier phase with the same magnitude but opposite signs. By differencing equations (2) and (3), we obtain the CMC combination:

$$CMC = \frac{E_5 - L_5}{2} = Iono_5 + \frac{\delta_5^P}{2} - \frac{(\lambda_5 N_5 + \delta_5^{\Phi})}{2} + \varepsilon_{CMC}. \quad (4)$$

CMC therefore contains only the ionospheric delay, plus an ambiguity term (constant over each continuous satellite track) and a constant term. The ionospheric delay, $Iono_5$, can be estimated by using a single-layer spherical ionospheric shell model [18], i.e.,

$$CMC = MF \cdot \left(ZID_0 + \nabla_{\varphi} \cdot (\varphi_{IP} - \varphi_0) + \nabla_{\lambda} \cdot (\lambda_{IP} - \lambda_0) \right) \\ + \frac{\delta_5^P}{2} - \frac{(\lambda_5 N_5 + \delta_5^{\phi})}{2} + \varepsilon_{CMC},$$

where MF is the elevation-dependent mapping function, ZID_0 denotes the zenith ionospheric delay at the station position, ∇_{φ} and ∇_{λ} are latitudinal and longitudinal gradients, respectively, φ_{IP} and λ_{IP} are the geodetic latitude and longitude of the ionosphere pierce point (IPP); φ_0 and λ_0 are the latitude and longitude of the station. Using a least- squares fitting of all observations above a given elevation, it is possible to determine the TEC at the zenith plus latitudinal and longitudinal gradients. We tested this approach using simulated Galileo data (see later), and using the mapping function $MF=1/\cos z$, where z denotes the zenith angle of the satellite. The differences between the VTEC retrieved with this model and the simulated VTEC can reach the level of some TEC units (see Fig. 1), corresponding to more than one nanosecond for the GNSS frequencies. The technique can therefore not be used for our purpose as not enough precise.

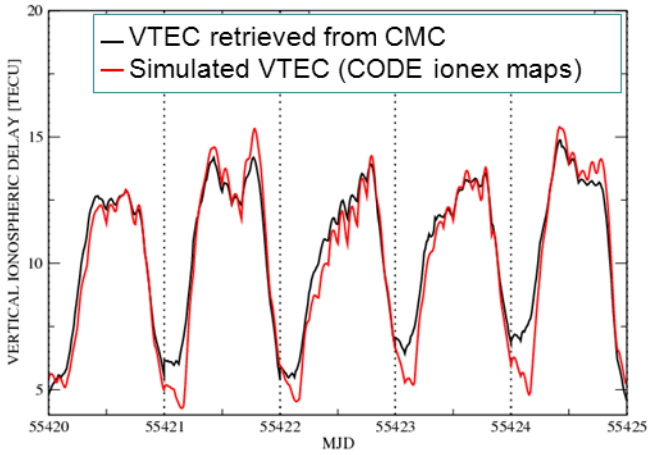

Figure 1. Comparison between the vertical ionospheric delay in TEC units for a 5-day period estimated with surface fitting based on a ionospheric shell model from CMC , and the simulated VTEC (taken from CODE IONEX maps).

2) Ionosphere correction for dual-frequency receivers

If dual-frequency data are available, a combination of carrier phases measured on two frequencies can be used to get the first order ionospheric delay for each signal path. First of all, as the ionosphere is a dispersive medium, the ionospheric delays for different frequencies f_i and f_j are related by the expression

$$\frac{Iono_i}{f_j^2} = \frac{Iono_j}{f_i^2}.$$

Then, the geometry-free combination of L1 and L5 carrier-phase observations can be expressed as

$$L_{GF} = L_1 - L_5 = Iono_5 \left(1 - \frac{f_5^2}{f_1^2} \right) + N'_{GF} + \varepsilon_{GF}^{\phi}, \quad (5)$$

where N'_{GF} is an ambiguity parameter that includes the difference between the ambiguities in the two frequencies, plus some biases. In order to estimate the ionosphere, this ambiguity must be first solved for. The latter can be done by means of the geometry-free combination of E1 and E5 codes, which retains the ionospheric delay plus a collection of biases of the receiver and satellite hardware (the so-called differential code biases, or DCBs), that is,

$$E_{GF} = E_5 - E_1 = Iono_5 \left(1 - \frac{f_5^2}{f_1^2} \right) - c(DCB_{rec} + DCB^{sat}) + \varepsilon_{GF}^{P}. \quad (6)$$

Then, by making the difference between (5) and (6) we can estimate the ambiguity parameter as

$$N'_{GF} = \left\langle (L_{GF} - E_{GF}) \right\rangle_{\substack{arc\ without \\ cycle\ slips}} - c(DCB_{rec} + DCB^{sat}).$$

And finally, we can obtain the ionospheric delay of each E5 measurement as

$$Iono_5 = \frac{1}{\alpha_{GF}}\left\{ L_{GF} - \left[\left\langle (L_{GF} - E_{GF}) \right\rangle_{\substack{arc\ without \\ cycle\ slips}} - \right.\right. \quad (7)$$
$$\left.\left. -c(DCB_{rec} + DCB^{sat}) \right] \right\},$$

where $\alpha_{GF} = 1 - f_5^2 / f_1^2$.

C. The E5 Code-Plus-Carrier combination

Instead of using the E5 observation only, we propose here to take advantage of the Code-plus-Carrier observable (CPC), which is at first-order ionosphere-free. By adding equation (3) to (2), we get CPC, which reads

$$CPC = \frac{E_5 + L_5}{2} = \| x_{rec} - x^{sat} \| - c\Delta t_{rec} + c\Delta t^{sat} + Trop + \quad (8)$$
$$+ \frac{\delta_5^P}{2} + \frac{\left(\lambda_5 N_5 + \delta_5^\phi\right)}{2} + \varepsilon_{CPC}.$$

It is important to note that the noise and multipath ε_{CPC} of this combination are mainly the noise and multipath of the pseudoranges, as the carrier-phase noise is significantly lower. Then,

$$\sigma_{CPC} = \frac{1}{2}\sqrt{\sigma_{E_5}^2 + \sigma_{L_5}^2} \approx \frac{\sigma_{E_5}}{2},$$

that is, CPC has half the noise and multipath of the E5 code. Therefore, the time transfer solution obtained with CPC should have a noise reduction by a factor of 2 with respect to the solution obtained with E5 only. Moreover, the CPC combination also mitigates higher-order ionospheric effects, with a reduction of 25% of the second-order delay (*~1/f³*) and 33% of the third-order delay (*~1/f⁴*) with respect to the code observable [19]. However, the CPC combination is ambiguous, so that the time transfer method based on this combination will have to deal with the ambiguity resolution in the first step.

In [12] we presented some results of the time transfer solution obtained with CPC once the ambiguities were solved, with current data available from GIOVE satellites. These are reported in Fig. 2, which presents for the time link GNOR-GUSN, i.e. Noordwijk (Netherlands)-USNO (US), the clock solutions obtained with either the CPC, or the ionosphere-free codes using the combination of E1 and E5AltBOC (labelled as E5(a+b)) for GIOVE, and P1 and P2 for GPS. The results are shown for one satellite track of GIOVE-B and of GPS PRN 19, these two satellites appearing visible at the same time for both stations. The clock solutions have been computed using pseudorange observations at a 30 second sampling rate, and correcting them for the geometric distance satellite-receiver, for the satellite clock and for the relativistic effect due to the satellite orbit eccentricity, using the IGS orbits for GPS and the CONGO orbits [20] for GIOVE-B. The tropospheric delays were taken from the IGS products [19] for USNO and for DLFT (25 km far from GNOR). The station positions were fixed to *a priori* known coordinates. The clock solutions are presented in Common View in order to get rid of the reference time scale which is different for GPS and for GIOVE satellites clock products.

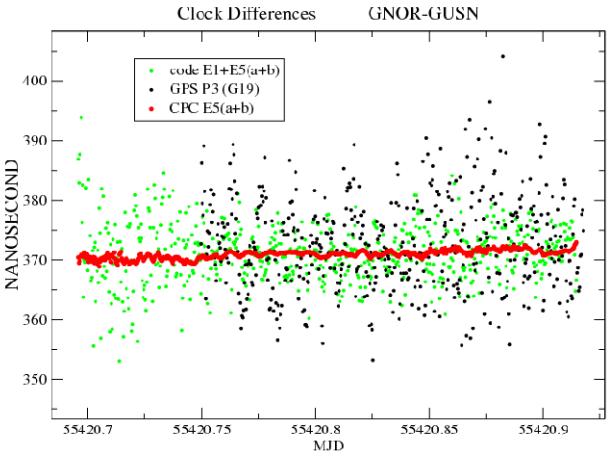

Figure 2. From [12]: Comparison between the clock solutions obtained with either dual-frequency ionosphere-free combination of pseudoranges, or the CPC combination.

The improvement in terms of noise level obtained with the CPC with respect to the classical dual-frequency ionosphere-free codes appears clearly. The rms of the GPS P3 and of the GIOVE E1+E5 combinations are about 7.8 and 4.8 ns, respectively, whereas the rms of the CPC E5 falls down to 0.4 ns. That means that the latter has a noise level about 10 times lower than the ionosphere-free E1+E5 and more than 15 times lower than GPS P3. The small variations of the CPC curve correspond to E5 multipath.

If we do not consider the instrumental calibration issues, the clock solutions so-obtained correspond to the quantity which determines the accuracy of the time transfer solutions. The advantage of the CPC will be therefore to improve the accuracy of time transfer with respect to the dual-frequency ionosphere-free combination, i.e. with CGGTTS (Common GPS GLONASS Time Transfer Standard) or PPP, provided that the ambiguities of the CPC are precisely determined. In order to do that, we can for instance use the Code-minus-Carrier combination (4), as it has the same ambiguity that appears in CPC (see (8)). However, this approach requires again the correction of the ionosphere effect, as with the E5 code only approach. To that purpose, the double-frequency geometry-free combination of carrier-phase and code measurements on E1 and E5 bands can be used.

Let's recall now that the time transfer solution with CPC E5 should be 2 times less noisy than that using only E5. This will be verified in the next section, where we investigate the two approaches that have been presented, with data simulated with the ASiF software [13]. To summarise, these two approaches are:

<u>E5-only approach:</u>

1. - Estimate the ionospheric delays from the geometry-free code and carrier-phase combinations of E1 and E5.

2. - Correct the E5 observable with the previous value and then, solve for the clock solution with a least-squares fitting: either determine the receiver clock, the station position and the wet troposphere path delays; or fix the position and troposphere, and determine only the receiver clock.

CPC E5 approach:

1. - Estimate the ionospheric delays from the geometry-free code and carrier-phase combinations of E1 and E5.

2. - Correct the ionosphere in the CMC equation to determine the ambiguities.

3. – Enter these ambiguities in the CPC observable and then, solve it as in the E5-only approach.

IV. Clock Results From Simulated Data

The ASiF software [13] simulates measurements in RINEX 3.0 format and satellite products in clk formats for the GPS and Galileo constellations. The satellite orbits are modelled with a keplerian motion; receiver and satellite clocks are simulated using the procedure proposed in [21]; tropospheric delays are taken from the IGS products [22]; ionospheric delays are generated from CODE IONEX maps [16]; a white noise is then added to the measurements. In the present study, we considered pseudorange white noise with a standard deviation of 6 cm for E5 and 13 cm for E1, with no multipath effect, and white noise with standard deviation of 13 mm for the carrier phases.

Following the two procedures previously described, we estimated the receiver clock using a least-squares inversion as in the Atomium PPP software [23], i.e. with an analysis of one-day data batches. The clock solution was computed either fixing the position and troposphere to *a priori* known values, or determining them in the same analysis. Figs. 3 and 4 show the difference between the simulated clock and the clock retrieved by the least-squares inversion with the two approaches (E5-only or CPC E5), for 5 consecutive days. The first conclusion that arises from these results is that, as expected, the noise of the clock solution obtained from the CPC combination is half the noise level of the solution obtained directly from the E5 pseudoranges. Secondly, we see that estimating also the troposphere and the position, as it is done in classical PPP, induces errors on the clock solution of the order of about 50 ps in the present case. Finally, we can consider that the accuracy of our clock solution is given by the average difference between the computed and simulated clocks over one day. This difference is smaller than 20 picoseconds in both cases. However, it is important to note that only white noise has been considered for E5 and E1 pseudoranges. Although E5 is not much influenced by multipath, this effect should be also taken into account in the future, as it will directly impact the clock solution accuracy. In the case of E1, or any other different from E5, the noise and multipath are more significant, and will then affect the precision on the ionosphere correction (see (7)). Moreover, the simulation did not consider different hardware delays for each frequency, which play also a very important role in the ionosphere determination. The uncertainty on these parameters will therefore be a parameter influencing the accuracy of the clock solution and will require further investigations.

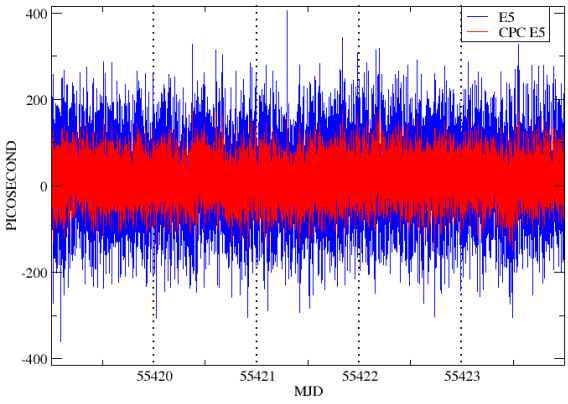

Figure 3. Differences between the computed and simulated clock; the computed clock was obtained using either the E5 code directly or the E5 CPC combination. The position and tropospheric delays are fixed to *a priori* known values.

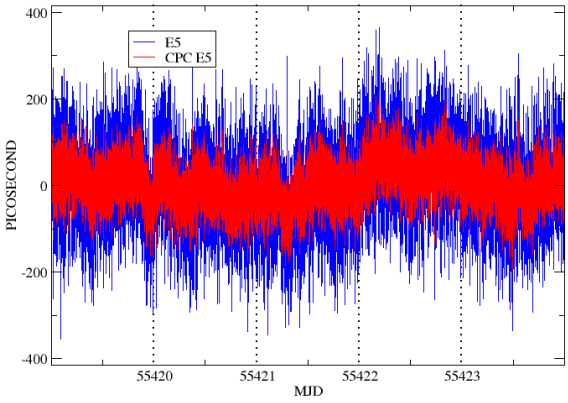

Figure 4. Same as figure 3, but here the position and tropospheric delays are also estimated in the least-squares analysis.

V. Conclusions

This paper investigated the applications of the future Galileo code E5AltBOC for time transfer. Thanks to its high precision and low multipath, this code can offer large improvement to the time transfer accuracy. The sum of code and carrier phase measurements (called CPC for Code plus Carrier) on E5AltBOC has been proved to be two times less noisy than the E5AltBOC code; its use for time transfer shows therefore a big interest. Some comparisons with true GPS and GIOVE data demonstrated that the CPC combination is more than 15 times less noisy than GPS P3. As the CPC is an ambiguous observable, the combination CMC (Code Minus Phase) has been proposed to solve for the ambiguities. This

combination needs however to be first corrected for the ionospheric effect, which can be precisely determined only from dual-frequency code and carrier-phase measurements. Some tests with simulated data have shown that the accuracy of the E5-based clock solution, measured as the mean offset between the computed and simulated clocks, is lower than 20 ps. However, the impact on the clock solution of multipath and of the precision of the differential code biases which were not considered here, need to be carefully investigated in future work.

ACKNOWLEDGMENT

This work has been partially supported by Spanish Science and Technology Ministry (Project AYA2007-67546), and by the Solar - Terrestrial Centre of Excellence (STCE, 2011). The authors also acknowledge the IGS for their data and products used in this study

New realization strategy for UTC(PTB)

A. Bauch, E. Staliuniene, D. Piester, W. Yang*
Physikalisch-Technische Bundesanstalt (PTB)
Bundesallee 100, 38116 Braunschweig, Germany
andreas.bauch@ptb.de

***Abstract*—The Physikalisch-Technische Bundesanstalt (PTB) realizes its atomic time scale UTC(PTB) as approximation to the international time reference UTC. It serves as the basis for PTB's time services, for the local clock comparisons and for international time comparisons. Since February 2010 UTC(PTB) has been realized using an active hydrogen maser steered in frequency via a phase micro stepper according to an algorithm described in this paper. Thereby the long-term stability and accuracy of PTB's primary clocks is combined with the typical short-term frequency stability of a hydrogen maser. During the last 12 months, the caesium fountain clock CSF1 was used as the steering reference on more than 98% of the days, which resulted in an excellent stability of UTC(PTB). During the last six months, including March 2011, its deviation from UTC was less than 4 ns.**

I. INTRODUCTION

The German Units and Time Act entrusts the Physikalisch-Technische Bundesanstalt PTB to realize UTC(PTB), a representation of Coordinated Universal Time UTC, as the basis for legal time in the country. It serves thus as the reference for PTB's time dissemination services, for the local clock comparisons and for international time comparisons. According to recommendations of the Consultative Committee for Time and Frequency the deviation of UTC(k) from UTC, where k stands for any laboratory active in this field, should be as small as possible, preferably below 100 ns. No unique prescription for the realization of UTC(k) follows thereof. UTC(PTB) used to have its physical representation as standard frequency and one pulse per second (1 PPS) signals based on its primary clock CS2 for the last 20 years [1]. Since February 2010 UTC(PTB) has instead been realized using an active hydrogen maser (AHM) steered in frequency via a phase micro stepper (PMS) according to an algorithm described below. Thereby the long-term stability and accuracy of PTB's primary clocks is combined with the short-term frequency stability of a hydrogen maser.

Subsequently we lay down the algorithm in current use (Section II) and briefly describe the practical realization (Section III). In Section IV results are presented. A discussion and outlook on further work closes the paper.

* on leave from NUDT, ChangSha. PR China

II. CONSTRAINTS ON THE REALIZATION OF UTC(PTB)

A. Available equipment

PTB currently operates two cold-atom based caesium fountain clocks, CSF1 [2] and CSF2 [3], two older thermal beam primary clocks, CS1 and CS2 [1], three commercial caesium clocks of type Symmetricom 5071 (high-performance option), and three AHM produced by Vremya-Ch. One motivation of going to a new scheme of realization of UTC(k) was to make better use of the available resources in the laboratory. As long as UTC(PTB) was based on CS2 alone, it already had a good reputation as one of the most long-term stable and predictable time scales. A deviation from UTC by more than 50 ns occurred only for a few ten days during the last 10 years. The day-to-day stability was, however, worse than that of time scales of other institutes realized with hydrogen masers as the signal source. This fact became even more obvious since two-way satellite time transfer and GPS carrier phase-based time transfer became standard methods in the field, and was considered no longer state-of-the-art. A final motivation was a rather technical one: The CS2 ovens were almost depleted of caesium, and clock operation could not be assured beyond some point in time in 2010.

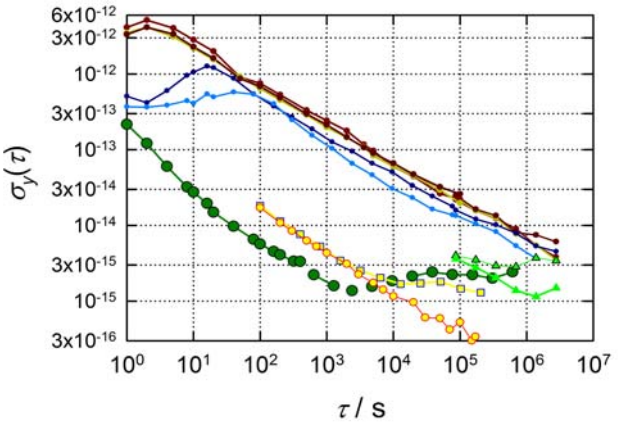

Figure 1. Relative frequency instability of PTB's atomic clocks, detailed explanations in the text

In Figure 1, the frequency instability of the available frequency standards in PTB is depicted. It illustrates that the performance of the various devices is quite different. Results of AHM comparisons (green symbols) are shown for local comparisons among two of them with averaging times between 1 s and 10 days, and for comparisons of the same two masers with the time scale UTC(NIST) of the US National Institute of Standards and Technology for averaging times between 1 day and 30 days. The performance of the fountain CSF1 is shown in yellow symbols, with respect to an AHM (squares) and to an optical frequency standard of PTB [4] (circles) with an instability superior to CSF1. The data span analyzed here is longer than that reported in Figure 3 of [4]. These data advised us to steer the maser frequency through the PMS towards CSF1 at least once per day based on daily average values of the frequency difference. The frequency instability of all other available standards (CS1: dark blue, CS2: light blue, three commercial clocks: earth tones) equals that of the masers only after far more than 10 days of averaging. Thus daily steering the maser frequency towards those references has been based on linear fits to a number of daily average values, extrapolated to the current day.

B. *Basic algorithm design*

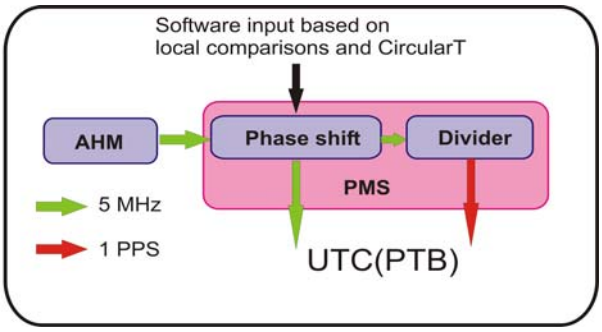

Figure 2. UTC(PTB) realization from a hydrogen maser

In the past, a frequency offset between UTC(PTB) and CS2 used to be introduced through a phase micro stepper (PMS) so that agreement of UTC(PTB) and UTC was assured in the long term. This offset was introduced manually once every few months based on the results published in the BIPM Time Department Circular T. Now this "steering of the AHM" is under software control as illustrated in Figure 2. The PMS is commanded daily to shift the 5 MHz input frequency by the relative amount δf_{steer} which has three additive components, δf_1, δf_2 and δf_3. The first component, δf_1, is intended to adjust the frequency of the maser to the rate of the reference clocks as just described. The second term, δf_2, represents the individual reference clock rates with respect to TAI. Three steering values $\delta f_1 + \delta f_2$ are calculated in parallel each day and one is selected based on a pre-selected priority and the availability of data:

Option 1: The AHM frequency is compared to PTB's fountain clock CSF1 hourly. If during day N-1 6 hours of data are available, then the mean value, corrected for the daily frequency drift of the maser is used as δf_1 during day N. When no valid data are available for day N-1, the steering for day N is calculated from a linear fit to the last three daily values. If less than two such data are available (e.g. two extrapolated, but not measured data), the steering is calculated based on another option. For δf_2 we use the estimated d, representing the fractional deviation of the scale interval of TAI from the SI second on the geoid, as published in the last line of the Circular T Section 4.

Option 2: The AHM frequency is compared to all caesium beam clocks. δf_1 is updated daily, based on extrapolation of past data for an interval adapted to the frequency instability of the reference clocks, mostly 25 days. To estimate δf_2 the monthly published rates rTAI of the clocks with respect to TAI from the ALGOS data base are used. Individual clock results are combined using their most recent statistical weights wTAI as published in the ALGOS data base.

Option 3: As a fall-back option, steering is made based either on CS2 or CS1, similar to Option 2.

The third term δf_3 is common to all three options. It assures the long term steering of UTC(PTB) to UTC and is currently calculated as $\{\text{UTC-UTC(PTB)}\}_{\text{LRD}}$ / 60 d, where the time difference is taken at the last reported day in the most recent issue of the Circular T, LRD. The values of δf_3 (and also δf_2) are thus constant for about one month after a new issue of the Circular T was received.

C. *How to ensure reliability and availability?*

The first steps of realizing a time scale based on CSF1 were made in 2002 [5]. Since then we collected a lot of experiences of equipment failures and weaknesses of the chosen strategies. Figure 2 should make clear that a maser output failure is fatal. Therefore the realization of the time scale is made in duplicate, named UTC(PTB) and UTH(PTB), based on two different AHM, and both time scales should be in close agreement. Switching of all signals (5 MHz and 1 PPS) requires manual intervention, but is simple to do. The PMS has proven very reliable, so it appears a more likely event that no software input is available. In this case the frequency steering remains unchanged, and alarms are distributed. The data required for the calculation of δf_1 are collected using well developed measurement infrastructure.

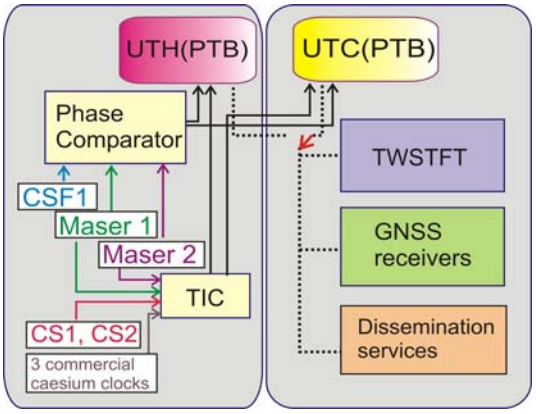

Figure 3. Implementation of duplicate realization of PTB's reference time scale UTC(PTB)

The generation of three optional inputs has proven as sufficient to provide a steering value each day and also allows cross-check among the results. The software can be re-started manually at any point in time so that during working days corrected input data could be used to produce a refined steering value if necessary.

III. Practical Implementation

Figure 3 gives a simplified view of the implementation. In order to implement Option1, a phase comparator is used to get hourly mean frequency differences between CSF1 and two AHM which provide the physical input to the generation of UTC(PTB) and UTH(PTB), respectively. The same measurement infrastructure is available for CSF2, but the interfaces to the time scale generation have not been established yet. These interfaces proved as one of the key issues to be solved. Other than most fountain clocks operated world-wide, both fountains output 5 MHz signals from a quartz oscillator (XO). Such a signal is available even if the XO is deliberately not locked to the fountain or if the regular fountain operation failed, e. g., because of a loss-of-lock of one of the lasers used for atom cooling and detection. Using data in such a condition would result in an erroneous steering command. The interface thus contains a two-level check of data quality: use or do not use.

Figure 3 shows also part of the measurement infrastructure linking the CS1 and CS2 in the clock hall and the commercial caesium clocks with the two AHM, in order to implement Options 2 and 3. In duplicate (not shown), the 1 PPS signals are routed to signal switches and compared by two time interval counters (TIC). Routinely the software accesses the data files produced daily after midnight to get the required clock differences. These are combined with previously acquired data to get the frequency prediction of each clock with respect to both AHM. These predictions are then combined with rTAI-values of each clock, and in Option 2 a weighted average is calculated based on the recent wTAI-values.

The software selects the daily steering command according to pre-selected priorities: Priority 1 has always been given to the use of CSF1 data (Option 1). A newly calculated value δf_{steer} should agree with the value calculated one day before within 2×10^{-14}. If this condition is not met, the software checks all available options. If a large step is found in all options, then this step is applied and an alarm is generated. Such a large step would point to a malfunction of the maser involved.

After a steering command was sent to the PMS, the instrument is queried, and proper reception of the command is verified. For each option and for each implementation, daily log-files and archive files are produced which allow a check of all calculations after the fact. Last but not least the software supports two events which cannot be excluded to happen. Based on auxiliary data, a change between the AHM in use to the third one available in the lab is quickly made in case that service is needed to the AHM in operation. Even an AHM with cavity auto-tuning exhibits a (linear) frequency drift, and the synthesizer which is part of the AHM electronics needs to be stepped once in a couple of months as for practical reasons the relative frequency difference between the AHM frequency and the fountains should be limited to about 10^{-13}.

IV. Results

The new realization scheme was implemented after 27 February 2010, MJD 55254, and was accompanied by a replacement of some older cables (RG 58) by a more appropriate double-shielded variant. All cable delay changes were measured and later documented as required such that the transition could be made without a step in the time scale. On the other hand, the UTC(PTB) stability improved immediately, as illustrated by a comparison to UTC(NIST) using a GPS carrier phase comparison (NRCan PPP software [6]) whose result is shown in Figure 4.

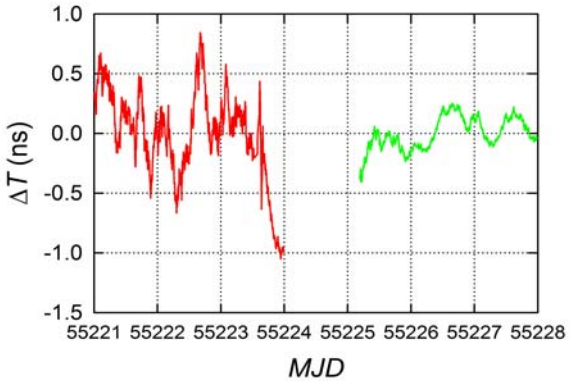

Figure 4. Phase comparison UTC(PTB) – UTC(NIST) based on a GPS carrier phases analysis using the NRCan PPP software [6] for a few days before and after the change of the UTC(PTB) realization; independent phase offsets removed in both data sets.

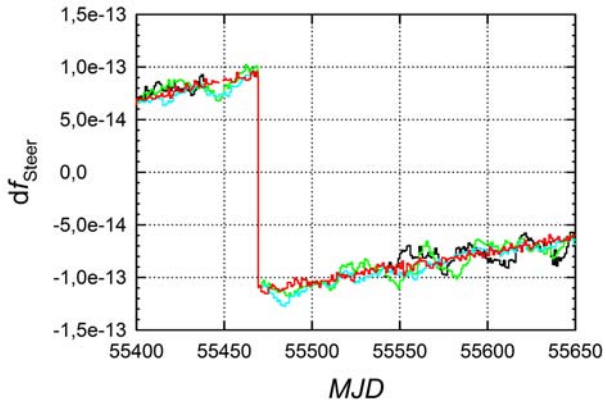

Figure 5. Steering corrections calculated since October 2010, red: Option 1, cyan: Option 2, green Option 3 (CS1), black based on CS2 with showing the interruption of its operation in fall 2010

Since then, including March 2011, the frequency steering could be based on Option 1 (CSF1 data) on about 98% of the days. Of course, during many days CSF1 was useful for less than 24 hours, but during the 13 months CSF1 was also used in 7 measurements of the TAI scale unit (see Figure 9) during which its operation has been ensured with a duty cycle

approaching 100%. The combination software (Option 2) became operational only in October 2010. Before that CS2 alone was used in Option 2 and CS1 in Option 3. In Figure 5 we show the steering values calculated since October 2010. They include one intentional maser frequency adjustment. As a matter of fact, the AHM selected as the physical source of UTC(PTB) behaved quite predictable during the last months. The alternate channel (UTH(PTB)) faced some abnormal events. In Figure 6 we compare six months of *UTC-UTC(PTB)*, in 2009 - 2010 (CS2 based) and 2010 – 2011 (hydrogen maser based) , respectively. The improvement in stability and thus predictability is appealing. During the last six months, including March 2011 UTC(PTB) deviated from UTC by less than 4 ns. In comparison with other timescales of renown quality, we see that UTC(PTB) is now quite competitive, despite of the fact, that a rather limited number of clocks has been involved in its realization.

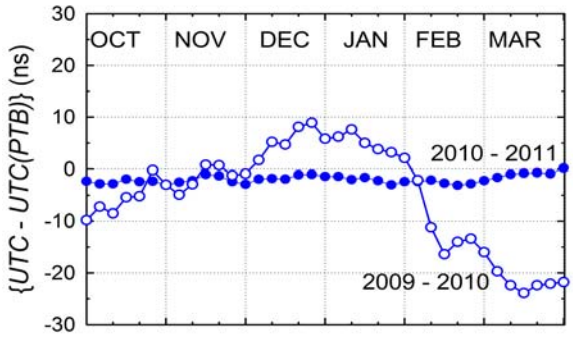

Figure 6. Time scale comparison UTC-UTC(PTB) in 2009 - 2010 and 2010 – 2011, respectively

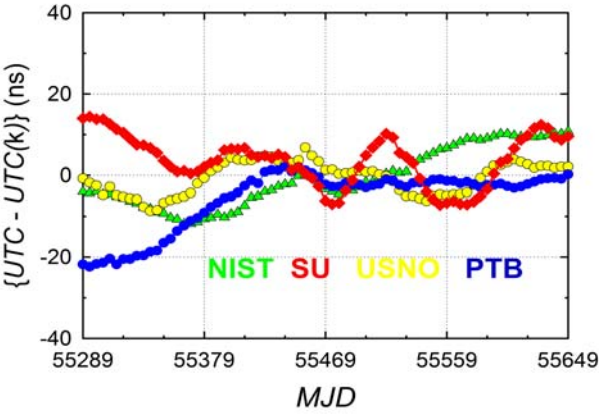

Figure 7. Time scale comparison UTC-UTC(k) during one year, including March 2011; k as indicated in the figure

As mentioned before, the realization of UTC(PTB) is made in duplicate, and in order to facilitate switching between the two signals they should be in close agreement. One option is that one realization is given the master status and the other slaved to follow it. This is not what we do. In Figure 8 we illustrate the relation between the two independently realized time scales, UTC(PTB) and UTH(PTB) (see Figure 3), during 100 days. The cause of the oscillatory behavior is under study, nevertheless the two independently realized time scales are typically within ±1 ns.

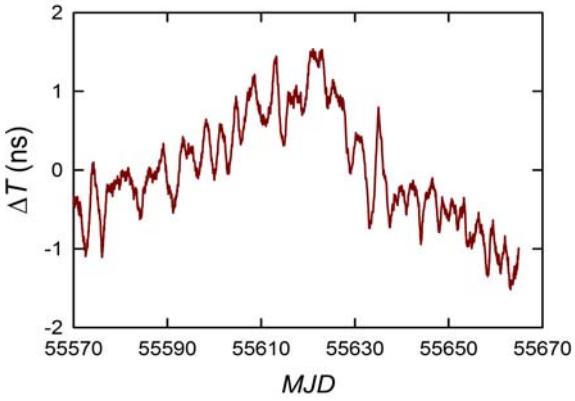

Figure 8. Comparison among the two realizations of PTB's time scale during 100 days

V. Discussion and Outlook

From the very beginning of the project, the use of fountain data as the reference for steering the AHM frequency was given the highest priority. One issue in debate was the optimum way to determine at all times the relation between CSF1 and the rate of TAI. We opted initially to use the estimated *d* from Circular T, Section 4, although *d* depends in a complicated way on the past contributions of several primary frequency standards, including CSF1 from time to time [7]. Another choice would have been to rely always on the last published value *d(CSF1)* or a mean value over recent data of that kind.

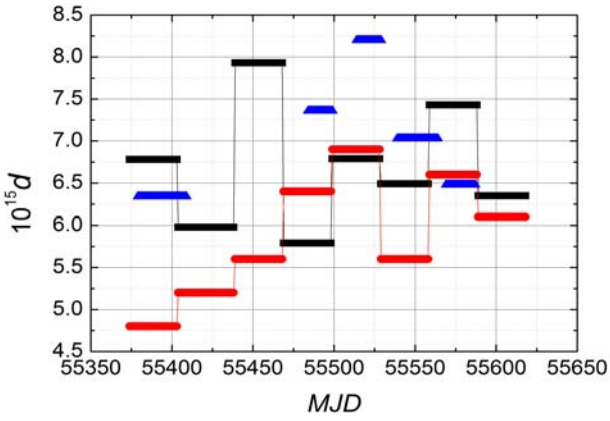

Figure 9. Three options to make the relation between CSF1 and the rate of TAI: blue: reported vales *d(CSF1)* for periods when CSF1 is used to measure the TAI scale unit; black: monthly values r(TAI-CSF1) as described in the text; red: monthly reported value *d* from Circular T, Section 4, which was actually used.

We also combined monthly average frequency values $\langle y(\text{CSF1-AHM})\rangle_M$ built from the daily values, collected as described above, with the monthly values rTAI for the AHM

involved to yield r(CSF1-TAI) for a full month. There are two subtle difficulties involved. As described before, a value $\langle y(\text{CSF1-AHM})\rangle_M$ practically never covers 100 % of a month, but the rTAI value for the AHM does. These rTAI-values, on the other hand, do not represent true frequency averages but are calculated by the BIPM from the slope of a linear fit to the seven time difference values reported monthly according to the ALGOS schedule. In Figure 9 we illustrate that the three options lead to steering values differing by a few parts in 10^{15} in some cases. In consequence, the time scale built thereon would behave differently. The result of one simulation made is shown in Figure 10 where the fictive time difference $\{UTC\text{-}UTC(PTB)\}_F$, based on the monthly r(CSF1-TAI), shows significantly larger deviations from zero as what was achieved in reality. Fortunately, the use of *d* is the simplest to implement, and as it provided good results we will continue to follow this practice for a while.

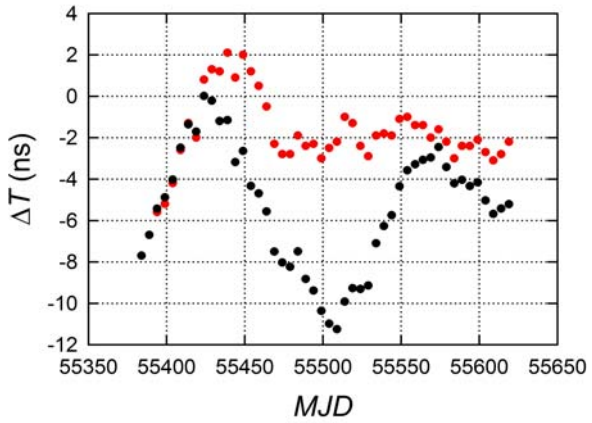

Figure 10. Deviation of UTC(PTB) from UTC: fictively calculated (black) based on the monthly values r(TAI-CSF1) (black in Figure 9) and realized in practice (red).

Simulations also covered the situation that one of the other options had to be used all times instead of Option 1. They included deviations from the practice of calculations described above, namely the use of the most recent or an average value for rTAI, and also the averaging interval for the calculation of δf_1 was questioned. We prefer to skip all details here, as in all cases a realization of UTC(PTB) based thereon would by far not have had the quality that was actually achieved using Option 1.

In view of this, the work program ahead of us is obvious. At first we implement the interfaces between the fountain CSF2 and the time-scale generation software and later use that input either as a separate option or we combine the data from the two fountains. Having achieved this, the steering of the hydrogen maser can be made twice per day. We also noted a few minor inconveniences in the operation of the software which shall be avoided in a future update.

One has to keep in mind that the UTC-UTC(PTB) differences obtained during the last 6 months are no longer large compared to the uncertainty with which they have been determined [8]. Delay changes in the time transfer equipment have to be avoided or at least have to be corrected for as otherwise they spoil the quality of the timescale. Periodic calibrations of the signal delays in the time transfer equipment are a way to support this. Such activities are, however, on our agenda anyway [9, 10] since PTB serves as the pivot laboratory for all time comparisons made in context of the realization of TAI.

ACKNOWLEDGMENT

The availability of fountain data was instrumental for the success. We appreciate the devotion of Stefan Weyers and his team at PTB to operate CSF1 in an extremely reliable way. Testing and documentation of the software was supported by Jürgen Becker and Thomas Polewka. Yang Wenke thanks China Scholarship Council for funding her one year scholarship in PTB.

Contribution to TAI frequency by a travelling Primary Frequency Standard

G. D. Rovera, M. Abgrall, Ph. Laurent
LNE-SYRTE, Observatoire de Paris - CNRS - UPMC, France
e-mail: daniele.rovera@obspm.fr

***Abstract*— The Mobile Atomic Fountain has been used to steer the TAI frequency when operating in sites without regular link to BIPM. A brief description of the method used to link this standard to a fly-wheel clock included in BIPM database and results are presented. There is no evidence of different behavior when the FOM is sitting in LNE-SYRTE or in remote laboratories.**

I. Introduction

The steering of the frequency of TAI by the Primary atomic Frequency Standards (PFS) has been introduced after that was found a systematic bias in the majority of the commercial cesium beam frequency standards of first generation [1].

With a few exceptions PFS do not run continuously to allow the necessary tests necessary to the accuracy evaluation. For this reason they are only used to steer the TAI frequency. In normal practice a PFS measures the frequency of a high stability flywheel oscillator. This oscillator participates to the computation of TAI and a monthly report of its the frequency measured by the PFS is sent to BIPM. The link uncertainty in this case is very low because usually the PFS and the flywheel clock are located in the same building, or at least in the same campus as is the case for FO1 and FO2 at Paris Observatory.

The Mobile atomic FOuntain FOM developed at SYRTE has contributed to TAI in this way for several years. In June 2008 the FOM has been moved to CNES in Toulouse for a long campaign of test of the space clock PHARAO[2]. Two Hydrogen Maser were available as flywheel at CNES but unfortunately both of them were not included in the BIPM database and therefore useless to report to BIPM. The main goal of the campaign was to check the PHARAO Performances, and a complementary task was to continue the synchronous comparison between all the PFS of LNE-SYRTE, and possibly continue to report to TAI.

First result of comparison of distant fountain have been achieved in October 2008 via a GPS carrier phase time transfer link. After a period of validation of the method a first report has been sent to BIPM with data of April 2009, followed by 3 others from the same location. In all report from CNES the carrier phase GPS data processing has been performed by CNES staff using a proprietary software[3].

In the following FOM has been moved to Max Plank Institute in Garching for a measurement of the frequency of 1S-2S Hydrogen transition [4]. During summer 2010 FOM has been moved to Observatoire de la Cote d'Azur OCA, near Grasse, to serve as a reference clock for the T2L2 experiment

Fig. 1. FOM Hardware

and from here 3 reports have been sent to BIPM. For the last two campaigns the GPS data processing has been done with the PPP software kindly licensed to SYRTE from NRCan. The method of frequency transfer described here is a demonstration of the possibility of operate a PFS outside of Metrology Institute regularly contributing to TAI.

II. The Mobile Atomic Fountain

Motivations:

- The mobile fountain FOM has been built when there was no link allowing frequency comparisons at 10^{-15} in a few days of operation.
- It was necessary to build a reference clock for the ground test of PHARAO clock at CNES integration facility.
- In almost 10 years of operation FOM has been used as primary frequency standard for several measurements of

978-1-61284-110-6/11/$26.00 ©2011 IEEE

optical/microwave frequency standards.

- The mobile fountain FOM can be used to test the performances of newly developed time/frequency links.
- Since 2006 the mobile fountain FOM has contributed 25 times to the steering of TAI.
- Since 2008 the mobile fountain FOM has contributed 8 times to the steering of TAI from 3 different sites not usually linked to UTC.

FOM can be operated in three different configurations to match the availability of a local frequency reference:

- Autonomous mode, by using a low noise BVA quartz-oscillator. This configuration delivers signals at 10 and 100 MHz with a short term instability of $1.4 \cdot 10^{-13} \tau^{-1/2}$, limited by the noise of local oscillator.
- Maser mode, by filtering the 100 MHz signal from an H maser with a low noise BVA quartz-oscillator. This configuration measure the maser frequency with a short term instability of $1.2 \cdot 10^{-13} \tau^{-1/2}$.
- Cryo mode, by using directly a 100 MHz or 1 GHz signal from a cryogenic oscillator[5]. This configuration measure the cryo frequency with a short term instability of $8 \cdot 10^{-14} \tau^{-1/2}$. In this case the stability is limited by the quantum projection noise

B. FOM uncertainty budget

TABLE I
FOM UNCERTAINTY BUDGET

	Correction 10^{-16}	Uncertainty 10^{-16}
Quadratic Zeeman effect	-295.9	1.2
Black body radiation	165.8	0.6
Cold collisions & cavity pulling	25.1	5.0
Microwave power dependence	0	6
Ramsey & Rabi pulling	0	<0.1
Microwave recoil	0	<1.4
Second order Doppler	0	<0.1
Background gas collisions	0	<1.0
Total	-105.0	8.1
Red shift OCA	-1384.1	3.0
Red shift MPQ	-520.5	3.0
Red shift CNES	-160.1	1.0
Red shift LNE-SYRTE	-68.7	1.0

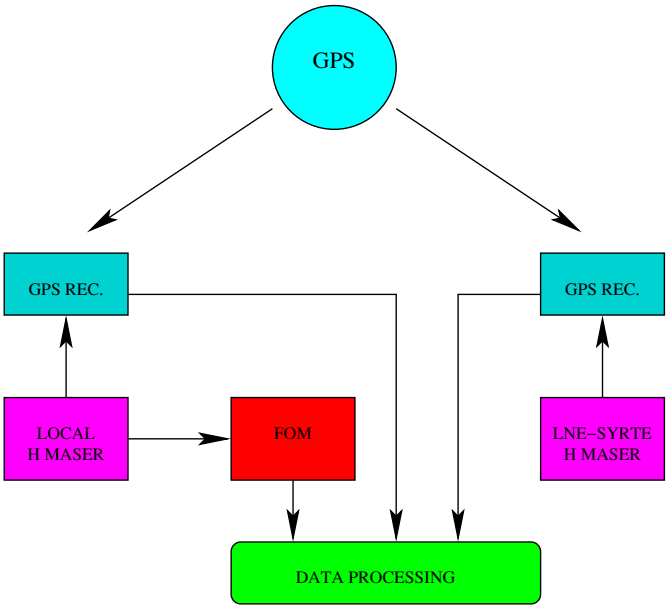

Fig. 2. Link Diagram

A typical uncertainty budget of FOM is presented in table I. The largest value of the red shift is obviously obtained at OCA (h=1268.72 m) A recent a survey[13] report the height of a reference point located nearby the fountain with a uncertainty of 1 cm. The same source also reports the local gravity g with 0.1 mGal. As the value of the red shift depends on the local potential we take a conservative uncertainty of 3^{-16} We take the same uncertainty in Garching because we have a poorer determination of height. The agreement of the frequency of the FOM with the SI at different heights is a confirmation of the good estimation of the red shift.

III. LINK OF FOM TO TAI

The basic idea is to set up a link allowing the measurement of the frequency of a flywheel oscillator that is inserted in BIPM database and contributes to the generation of TAI. Considering the experience gathered in years of fountain comparison inside LNE-SYRTE we have decided to continue on the same basis, that is the measurement of the maser frequency averaged over a period that is slightly shorter then the optimum time where the fountain and maser noises crosses.

Figure 2 shows the block diagram of the link between the FOM and one of the Maser of LNE-SYRTE used as flywheel oscillator for FO1 and FO2 fountains. In all the visited laboratories the local maser is not inserted in BIPM database and in some case not stable as the one in Paris.

When operating in Maser or Cryo mode FOM produces files with 1 line of data per cycle. The most relevant information is the central frequency of the microwave synthesizer, that is the measured uncorrected frequency of the maser.

- The 1 cycle raw files are processed line by line by applying all the estimated correction, included gravitational red

shift. The result is a 2 column file with the cycle time-stamp and the relative frequency of the local H maser.
- To avoid manipulation of huge amount of data dominated by white frequency noise the 1 cycle files are packed in files with one point ever 0.1 day.
- GPS rinex files are processed with the NRCan PPP software and used to calculate the time difference between the local H maser and the H maser 140 0890 located at LNE-SYRTE.
- The maser's frequency difference, averaged over period of 0.1 day, is obtained by smoothing and differentiation of time differences.
- The frequency of H maser 140 0890 is obtained by difference of local and GPS frequency files.
- Usual techniques are applied to estimate the frequency and drift of the LNE-SYRTE H maser 140 0890 in a standard BIPM interval, as well the Allan standard deviation and the link uncertainty.

Figure III shows the frequency difference between FOM and TAI. For comparison on the same graph the red line shows the difference between SI, that is the best estimation of the realization of the second, and TAI. From this plot it is evident that the frequency of FOM is in good agreement with SI not only when it is sitting in Paris Observatory but also when it is travelling around Europe.

IV. Conclusion

This is the first time that a Primary Frequency Standard contributes to steering of TAI from different sites with different gravitational red shift.

The perfect agreement of the frequency of the standard with SI from locations differing in height more than a thousand meter is confirmation of the correctness of the evaluation of gravitational red shift.

Acknowledgments

Thanks to colleagues of LNE-SYRTE for supporting this activity. CNES has supported FOM development, its utilization in Toulouse and Grasse and has provided GPS data analysis for the Toulouse campaign. Thanks to MPQ and OCA for hosting the FOM. Thanks to NRCan for the PPP software, with a special mention to François Lahaye for the support. One of the authors (G. D. Rovera) will acknowledge INRiM for the intensive training in GPS data analysis.

***Abstract*—We have compared the frequency of a room-temperature cesium-fountain primary frequency standard with that of a cryogenic (~80K) cesium fountain. This comparison yields a measurement of the blackbody frequency shift of the room-temperature fountain.**

I. INTRODUCTION

NIST-F1 is a well characterized cesium-fountain primary fractional frequency standard with frequency inaccuracy at the $\delta f/f \sim 4\times10^{-16}$ level. This inaccuracy is dominated by the uncertainty in the blackbody correction of about $\delta f/f \sim 3\times10^{-16}$. NIST-F2 and IT-CsF2 are cryogenic (80K) cesium-fountain frequency standards coming into operation at the National Institute of Standards and Technology (NIST) in Boulder, CO and at Istituto Nazionale di Ricerca Metrologica (INRIM) in Torino, Italy. Frequency comparisons among these fountains yield a measurement of the blackbody shift

II. ROOM TEMPERATURE FOUNTAINS

A. NIST-F1

NIST-F1 is the US primary frequency standard and has been previously described in great detail [1],[2],[3]. Thus we will give only a cursory overview of the salient points regarding its performance and uncertainties.

B. Error Budget

An abbreviated error budget for NIST-F1 is shown in Table 1. It can be seen that the overall uncertainty of the standard is dominated by the $\delta f/f \sim 2.8\times10^{-16}$ fractional uncertainty in the blackbody shift. This uncertainty corresponds to a 1 K uncertainty in the effective radiation temperature of the standard, and is the uncertainty that the cryogenic fountains are designed to effectively eliminate. A comparison of the room temperature fountains with the cryogenic fountains combines the systematic errors in the fountains in ways that require individual treatment of these systematic uncertainties: an obvious example is the gravitational shift that largely cancels for both clocks with the uncertainty in the shift dropping from $\delta f/f \sim 3\times10^{-17}$ to $\delta f/f \sim 1\times10^{-18}$.

III. CRYOGENIC FOUNTAINS

A. NIST-F2 and INRIM CsF-2

The NIST and INRIM cryogenic fountains are similar in that the design of the Physics package is essentially identical. Details of the optical systems and control electronics are however idiosyncratic to each particular fountain. The physics package has been described previously and only a short review is given here [4],[5].

The fountains operate on a pure optical-molasses atom-loading scheme (no MOT), with the beam geometry being (1,1,1) (crystallographic notation that defines the beam geometry). The atoms are launched upwards at about 4.5 m/s and post-cooled in the moving frame to temperatures around 500 nK. The

atoms fly upward through the room-temperature vacuum system before entering the magnetically shielded cryogenic region. In the cryogenic region the atoms are state-selected and Ramsey interrogation takes place. The microwave structure is essentially identical to that of NIST-F1 [1],[2],[3] with the exception that the microwave cavities are tuned to resonance at 80 K instead of 318 K (NIST-F1) or 340 K (IT CsF-1). Detection takes place at room temperature after the atoms have left the magnetically shielded cryogenic region. The detection region is very similar to that used in NIST-F1, and was specifically designed to minimize vignetting, with the modeled detection efficiency being uniform over the entire cloud and vignetting being less than 10 %.

TABLE I. NIST-F1 ERROR BUDGET – BIASES AND UNCERTAINTIES ARE GIVEN IN UNITS OF $\delta F/F = 10^{-15}$. THIS IS CURRENT AS OF MARCH 2011.

Physical Effect	Bias	Type B Uncertainty

B. Error Budget – NIST-F2 & IT CSF-2

An abbreviated error budget for NIST-F2 is shown in Table 2. This is a preliminary error budget and several systematic shifts, notably systematic frequency shifts associated with microwave effects (eg. microwave leakage, distributed cavity phase, microwave spurious signals etc) are not yet completely evaluated. The entries in the error budgets generally reflect our most pessimistic measurements and estimates and are usually limited by statistical uncertainties in those measurements. At this time the error budget for INRIM IT-CsF-2 is similar to that for NIST-F2.

TABLE II. NIST-F2 ERROR BUDGET – BIASES AND UNCERTAINTIES ARE GIVEN IN UNITS OF $\delta F/F = 10^{-15}$. THIS IS CURRENT AS OF MARCH 2011.

Physical Effect	Bias	Type B Uncertainty

IV. BLACKBODY SHIFT MEASUREMENT

Three measurement campaigns using NIST-F1 and NIST-F2 have been completed. These campaigns (in Sept 2010, Dec 2010 and March 2011) after appropriate data processing yield a measurement of the blackbody shift in NIST-F1. In the course of a measurement, NIST-F1 and NIST-F2 are run concurrently. Each fountain is corrected for systematic frequency shifts associated with the Zeeman effect, spin-exchange collisions, and differential gravitational effects. The frequency difference between the two fountains is then compared to the frequency difference calculated for the differing blackbody shifts in NIST-F1 and NIST-

F2. That comparison yields a measurement of the blackbody shift in NIST-F1.

Preliminary results from comparison of the NIST fountains suggests that the difference between the blackbody shift as predicted by theoretical calculations [6] and the measured blackbody shift is well within the experimental uncertainties ($\delta f/f$ ~5-7*10^{-16}) of the comparison.

Further measurements are underway and full results will be published in a forthcoming paper.

ACKNOWLEDGMENT

The authors are indebted to many people who contributed to this effort over the past several years. In particular, Doug Gallagher of the NIST Instrument Shop for his fine workmanship in the construction of the cryogenic fountains, and Mike Lombardi and David Smith for their always useful and pertinent suggestions on manuscripts.

***Abstract*— The continuous atomic fountain primary frequency standard FOCS-2 is quite unique since all the atomic fountain clocks presently contributing to the international atomic time (TAI) are operating in pulsed mode [1]. Our alternative approach offers the possibility to operate with a high atomic flux without the collisional shift limiting the accuracy or the Dick effect limiting the stability when a quartz is used as local oscillator [2], [3]. Moreover, it contributes to the metrological diversity since the relative importance of the error budget contributors is different in the two types of fountains, notably for microwave cavity and density related effects. In this contribution we present the status of the metrological evaluation of the continuous fountain FOCS-2. Thanks to an innovative atomic beam source followed by an atomic state preparation stage, we reach a signal-to-noise ratio of $600\sqrt{\text{Hz}}$ and thus a relative frequency instability of $6 \times 10^{-14}\,\tau^{-1/2}$. A detailed investigation of the frequency shifts which are specific to the continuous operation (light-shift from the source and cavity end-to-end phase shift) shows that the continuous fountain is compatible with an inaccuracy at the 10^{-15} level or below.**

I. Introduction

In this work, we report on the evaluation of the frequency shifts in our continuous atomic fountain clock FOCS-2. We start in Section II by describing the atomic resonator with an accent on the elements which are unique to the continuous mode of operation: the light-trap and the microwave cavity with two distinct interaction regions. In Section III we describe the operation of the fountain, from the acquisition of Ramsey fringes to frequency stability measurements and state preparation. In Section IV, we discuss the evaluation of the frequency shifts which are specific to the continuous fountain and therefore required the development of new experimental methods. The light-shift produced by the source of the atomic beam is reduced to a negligible level with a rotating light-trap as described in Section IV-A. The microwave cavity is substantially different in a continuous fountain since the upward and downward interactions zones must be separated. As a consequence, a cavity reversal technique was developed for the evaluation of the end-to-end phase shift and the results are presented in section IV-B. Evaluation of the second-order Zeeman shift requires a precise knowledge of the magnetic field in the atomic free evolution zone. The methods developed to measure this magnetic field are presented in Section IV-C. Finally, we present the status of the inaccuracy budget in Section V and conclude in Section VI.

II. Description of the continuous atomic fountain FOCS-2

A. Atomic resonator

A scheme of the continuous atomic fountain FOCS-2 is shown in Fig. 1. The atomic beam is produced with a two-dimensional magneto-optical trap (2D-MOT) [4]. Then, the atoms are captured, cooled, and launched at a speed of 4 m/s with a moving molasses [5]. The atomic beam temperature at the exit of the moving molasses is approximately 70 μK. Before entering the microwave cavity, the atomic beam is further collimated by transverse laser cooling. Moreover, the atoms are pumped into $|F = 3, m = 0\rangle$ with a state preparation scheme combining both optical pumping and laser cooling [6]. After these two steps, the transverse temperature is reduced to ≈ 3 μK.

Then, the atomic beam passes through the light-trap which stops the light coming from the source. A photodiode has been installed which measures the light intensity after the light-trap and is used for the evaluation of the light-shift and long term monitoring, see Sec. IV-A.

During the first passage into the microwave cavity, we apply a $\pi/2$-pulse (duration of 10 ms) and thereby produce a superposition state which evolves freely for 0.52 s before the second $\pi/2$-pulse is applied during the second passage. Finally, the transition probability between $|F = 3, m = 0\rangle$ and $|F = 4, m = 0\rangle$ is measured by fluorescence detection of the atoms in $F = 4$.

B. Light-trap

The atomic beam source described in the previous section operates in a continuous mode, which means that the lasers producing the cold atomic beam are always switched on, and as a consequence their light may produce a shift of the clock transition frequency. Therefore, a rotating light-trap has been installed to prevent the source light to reach the free evolution zone situated above. It is composed of 18 glass blades oriented at 45^o as shown in Fig. 2. The rotation speed is adjusted such that the horizontal velocity v_t of the blades matches the longitudinal velocity v_l of the atomic beam, see Fig. 2(a). When this condition is satisfied, the atoms can pass with a minimal attenuation $< 15\%$. On the contrary, the photons are either absorbed or deviated into a beam block after two reflexions on the blades as shown in Fig. 2(b). The light

978-1-61284-110-6/11/$26.00 ©2011 IEEE

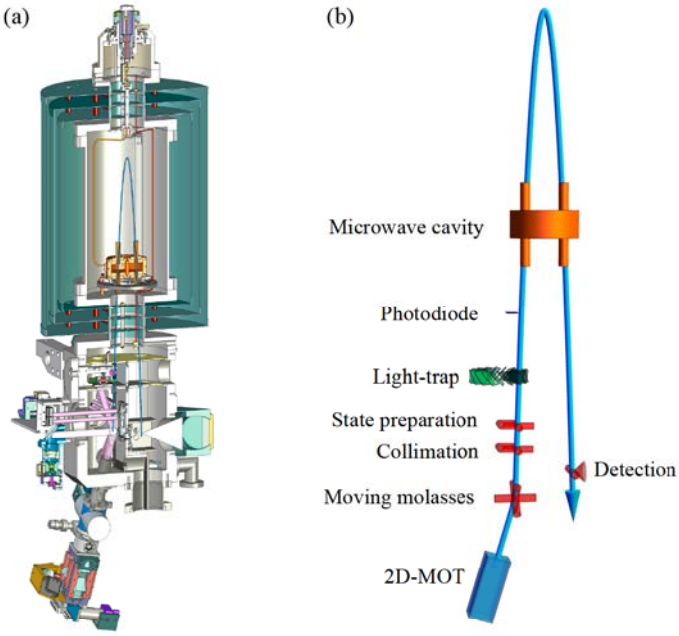

Fig. 1. Scheme of the continuous atomic fountain FOCS-2. (a) Atomic resonator. (b) Scheme of principle. An intense atomic beam of pre-cooled cesium atoms is produced in the two-dimensional magneto-optical trap (2D-MOT). The atoms are then captured by the 3D moving molasses which further cools and launches the atoms at a speed of 4 m/s. Then the atomic beam is collimated with Sisyphus cooling in the transverse directions and, before entering the microwave cavity, the atoms are pumped in $|F = 3, m = 0\rangle$ by state preparation. Finally, after the second passage in the microwave cavity, the transition probability is measured by fluorescence detection of the atoms in $F = 4$. The free evolution time between the two $\pi/2$-pulses is $T = 0.52$ s. The light-trap prevents the stray light from the atomic beam source from reaching the free evolution zone situated above.

attenuation factor was measured to be 10^4. The trap is driven by a home-made electrostatic motor which is compatible with ultra-high vacuum and entirely non-magnetic [7].

C. Microwave cavity

We use a coaxial cylindrical cavity with two interaction regions as shown in Fig. 3. The cavity is mounted on a rotation stage which allows us to exchange the interaction zones for the evaluation of the end-to-end phase shift. There are two feeding ports which are placed at 90 degrees with respect to the plane containing the interaction zones and we excite the mode TE_{021}. The quality factor is 15000 loaded and 22000 unloaded. The coupling factors are approximately 0.2.

III. Operation of the Continuous Atomic Fountain FOCS-2

A. Ramsey fringes

In our continuous fountain, Ramsey fringes are measured by continuously recording the transition probability while scanning the microwave frequency. Figure 4 shows a measurement of the Ramsey fringes observed on the clock transition, acquired in a single scan, at a speed of 2 Hz per second. The

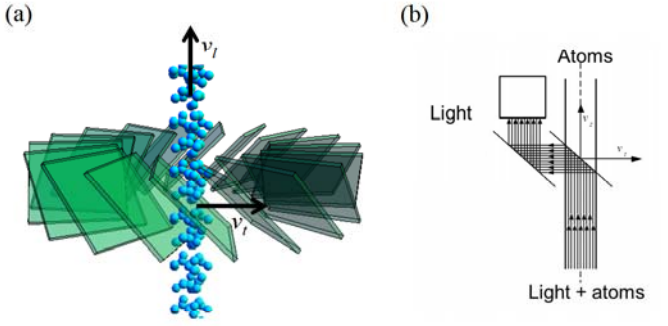

Fig. 2. Scheme of the light-trap. (a) The atomic beam can pass through the trap when the blades horizontal velocity v_t matches the atomic beam vertical velocity v_l. (b) The light is stopped after two reflexions on the blades.

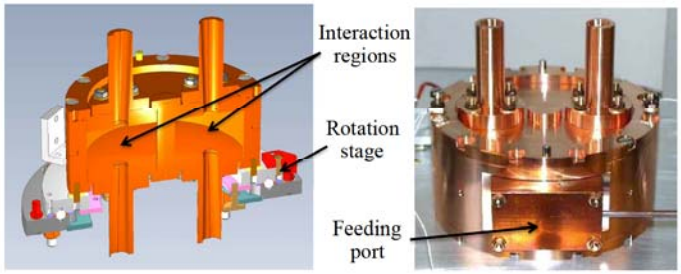

Fig. 3. The microwave cavity has two distinct interaction regions, and two feeding ports. It is mounted on a rotation stage which enables to exchange the interaction zones for the evaluation of the end-to-end phase shift.

contrast is $> 98\%$ and the signal-to-noise ratio is approximately $600\sqrt{\text{Hz}}$ [1].

B. Frequency stability measurement

We compare the frequency of the fountain FOCS-2 to an active hydrogen maser using the scheme presented in Fig. 5. A commercial microwave synthesizer (from SpectraDynamics Inc.) referenced to the hydrogen maser is used to interrogate the atomic transition. We use square wave phase modulation

[1] Here, the signal is the peak-valley amplitude of the central fringe, and the noise is measured on the top of the central fringe.

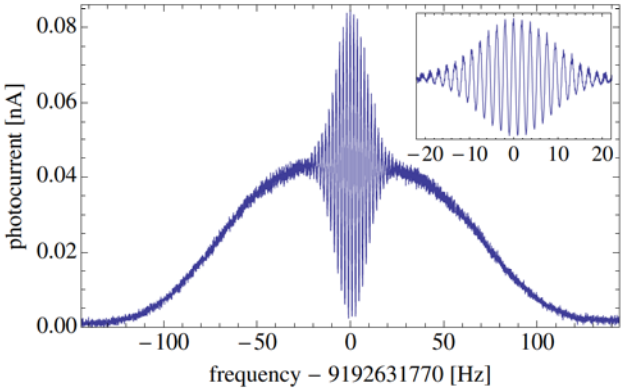

Fig. 4. Measurement of the Ramsey fringes observed on the clock transition, acquired in a single scan, at a speed of 2 Hz per second.

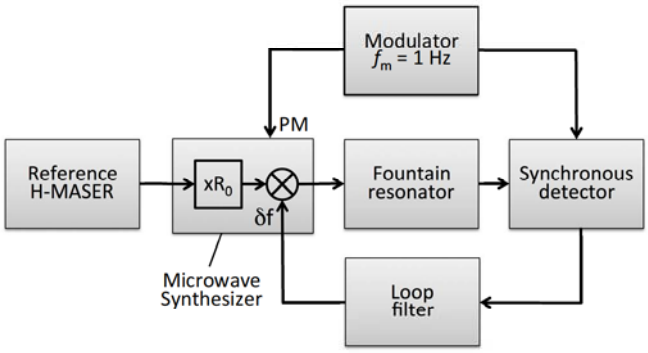

Fig. 5. Scheme of the frequency control loop. A commercial synthesizer, referenced to an active hydrogen maser, generates the microwave which is used to interrogate the atoms. By modulating the phase of the microwave at 1 Hz and demodulating the resulting transition probability, one obtains the error signal which is integrated to produce the frequency correction δf. See section III-B for details.

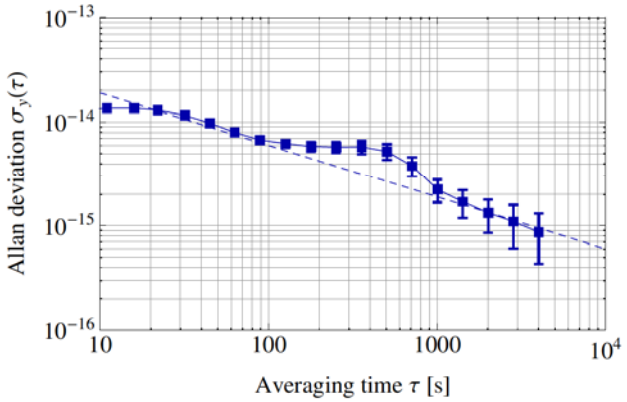

Fig. 6. Allan deviation of FOCS-2 compared to an active hydrogen maser. The dashed line indicates $6 \times 10^{-14}\,\tau^{-1/2}$. The bump at 500 s is due to temperature variations (± 1 K) in the laboratory.

at 1 Hz of the microwave, and subsequent square wave synchronous detection of the transition probability, to generate the error signal which is then integrated by the loop filter to control the synthesizer frequency. The resulting frequency correction δf is a measure of the frequency deviation of the fountain with respect to the maser. Note that the synchronous detector is digital, the servo loop filter as well, and the synthesizer frequency is numerically controlled.

With this scheme, we obtain the Allan deviation shown in Fig. 6 which follows a $6 \times 10^{-14}\,\tau^{-1/2}$ behavior. The bump at 500 seconds is due to temperature fluctuations of ± 1 K in the laboratory and should disappear with a better stabilization of temperature. Let's note that the first 2 points are not relevant since they are out of the servo loop bandwidth.

C. State preparation for an improved frequency stability

State preparation is a key point to reach the high stability shown in Fig. 6. We use two-laser optical pumping to bring all the atoms in $|F = 3, m = 0\rangle$. A first laser excites the $F = 4$ ground state in order to pump the atoms toward $F = 3$ while a second π-polarized laser excites the $F = 3 \rightarrow F' = 3$ transition of the D2 line in order to produce Zeeman pumping toward $m = 0$. To avoid trap states, the first laser is implemented in a 2D optical lattice geometry, thereby creating polarization gradients. This configuration has the advantage of simultaneously producing Sisyphus cooling when the optical lattice laser is tuned on the blue side of the $F = 4 \rightarrow F' = 4$ transition, which is important to remove the heat produced by optical pumping [6].

Thanks to state preparation, we were able to bring approximately 60% of the atoms in $|F = 3, m = 0\rangle$ which produces a notable increase of the useful flux. As a consequence, we observe an increase of both the signal-to-noise ratio and the frequency stability by a factor > 4 [8]. The resulting Allan deviation is shown in Fig. 6.

IV. Evaluation of the Frequency Shifts

In this section, we discuss the evaluation of three frequency shifts which are specific to the continuous fountain and therefore required the development of new experimental methods.

A. Reduction of the light-shift from the source

As mentioned in section II, the lasers producing the atomic beam are always switched on in our continuous fountain, and therefore they produce a light-shift of the clock transition which has to be reduced. To this end, we installed a rotating light-trap to prevent the source light from reaching the interrogation zone. A photodiode installed a few centimeters above the light-trap (see Fig.1(b)) allows us to measure the amount of light coming from the source along the atomic beam trajectory in the direction of the microwave cavity. By measuring the detected light before and after the installation of the light-trap, we obtained an attenuation factor of 10^4.

Before installing the light-trap, we measured the light-shift by comparing FOCS-2 frequency to UTC via a GPS link. In order to identify the light-shift contribution, we measured both the fountain frequency and the amount of light along the atomic beam trajectory (with the photodiode mentioned above) for different values of the source fluorescence light. In order to change the source fluorescence light, we varied the atomic flux by changing the 2D-MOT laser power. The results are presented in Fig. 7. The linear dependence indicates that the source fluorescence light is the main contributor. Moreover, the value of the light-shift at nominal flux and without light-trap is

$$\Delta\nu_{\rm LS}/\nu_{\rm Cs} = -1.6 \times 10^{-12} \text{ without light-trap} \qquad (1)$$

After installation of the light-trap, we measured the amount of fluorescence light collected by the photodiode and obtained an attenuation factor of 10^4. Since the light-shift is proportional to the light intensity, we can conclude that the light-shift with light-trap is reduced down to

$$\Delta\nu_{\rm LS}/\nu_{\rm Cs} - -1.6 \times 10^{-16} \text{ with light-trap} \qquad (2)$$

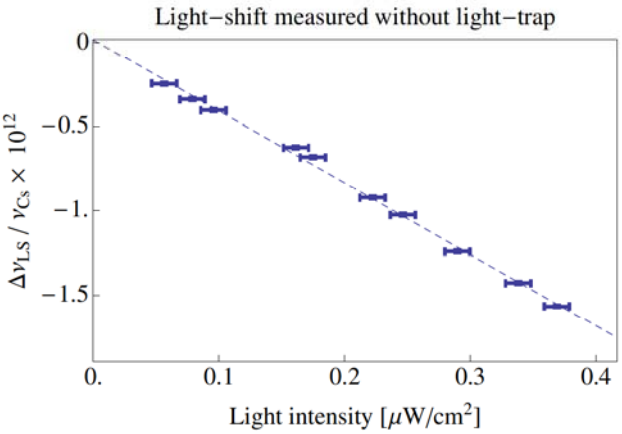

Fig. 7. Light-shift measured in FOCS-2 before the installation of the light-trap. The horizontal axis is the light collected by the photodiode shown in Fig.1(b). It is a measurement of the stray light emitted by the atom source toward the microwave cavity. This stray light is attenuated by a factor 10^4 with the light-trap. See section IV-A for details.

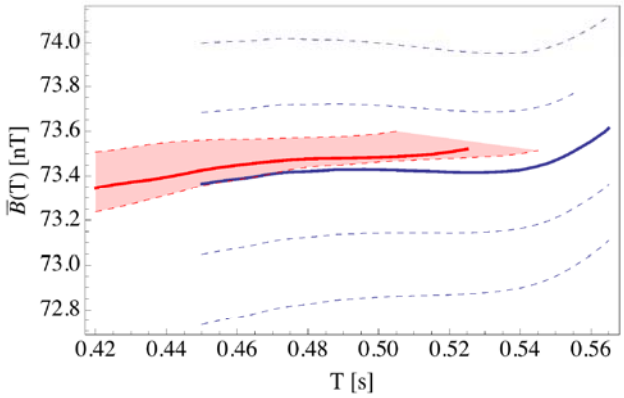

Fig. 8. Time-averaged magnetic field $\overline{B}(T)$ as a function of the transit time T. The blue solid line was obtained from the phase of the Fourier transform of the Ramsey fringes measured on $m_F = -1$. Due to the 2π ambiguity of the phase, this function is not uniquely determined. The blue dashed curves represent possible realizations which differ by a multiple of $1/(K_z T)$. The red band has been obtained from the time-resolved Zeeman spectroscopy measurement of the magnetic field profile. It allows us to identify one of the curves from the Fourier analysis. See Section IV-C for details.

B. Microwave cavity end-to-end phase shift

As mentioned in section II, the microwave cavity has two distinct interaction zones, and thus a cavity end-to-end phase shift $\Delta\phi$ results in a frequency bias $\Delta\nu_\phi = -\Delta\phi/(2\pi T)$ where T is the effective free evolution time. In order to measure this shift, the microwave cavity is mounted on a rotation stage which allows us to rotate it by 180^o around the vertical axis, thereby exchanging the two interaction zones, and thus changing the sign of $\Delta\phi$. This high quality rotation stage enables to reproduce the absolute position of the microwave cavity with a precision better than 0.01 mm. In order to measure $\Delta\nu_\phi$, we successively compare the frequency of FOCS-2 in positions A (original position) and B (rotated by 180^o) with the hydrogen maser during a short period of time such that the maser frequency drift is negligible. The cavity end-to-end phase shift is then given by $\Delta\nu_\phi/\nu_{Cs} = y(\text{position A} - \text{position B})/2$.

We performed a frequency measurement of eight hours, alternating between positions A and B every 30 minutes, and after averaging the frequency differences as explained above, we obtain the cavity end-to-end phase shift

$$\Delta\nu_\phi/\nu_{Cs} = (1.7 \pm 0.9) \times 10^{-15} \qquad (3)$$

C. Second-order Zeeman shift

Evaluation of the second order Zeeman shift $\Delta\nu_Z = K_0\overline{B^2}$ where $K_0 = 42.745$ GHz T^{-2} and $\overline{B^2} = (1/T)\int B^2(t)dt$ requires a precise knowledge of the magnetic field in the free evolution zone. The methods developed in pulsed fountains to measure the magnetic field in the resonator are based on throwing balls of atoms at different altitudes. This is not applicable to our continuous fountain since the atomic trajectory is not vertical and therefore the launching velocity is limited by geometrical constraints. Moreover, the atomic beam longitudinal temperature is higher in our continuous fountain (75 μK) than in pulsed fountains (1 μK) and as a consequence the distribution of apogees is wider. The effect of this large distribution of transit time is to modify significantly the Ramsey pattern, reducing the number of visible fringes but also increasing its sensitivity to magnetic field inhomogeneities. As a consequence, identification of the central fringe on a Zeeman sensitive Ramsey pattern showed to be difficult in FOCS-2, and thus we developed novel methods to determine the magnetic field.

The first method makes use of the Fourier transform of Ramsey fringes measured on Zeeman sensitive components ($m \neq 0$). It is based on the observation that Ramsey fringes observed in an atomic fountain are formed by the superposition of the individual atomic signals. Due to the atomic beam residual temperature, the atoms have slightly different trajectories and thus are subject to a different average magnetic field. As a consequence, both the velocity distribution and the magnetic field profile are imprinted on the Ramsey patterns observed on Zeeman sensitive transitions. In Ref. [9] we demonstrated that one can retrieve the time-averaged magnetic field $\overline{B}(T)$ associated with different trajectories (of transit times T) from the phase of the Fourier transform. By applying the procedure described in [9] to FOCS-2, we obtain the time-averaged magnetic field shown in Fig. 8. As discussed in Ref. [9] there is a 2π ambiguity in the determination of the phase which generates an ambiguity in $\overline{B}(T)$ of $\pm n/(K_z T)$ where $K_z = 7\,\text{Hz/nT}$ and n is any integer number (see the dashed lines in Fig. 8). In principle, it would be possible to identify the correct curve ($n = 0$) by extending the domain of T values, but this is not possible in FOCS-2 since the transit time values are limited by geometrical constraints. As a consequence another method is necessary in order to solve this ambiguity.

The second method consists in measuring the magnetic field profile $B(z)$ in the free evolution zone by using time-resolved Zeeman spectroscopy. The basic principle is to measure the Zeeman frequency f_z by exciting $\Delta F = 0, \Delta m = \pm 1$

TABLE I

PRESENT STATUS OF THE EVALUATION OF FOCS-2.

Physical effect	Bias	Uncertainty	Unit
Light-shift from the source	-0.16	0.08	10^{-15}
Cavity end-to-end phase shift	1.7	0.9	10^{-15}
Second-order Zeeman	25.0	0.2	10^{-15}
Blackbody radiation	-18.9	0.1	10^{-15}
Gravitational shift	54.66	0.13	10^{-15}
Second-order Doppler	-0.012	0.001	10^{-15}
Rabi pulling	< 0.005	0.005	10^{-15}
Cavity pulling	-	-	-
Collisional shift	-	-	-
Distributed cavity phase shift	-	-	-
Power shifts	-	-	-
Electronics shifts	-	-	-
Background gas	-	-	-
Majorana	-	-	-

transitions and then deduce the magnetic field from $B = f_z/K_z$. Finally, from the magnetic field profile $B(z)$ and with the knowledge of the atomic beam trajectory, one can calculate the time-averaged magnetic field $\overline{B}(T)$. The result is presented in Fig. 8 together with the measurement obtained from the Fourier analysis of Ramsey fringes. In the Zeeman spectroscopy measurement, the main contribution to the error bar comes from the uncertainty on the atomic beam trajectory. Therefore, starting with the same experimental data, we repeated the same analysis but with trajectories differing by $\pm 1\sigma$ from the nominal trajectory, and we obtained the $\pm 1\sigma$ error band shown in Fig. 8.

With this knowledge of the magnetic field, combined with the distribution of transit times, we obtain the second-order Zeeman shift

$$\Delta\nu_Z/\nu_{\mathrm{Cs}} = (25.0 \pm 0.2) \cdot 10^{-15} \tag{4}$$

V. PRESENT STATUS OF THE INACCURACY BUDGET

The present status of the evaluation of the frequency shifts in our continuous fountain FOCS-2 is shown in table I. In section IV, we discussed in detail the frequency shifts which are specific to the continuous fountain and therefore required the development of new experimental methods: the light-shift from the source, the cavity end-to-end phase shift and the second-order Zeeman shift. The blackbody radiation shift, the gravitational shift, the second-order Doppler shift and Rabi pulling were treated like in pulsed fountains. The second part of the table shows the shifts that we plan to evaluate next.

VI. CONCLUSION

In conclusion, the continuous cesium fountain frequency standard FOCS-2 is now in the metrological evaluation phase. Thanks to an innovative atomic beam source followed by state preparation into $|F = 3, m = 0\rangle$, we reached a high-level of frequency stability with an Allan deviation of $6 \times 10^{-14}\,\tau^{-1/2}$. We started the metrological evaluation of FOCS-2 with a detailed investigation of the frequency shifts which are specific to the continuous mode of operation and/or required the development of new experimental techniques. More precisely, we measured the light-shift from the source and showed that it is reduced to a negligible level with the help of our home-made rotating light-trap. The microwave cavity end-to-end phase shift has been evaluated with the cavity reversal technique. It represents the first direct measurement of a dephasing of the field between two distinct points of a microwave cavity in an atomic fountain. The methods developed for the evaluation of the second-order Zeeman shift in pulsed fountains are not applicable to our continuous fountain because of the difference in atomic beam geometry and temperature. We thus developed a new experimental technique involving the Fourier transform of Ramsey fringes which could find applications in other similar experiments. Finally, all the frequency shifts evaluated so far show that the continuous fountain FOCS-2 is compatible with an inaccuracy budget at the level of 10^{-15} or below.

Abstract— **Presented is quantitative evaluation of two leading uncertainties in the NPL-CsF2 fountain frequency standard. The distributed cavity phase shift evaluation is based on recent theoretical model where the cavity field is decomposed into a series of 2D Fourier components in azimuthal angle in the cylindrical cavity. Predictions of the model are reproduced experimentally. The microwave lensing effect is caused by dipole forces originating from radial variation of the microwave field amplitude and cavity apertures. The new evaluation of the two effects together with other recent improvements reduce the total type B uncertainty of NPL-CsF2 to 2.3×10^{-16}.**

The first accuracy evaluation of the primary frequency standard NPL-CsF2 was performed in 2009 [1]. The largest contributions to the total type B uncertainty were distributed cavity phase shifts (DCP) and the microwave lensing of the atomic cloud. Here we quantitatively evaluate these leading uncertainties.

Our DCP uncertainty evaluation is based on a recent theoretical model [2]. The difficulty of accurate three-dimensional finite element modeling of the cavity field's phase is overcome by decomposing the field into a series of two-dimensional Fourier components $\cos(m\phi)$; ϕ is an azimuthal angle in the cylindrical cavity. After measuring a number of cavity resonances to precisely determine the cavity geometry, the fields and atomic response were then calculated for typical operational parameters of the NPL-CsF2 fountain. Frequency errors due to $m \geq 3$ modes are negligible since the atomic trajectories are localized near the cavity axis. Predictions of the amplitude dependence (Rabi frequency for the interaction in the cavity) for $m = 0$ and $m = 1$ were reproduced experimentally.

The agreement of the power dependence for $m = 0$ DCP shifts validates the model, which allows us to make a correction of 1.6×10^{-17} for the predicted shift at optimal power; we take half of this value as an uncertainty. We experimentally evaluate the $m = 1$ DCP uncertainty by tilting the fountain [3], operating at optimal power. This gives an $m = 1$ DCP uncertainty of 7.7×10^{-17}, with a 0.3 mrad uncertainty of the fountain tilt from vertical along two orthogonal axes. For $m = 2$, we model the imaging of the atomic cloud at the detection and use the model to set a DCP uncertainty at 7.8×10^{-17}. We also apply a correction of 13.8×10^{-17} for the $m = 2$ DCP frequency shift [4]. The total DCP uncertainty of 1.1×10^{-16} is dominated by the $m = 1$ tilt sensitivity and $m = 2$ uncertainty.

With a reduced DCP uncertainty, the largest uncertainty is then the yet unobserved microwave lensing of the atomic cloud by the dipole forces of the microwave clock field. The dipole forces occur due to the radial variation of the microwave field amplitude and a frequency shift results from the system apertures [5]. We evaluate the shift to be 6.2×10^{-17} for the circular apertures and the 2D dipole forces of our cylindrical cavity in NPL-CsF2. The shift is corrected, with an assigned uncertainty of 50% of its value. Future measurements will allow this to be further reduced.

Further improvements recently introduced to NPL-CsF2 fountain standard optimize the operation near the zero-collisional shift point [6] and include a re-evaluation of microwave leakage. These improvements and the quantitative evaluation of the DCP shift and the microwave lensing reduce the type B uncertainty of NPL-CsF2 by about a factor of 2, to 2.3×10^{-16}.

***Abstract*—Performance of the first two operational rubidium fountains at the USNO is presented using relative measurements and comparisons against other timescales. Recent results with four fountains indicate frequency agreement at the 10^{-15} level and good agreement with the primary frequency standards contributing to TAI.**

I. Introduction

The U. S. Naval Observatory (USNO) maintains an ensemble of atomic clocks for generation of a Master Clock, the physical realization of UTC(USNO). As many as 20 hydrogen masers and 70 commercial cesium clocks can contribute to the ensemble. The timescale used to generate UTC(USNO) relies on the short-term frequency stability of the masers and the long-term stability of the cesium clocks. In order to advance timekeeping activities, 7 rubidium fountain clocks are being added to the clock ensemble.

The fountains will serve as a long-term frequency reference, similar to but better than the lower-stability cesium clocks, but will not provide any tie to the SI second. In order for a fountain to be integrated into the USNO clock ensemble like any other clock, it generates a continuous 5 MHz output that can be measured against the Master Clock. The 5 MHz is generated from a precision synthesizer referenced to a maser that also serves as the LO reference for a fountain; the fountain adjusts the synthesizer's output based on its measurement of the maser frequency. The maser can act as a flywheel to minimize the effect of interruptions to fountain operation, but the fountains have been designed to operate continuously for long periods of time.

II. NRF2 and NRF3

The design and operation of the first operational fountains, NRF2 and NRF3, have been described in [1]. The fountains were installed in a new clock building at the end of 2008, and have been under evaluation for about 2 years. During that time, much has been learned about obstacles to continuous, uninterrupted operation. Imperfections in the environmental controls in the clock building and faulty commercial electronics have disrupted fountain performance. Additionally, the semiconductor laser systems that we use need to be serviced at intervals of 1 to 2 years.

A. Relative Comparison

Despite these obstacles, several good periods of evaluation were obtained. Data from an uninterrupted 100-day comparison between NRF2 and NRF3 are shown in Fig. 1. The plot in Fig. 1(a) is the relative phase between the fountains after a single relative phase and frequency have been subtracted. The relative frequency removed from the data is 7.4×10^{-16}. A linear fit to the corresponding frequency data returns a slope of $4.2(2.7)\times10^{-18}$/day. The uncertainty is derived from the result in [2] for determining errors on frequency drifts in the presence of white frequency noise. In general, we measure frequency drifts that are consistent with zero (see section III. D.)

The Allan deviation between the two fountains, shown in Fig. 1(b), exhibits white frequency noise out to an averaging time of at least 23 days, with an average stability per fountain of $1.6\times10^{-13}/\tau^{1/2}$. During this 100-day comparison, each fountain operated virtually hands-free.

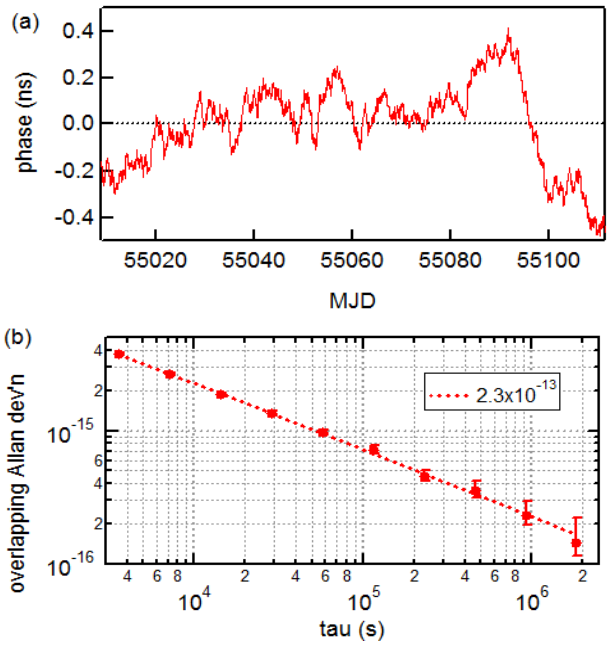

Figure 1 Data from 100-day comparison of NRF2 and NRF3. (a) Relative phase after removing single relative frequency and phase. (b) Overlapping Allan deviation versus integration time.

B. *Comparison to USNO Timescales*

Fig. 2 shows a plot of the relative phase of NRF3 versus the USNO cesium mean and maser mean. The cesium mean is a timescale based solely on the cesium clocks and represents a long-term frequency reference; the maser mean tracks the cesium mean because each maser is characterized against the cesium timescale before the maser mean is generated. The plot in Fig. 2 demonstrates a relative drift between the long-term reference and the two rubidium fountains measured to be $2.1(0.5)\times10^{-17}$/day.

While the comparison between NRF2 and NRF3 was limited to 100 days, NRF3 ran uninterrupted for a period of 6 months. Over this period of time, NRF3 served as an internal UTC predictor; because the Circular T provides UTC some number of days in the past, the present value of UTC needs to be estimated.

III. Fountain Ensemble

A. *Fountain Mean*

Recently a second pair of fountains, NRF4 and NRF5, has begun operation, and all four fountains have been running for about 2 months. One of the ways the rubidium fountains will be used for timekeeping is to characterize the frequencies and frequency drifts of individual masers, which is currently carried out with the cesium clocks. With four fountains running, a fountain mean is in the process of being implemented as part of standard timescale generation.

Fig. 3 shows the relative phase of a preliminary fountain mean over 60 days versus the maser mean, as well as the relative phase of the cesium mean and the maser mean. No relative frequencies have been removed, and the masers are characterized by the cesium mean in each case. The plot demonstrates the dramatic improvement in short-term noise of a timescale generated with only four fountains compared to that generated with dozens of commercial cesium clocks, which directly translates to improved efficiency with which the masers can be characterized, as well as the relative drift between the fountain mean and cesium mean.

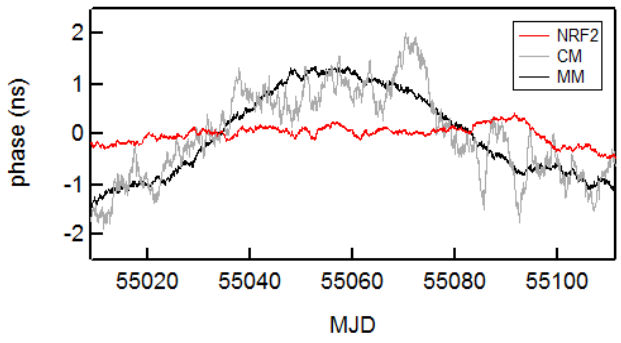

Figure 2 Relative phase of NRF3 and the cesium mean (grey), maser mean (black) and NRF2 (red), versus MJD. Each set of data has had its own relative phase and frequency removed. The NRF2 curve is the same data as in Fig. 1(a).

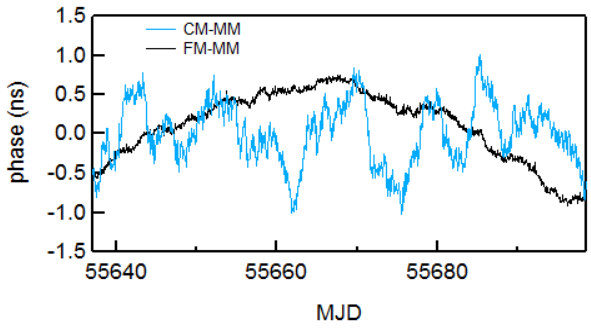

Figure 3 Plot of the relative phase of the fountain mean and the maser mean (black) and the cesium mean and the maser mean (blue) versus MJD.

B. *Relative Frequencies*

How well the frequencies of the four fountains agree is an interesting question. This is a question of the reproducibility of building and fielding these systems; in addition, the two pairs of fountains (NRF2 and NRF3 versus NRF4 and NRF5) have some different design elements.

The most significant potential source of frequency differences between fountains is the second-order Zeeman shift. The size of this shift is $575B^2$ (Hz/G^2). The fountains' magnetic fields are adjusted to be very close in value, to better than 1 μG, using the frequency of the central fringe of the magnetic field-sensitive $1\rightarrow1$ transition. Any error in determining this central fringe could lead to a frequency difference between fountains. The other most significant frequency biases, the black-body and gravitational shifts, should be common mode to a very high degree for the four systems. Other potential biases that could introduce frequency differences among the fountains are the cold-collision shift, cavity pulling, distributed cavity phase shift, and AC stark shift from stray laser light. The parameters determining these biases vary among some of the fountains.

Using data from the first 60 days when all of the fountains were running, the relative frequencies of all fountain pairs are measured. The results are shown in Fig. 4, where the error bars represent statistical uncertainties corresponding to the Allan deviation for a given comparison assuming white frequency noise. The raw frequencies (no biases adjusted for) all agree at the level of 10^{-15} or better.

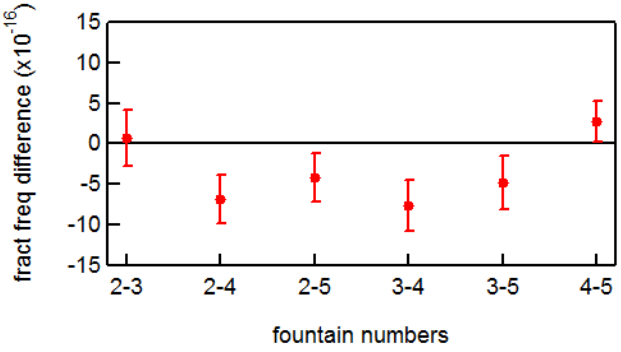

Figure 4 Fractional frequency difference between two fountains for all fountain pairs.

C. Frequencies Compared to Primary Standards

A rough measurement can be made of the fountain frequencies versus the frequencies of the primary standards used in determining International Atomic Time (TAI). The master clock is USNO's physical realization of UTC, which has the same frequency as TAI; a measurement of a fountain's frequency against the master clock, then, constitutes a measurement of the fountain compared to TAI. The frequency difference between TAI and the primary frequency standards is provided by the Circular T. The difference between these terms gives the frequency difference between a fountain and the primaries, which should correspond to the frequency bias of a given fountain.

We estimate the three most significant contributions to the frequency bias for a given fountain and remove them from the raw frequency difference between the fountain and the primaries. The results are shown in Table I. The values of the biases accounted for are -1.17×10^{-14} for the black-body shift for rubidium at T=295 K, 9.2×10^{-15} for the gravitational shift at an elevation of 84 m, and 6.97×10^{-14} for the second-order Zeeman shift at a bias field of 0.910 mG. In each case the uncertainty of the comparisons to the world's primary standards is dominated by the tie through TAI and UTC(USNO), which is estimated conservatively at 3×10^{-15}.

fountain number	Δv ($\times10^{-15}$)
NRF2	−.7
NRF3	−.8
NRF4	0
NRF5	−.3

Table I Average frequency difference between fountains and the primary frequency standards contributing to TAI after removing the frequency bias for each rubidium fountain.

D. Relative Frequency Drifts

The plot in Fig. 5 shows the measured relative frequency drift between all possible pairs of fountains over 60 days. All measured values are consistent with zero. The uncertainty is derived from the result in [2] for determining errors on frequency drifts in the presence of white frequency noise.

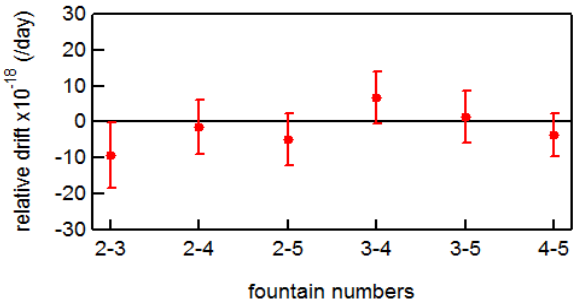

Figure 5 Plot of relative frequency drift for each pair of fountains.

IV. Scientific Application of Operational Fountains

Atomic clocks have found applications to fundamental science in addition to their roles in precise time and frequency metrology. According to current physical theories, which may need to be modified in order to arrive at a theory of quantum gravity, the relative frequencies of two atomic clocks using different atoms should be constant in both time and space. In particular, the principle of Local Position Invariance, an element of Einstein's Equivalence Principle, applied to atomic clocks dictates that the frequency difference between two different atomic clocks should stay constant as the clocks experience the same, varying gravitational potential. The varying gravitational potential that has been used to test this principle is provided by the elliptical orbit of the earth about the sun. This test therefore requires looking for an annual oscillation in the relative frequencies of two different types of atomic clocks.

The best test of this type to date has been carried out by comparing cesium primary frequency standards to hydrogen masers over the span of 7 years [3]. The discrete frequency measurements obtained with primary standards, typically several measurements per year, necessitates a long period of time to look for an annual variation. The authors of [3] relied on several primary standards to increase the rate of available measurements. Operation of a continuous fountain provides a high rate of frequency measurements against the reference maser (or other clock) that enables an annual variation to be searched for more efficiently. Estimates using a 6 month data set from NRF3 indicate that the statistical uncertainty achievable on a search for an annual term is comparable to the total uncertainty on the best current test of Local Position Invariance [3].

***Abstract*— We report measurements and *ab initio* calculations of the distributed cavity phase (DCP) shifts of the LNE-SYRTE FO2 atomic fountain clock. The measurements and validated model provide the first complete and quantitative evaluation of the DCP shift in an atomic fountain, reducing the FO2 DCP uncertainty to $\pm 8.4 \times 10^{-17}$. Here we emphasize the experimental techniques that precisely determine the fountain parameters to stringently test the DCP model.**

I. INTRODUCTION

The distributed cavity phase (DCP) shift is a first-order Doppler shift in atomic fountain clocks. The field in the microwave cavity used to interrogate the atomic transition is not a pure standing wave since the conductivity of cavity's copper walls is finite. Power flows from the feeds to the cavity walls, producing a small traveling wave and hence spatial variations of the phase of the field, the distributed cavity phase [1]. In a fountain, the atoms do not experience the same time-dependent phase variations on the two cavity traversals because of their transverse velocities, leading to this 1st order Doppler shift.

Our results demonstrating the first quantitative agreement between measurements and calculations of DCP shifts appear in [2]. In this paper, we do not repeat the results in [2] but instead present the supporting data that tightly constrain the fountain parameters, the position and velocity distributions of the atomic cloud, spatial variation of the atomic detection, and the truncation of the atomic cloud by apertures. We also illustrate the importance of using DCP shifts to balance the cavity feed amplitudes. This resolved a discrepancy in our first measurements. With the validated model, the DCP uncertainty of the SYRTE FO2 Cs fountain improves by a factor of 3.5, to $\pm 8.4 \times 10^{-17}$.

II. RABI OSCILLATIONS AS TEST OF THE MODEL FOR THE FOUNTAIN GEOMETRY

DCP shifts depend sensitively on a number of fountain parameters. Therefore, sufficiently stringent and independent confirmation of the parameters is helpful to critically validate the DCP calculations. We demonstrate that the Rabi flopping probability on the upward and downward fountain cavity traversals and the Ramsey contrast as a function of microwave amplitude provide sensitive and independent constraints.

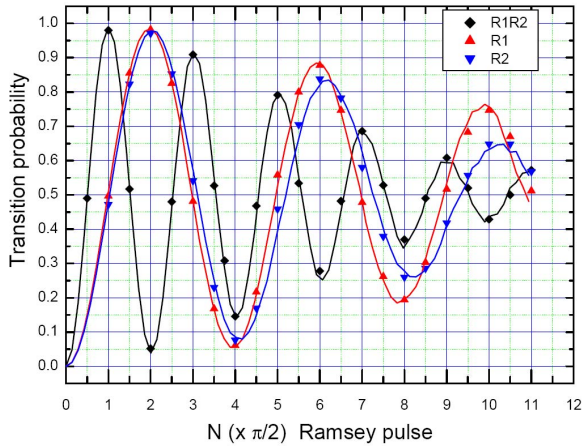

Figure 1. Comparisons between measured and predicted (curves) transition probabilities of resonant Ramsey pulses (R1R2) or a Rabi pulse on the upward (R1) and downward (R2) cavity traversals, as a function of the microwave amplitude, up to 11 $\pi/2$ pulses.

We begin with a knowledge of the fountain geometry and measurements of the initial atomic cloud size, position, and velocity distributions. A CCD image of the cloud, with a background of mechanical parts, and time of flight measurements are used. The detection response is determined by the detection laser beam power, spatial distribution, and detuning from the 852 nm atomic cycling transition, and a previous characterization of the spatial sensitivity of the fluorescence detection system. In Fig. 1 we show R1R2 in black, the usual Ramsey pulses, and then only Rabi pulses on the way up, R1 in red, and down, R2 in blue. For each of these, the microwave frequency is tuned to resonance. The points are measurements and the solid lines are from our model. The Ramsey R1R2 data essentially defines the amplitude scale, R1 measurements are most sensitive to the position distribution of the atoms during their upward passage, and R2 measurements probe the position distribution of the atoms during their downward passage, including the spatial inhomogeneities of the atomic detection. The excellent

This research was funded in part by CNRS, LNE, the NSF, and The Pennsylvania State University.

agreement is achieved with minor tuning of the detection curvature in one direction and the initial cloud transverse position. All other parameters in the model are the measured values. The contrast of these Rabi oscillations is very well reproduced for all three curves and, in particular, for the nominal clock operation (black point at 1 π/2) where our contrast is 0.985.

III. COMPARISON BETWEEN 2009 AND 2010 MEASUREMENTS OF THE M=0 DCP SHIFT

The importance of verifying the fountain parameters as in Fig. 1 became clear in our first measurements of the m=0 DCP shifts. The DCP calculation, with no tuning of parameters, reproduced the shape of the experimental data but with a clear discrepancy of a scale factor of about 1.5 [3]. We could find realistic values of the parameters to reproduce the m=0 DCP shifts, but these parameters were inconsistent with the Rabi flopping data in Fig. 1. Further work showed that there was a contamination of the m=0 shift by a residual m=1 shift due to feed asymmetries along with a small residual fountain tilt of about 200 µrad. We now balance the feeds by insuring that there are no frequency shifts at large tilts. Subsequent m=0 measurements with fountain tilts less than ±100µrad agree with the DCP calculations. In Fig. 2 the two data sets, before and after properly balancing the feeds (black and red squares) are plotted along with the simulations for the pure m=0 term with no free parameters (red curve) and a combined m=0 and m=1 with weights given by the known feed asymmetry and residual tilt (blue curve).

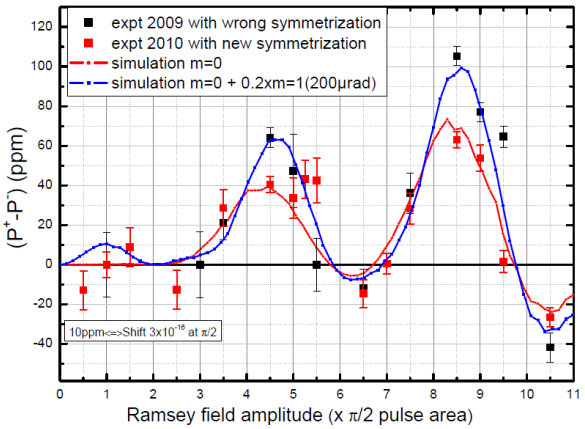

Figure 2. m=0 DCP shifts as a function of microwave power. The two data sets and calculations (curves) correspond to measurements with imbalanced feeds (black squares and blue curve) and with the feeds balanced to null the tilt sensitivity (red squares and curve).

***Abstract*— In this contribution we introduce a new approach for a piston temperature measurement system based on surface acoustic wave (SAW) resonators sensitive to temperature. The approach offers a new and competitive way to support the development of pistons and allows the research and improvement in combustion processes.**

I. INTRODUCTION

Piston temperature measurements face some major problems. The first measurements date back to the 1930s [1].They had been made on 12 inch bore diesel engines running at 250 rpm. One used sensors that were connected with cables to the measurement system. These cable led from the bottom of the piston over the moving crankshaft to the crankcase. The mechanical forces made the cables break, making long term measurements nearly impossible. A very commonly used method is based on active telemetric radio transmission. With the sender and receiver placed on the crankshaft. This approach also uses a wire connection between the piston, the transmitter and receiver unit with the threat of breaking wires. This measurement technique normally comes with a massive intervention in the engine parts.

Other measurement approaches are performed with mechanical linkage telemetry systems, where the sensor elements are connected directly to the data acquisition system with a metal arm with joints [2] as shown in Fig.1.

Further, the usage of metallurgical temperature sensors as shown on the leftside in Fig.1, often called as "Templugs", is a quite common approach [3]. Such sensors are made of steel alloys – serving as color indicators – which can be screwed or glued on parts that are exposed to temperature. The markers show an irreversible change in color depending on the temperature they are exposed to. The benefit of this temperature measurement approach is the easy handling and the low costs of the approach itself. Unfortunately, they can only serve as indicators for the maximum temperature they were exposed to without any further information of time of temperature gradients.

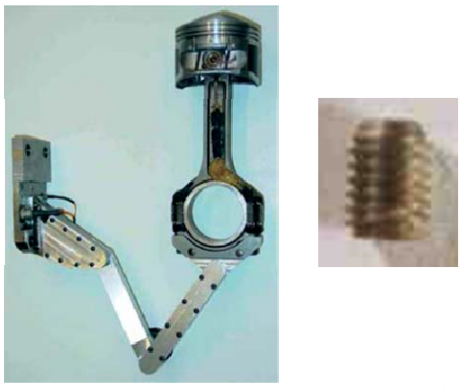

Fig. 1: Examples of piston temperature measurement approaches. *Leftside*: mechanical arm with joints. *Rightside:* metallurgical temperature sensor.

Regarding the requirements for measuring the temperature of a piston inside a running engine, surface acoustic wave temperature sensors seems to offer an easy to apply and low cost solution for an accurate validation of FEM simulated temperature profiles of pistons. Differential SAW resonators were used for achieving high accurate temperature measurements and minimizing effects like cross sensitivity due to acceleration, stress, frequency pulling or standing wave effects.

II. EXPERIMENTALS

A. Preparations before Testing

As first step to the measurement in the fired engine the optimal positions of the sensor and interrogation antenna with minor or no design changes to the engine were evaluated empirically. Therefore, sensor and antenna were mounted on potential positions and the signal link was evaluated by measuring the signal strength while turning the open engine manually until the optimal position for the

transmission with no design changes of the engine was found.
After having determined these optimal positions inside the engine, the piston and the crankcase were prepared for mounting the elements of the sensor system: SAW sensor, sensor and interrogation antenna to perform further reliability tests regarding the transmission on the open engine. Finally, a convenient signal strength up to a half stroke which resulted in an interrogation time slot of 10 ms at a speed of 2300 rpm was found.
The exact mounting was done as follows and shown in Fig.2. The machine parts were cleaned with acetone and isopropyl and an electric isolation layer for the sensor antenna was formed by an epoxy. On this layer the antenna and the cable to the SAW-sensor were screwed inside the piston and covered with the same epoxy suitable for high temperatures up to 300°C and resistant to engine fuels, oil and lubricants.
After tempering the glued piston in an oven with about 100°C over several hours, the piston was applied in the crankcase to verify the reception of the radio waves of the transceiver unit again.
The antenna in the crankcase was fixed with a hose clamp on the oil cooling injector. To support the cable with an additional protection it was placed in a small rigid pipe made of alumina.
To connect the antenna cable with the transceiver unit a hole in the crankcase was chosen that normally is used for the oil level gauge as shown in Fig. 4.

Fig. 2: Backside view of the prepared piston from the bottom of the oil pan. 1: transceiver antenna fixed to the oil cooling injector, a non moving part of the crankcase; 2: mounted sensor antenna inside on the bottom of the piston; 3: oil injector nozzle; 4: mounted SAW temperature sensor type TSEAS10 by SENSeOR; 5: Crankshaft.

The moving parts of an engine face beside the high temperature stress also forces cased by rough accelerations. Although the test engines are diesel engines that are typically used in heavy duty off-road applications that are operated at relatively low rotation speeds compared to spark ignited combustion engines that are used in passenger cars. The movement path of a typical piston in an typical consumer application sums up to 580 km operated at a speed of 1800 rpm for 24 hours [4].
The range of rotation speeds of interest were between 800 rpm and 2300 rpm. Within these ranges, a piston is exposed to rough acceleration values of approximately 400 g as shown in Fig. 3.

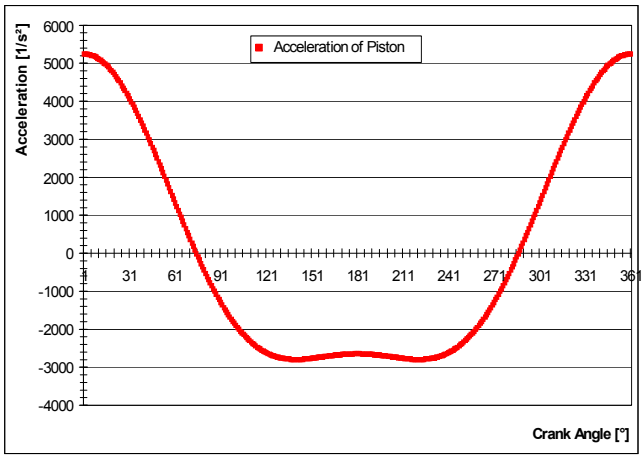

Fig.3: Acceleration about rotation angle

B. *Engine Test Set-Up*

Before the first run with the applied piston the transmission quality of the signal was tested with the mounted oil pan. No interferences were found with that setting.
These tests were repeated after installing the engine on the test cell (Fig. 4). Again the engine was turned by hand for safety reasons.

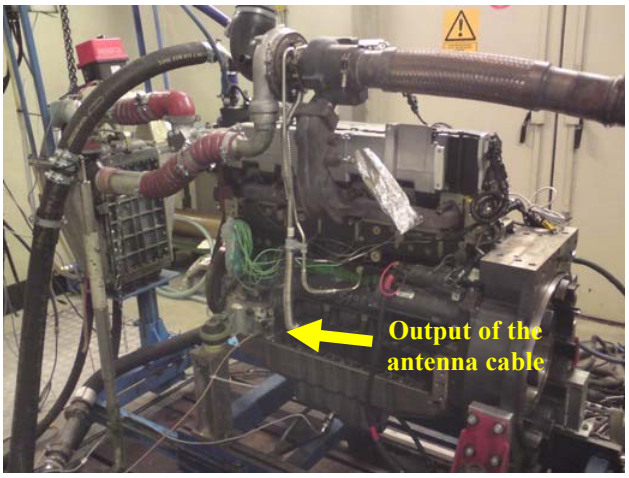

Fig.4: Engine TCD 7.8 in test cell before running.

C. *Engine Test Run*

The engine was fired and ran at 800 rpm. After a couple of minutes while reaching the optimal engine run conditions, the engine speed was changed to 900 rpm. The signal-strength was checked again to control the influence of oil dust. The risk of dumping the signal strength with the

increasing amount of oil dust was not observed and therefore the dust had no effects on the transmission of the radio waves and the measurements itself.
The engine speed was changed again after one could expect that the engine was in a stable work point. This implied that one did not expect significant temperature changes. Also the signal seemed to be stable enough to get a result for the temperature. The steps that were chosen for the engine speed change had been 100 rpm higher up to 2290 rpm as shown in Fig.8.
Occasionally the signal had to be optimized by changing the engine speed slightly for avoiding standing wave effects.
For all speed steps no load was put on the engine for this first run due to safety reasons.
After the test run the piston was removed of the engine and the screwed and glued antenna and the SAW-sensor were analyzed for damages or any relieves of the glue. The used adhesive component was robust enough to resist within the harsh environment inside a running and no damages of the sensor or the antenna was observed.

D. Signal Processing Strategies

Experimental data demonstrate that both resonances are rarely identified simultaneously as shown in Fig. 5 and Fig. 7. The differential measurement strategy is based on the principle that both a reference resonator with little temperature drift, and a measurement resonator with a strong temperature drift, patterned on a common piezoelectric substrate, are affected in a similar way by environmental disturbances (sensor aging, stress, radiofrequency parasitic components), and hence a frequency difference provides the needed long term stability and accuracy, independent of environmental conditions and interrogation unit aging.

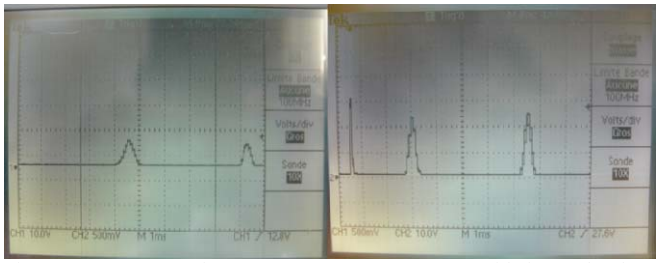

Fig. 5: Raw returned RF power measurement provided on the low frequency output of the reader. *Leftside*: the minimum acceptable signal level. *Rightside*: acceptable quality signal level. The output power is controlled using a proportional feedback loop in order to keep the returned power at the optimum level.

However, because the refresh rate is higher than several hertz, the reference and measurement frequencies are not needed during a same frequency sweep: measurements recorded during successive frequency sweeps are still close enough to validate the differential measurement strategy.
Hence, in order to increase the probability of a useful measurement despite the poor radiofrequency link budget, the last useful frequency measurement (either reference f_{ref} or measurement f_{mes}) were propagated to all successive unsuccessful measurement attempts. Nevertheless all frequency sweeps for which neither reference nor measurements frequencies were visible, were rejected.
Thanks to this strategy, a useful dataset has been gathered exhibiting a meaningful temperature evolution trend. The conversion from a frequency difference $\Delta f = f_{ref} - f_{mes}$ to a temperature requires the application of calibration coefficients individually identified during a preliminary calibration step. Indeed, based on a second order polynomial fit of the frequency f dependence with temperature T, the function

$$\frac{f_0 - f}{f_0} = CTF_1 \times (T - T_0) + CTF_2 \times (T - T_0)^2$$

classically used in the literature, with f_0 the frequency at reference temperature T_0 and CTF_1, CTF_2 the first order Coefficient of Temperature and second order Coefficient of Temperature respectively, a temperature dependence law was deduced as a function of frequency difference Δf following $T = A_0 + \sqrt{A_1 + A_2 \times \Delta f}$.
In the case of the sensor used during these experiments, A_0 (°C) = 109.6, A_1 (°C^2) = -118553 and A_2 (°C^2/Hz) = -0.1284. The calibration coefficients are classically identified in the -20 to +160°C range.
The application of calibration coefficients to the raw measurements of a sensor located in a piston, associated to the in-plane monopole antenna (35 mm interrogation range), yields the temperature measurement exhibited in Fig. 6.

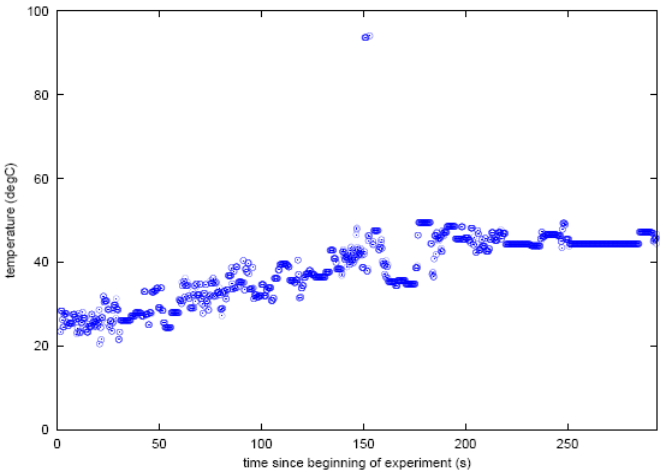

Fig. 6: Measurement of the temperature of a sensor located in the piston of an engine running from 800 to 2290 RPM. The frequency difference was converted to a temperature using calibration coefficients established prior to the experiment. Outlying points were filtered automatically.

This dataset was cleaned by removing the points below 433.3 MHz and above 433.7 MHz for the measurement resonance, and below 434.1 and above 434.44 MHz for the reference resonance. As seen in another measurement set (Fig. 7), obtained in the same rotation speed conditions and with the same antenna, these outlying points yield significant measurement dispersion. Our current

understanding of the source of these unwanted points is associated with the automatic gain control on the emitted power since the sensor is not seen by the interrogation antenna most of the time; the emitted power is maximum (+10 dBm). If the sensor happens to come close to the interrogation antenna – within reception range – while the emitted frequency is close to the resonance, then the received signal might appear as a local maximum even though it is not the global maximum of the resonance. This effect will be strongly reduced by extending the interrogation range (asymmetric dipole antenna), which will help the automatic gain control to remain locked most of the interrogation time, but most significantly also means that the unwanted points will remain far from the main measurement curve (since close the resonance, locking on a side-lobe has a low probability considering the frequency sweep rate compared to the duration the sensor is seen by the interrogation unit). Hence, a digital post-processing step will always easily remove these unwanted data.

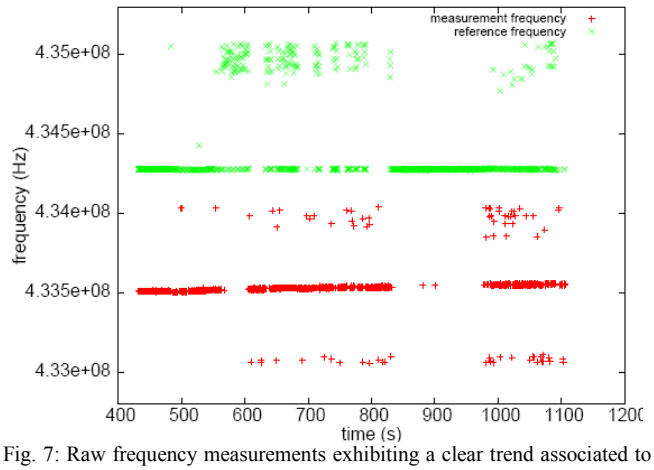

Fig. 7: Raw frequency measurements exhibiting a clear trend associated to the measurement (measurement frequency around 433.5 MHz, reference frequency around 434.2 MHz) and outlying points widely scattered above and below the actual measurement.

III. Results and Discussion

The temperature was calculated of the measured frequency values. The measurement showed frequency values which seemed to be induced by reflections of the signal.

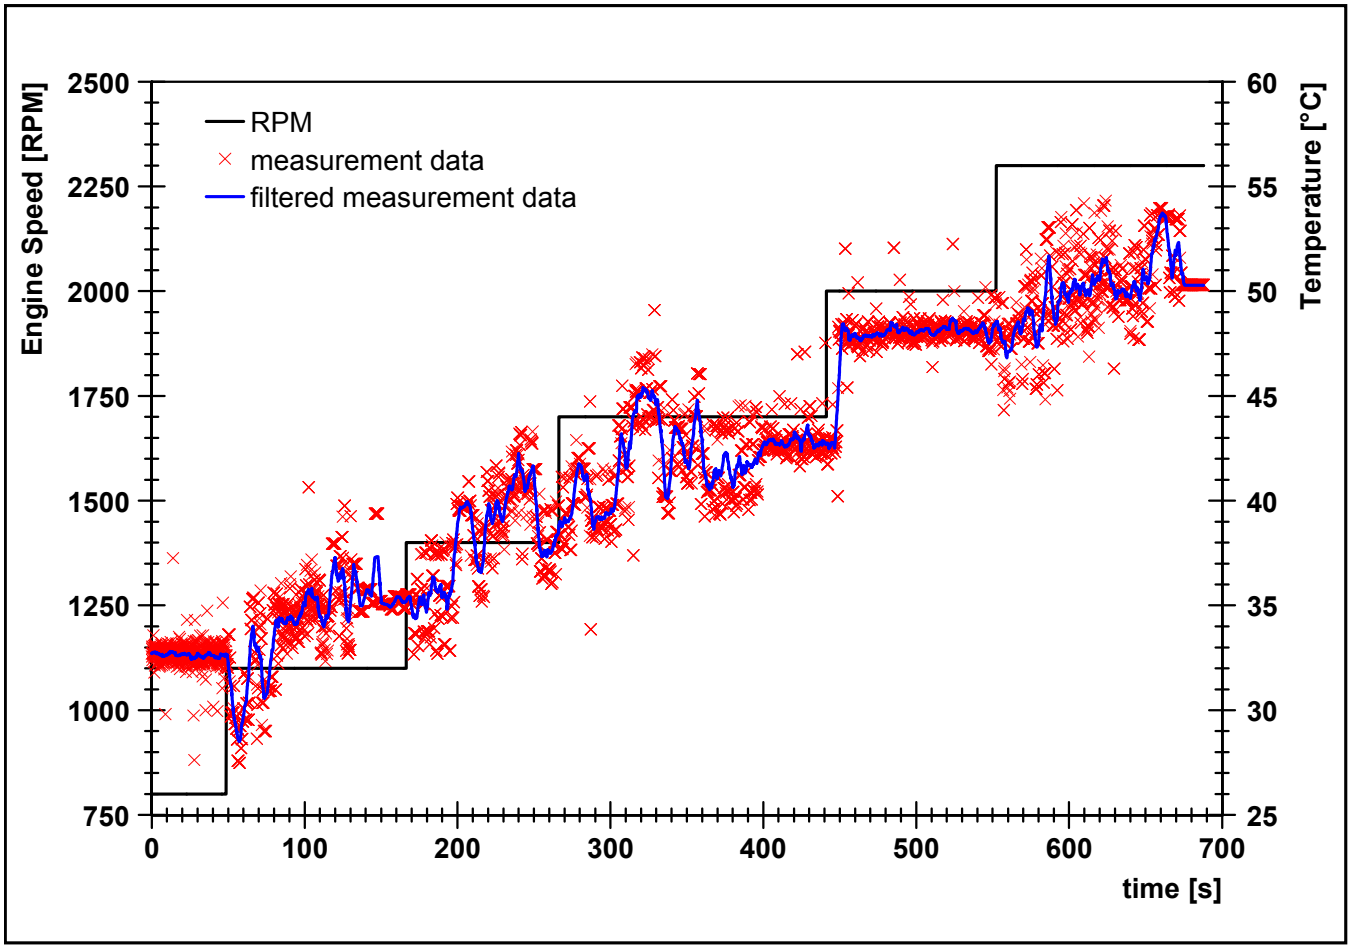

Fig.8: Measured and filtered temperature values in relation with the recorded engine speed during a test run.

After processing these data as described above, the temperature value at the piston could be determined as shown in dependency of the engine speed in (Fig. 8).

These first terms provide encouraging results since usable resonance frequency signals were obtained even with a poor interrogation range. Various antenna configurations have been identified which allow for an extended interrogation range, potentially up to the full displacement of the piston (yielding a continuous view of the sensor by the interrogation antenna). Further sensitive parameters have been identified during the tests on the site and have not necessarily been optimized yet. The signal processing steps to provide a consistent temperature reading were applied to the recorded signal successfully. As further steps, using an optimized antenna configuration and locating the sensor close to the final position appear as reasonable milestones, to be extended with the inclusion of multiple sensors which require an extended frequency interrogation range since each resonance occupies a different 900 kHz-wide frequency slot beyond the ISM range.

Therefore a new approach of a new and competitive way to support the development of pistons that allows the research and improvement in combustion processes had been identified. Successful tests with engine running at 800 rpm up to 2300 rpm had been demonstrated where SAW sensors able to withstand accelerations as high as 400 g inside running engines with an interrogation time of 10 ms.

***Abstract* — Surface acoustic wave (SAW) gas sensors generally require the use of a reactive layer for molecule adsorption. WO_3 has been identified for a long time as a high potential sensitive layer particularly for NH_3, NO_X, CO, etc. We report here on the characterization of elastic properties of such material using the dispersion behavior of SAW propagating under gratings passivated wich WO_3 films of various thicknesses. Quartz as well as $LiNbO_3$ SAW devices are used in that purpose, allowing for the derivation of a reliable data set. Complementary structural characterization using direct measurement techniques (DRX, AFM, TEM,) are reported to confirm the analysis deduced from SAW measurements. As a conclusion, the exploitation of WO_3 for SAW-based sensor is discussed.**

I. INTRODUCTION

Surface Acoustic Wave (SAW) sensors are presently receiving an increasing interest, although many works has been dedicated to operate to such developments. A particular effort is paid to develop devices capable to detect gas flows in common environment for health protection or security purposes. The arising of new materials and technologies actually pushes to re-investigate the capability of such devices to efficiently operate, particularly in harsh environment such as toxic atmospheres and high temperature. Hence, the possibility to remotely interrogate gas sensors based on resonator structures can be actually implemented and tested. In this work, we propose to characterize the operation of SAW resonator sensors coated with tungsten trioxide (WO_3), a layer which exhibits selective detection capabilities when heated near 350°C. The exploited principle consists in the change of dielectric properties of the film when adsorbing specific molecules (O_3, NO_2, NH_3 and ethanol). The design of such sensors requires the knowledge of the actual properties of the detection film as it is directly deposited atop the resonator electrodes, yielding modal dispersion which must be accounted for to guaranty the device operation according given requirements (such as those imposed by wireless interrogation in ISM bands). In that purpose, test devices have been fabricated, based AT Quartz and (YX*l*)/128° $LiNbO_3$ synchronous resonators operating near the 434-MHz-centered ISM band, coated with various WO_3 thicknesses (100, 200 and 300 nm). These thins films were characterized using X-ray diffraction/Rietveld refinement and the samples morphology were analyzed by Atomic Force and transmission electron microscopy. The diffract pattern showed the monophasic layers with the same crystallinity and they reveal a pseudo cubic phase (isotropic behaviour). We then have measured the reflection coefficient of the resonators allowing for fitting the coating elastic properties by model updating. This fit has been first achieved using quartz resonators and we have obtained the fitted coefficients (apparent elastic constants C_{11}, C_{12}, C_{44} and mass density ρ). They have been used to predict the coating-induced frequency shift on lithium niobate resonators. Although mass density is found to change dramatically versus WO_3 thickness (from 6500 to 3900 $kg.m^{-3}$), the elastic constants reveal more stable (C_{11} and C_{44} typically equal to 15, 8 and 2.5 GPa respectively). The max coating thickness actually is found near 300 nm, but it turns out that above 200 nm, the resonator response is too degraded to allow for any operation. A specific design then is proposed on $LiNbO_3$ for assessing the actual operation of the sensor.

In the first section of the paper, we report a direct analysis of the deposited material also has been achieved to complement and justify effective data derived using SAW–based measurements. Next, we briefly describe WO_3 coating properties, with a particular insight in physical parameter changes related to gas adsorption and the subsequent SAW-sensor application. As such devices need accurate design procedure to optimize their actual operation; the characterization of WO_3 elastic properties was a prerequisite and therefore the experimental measurements of the corresponding physical coefficients then is reported.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

Finally, exploitation of the corresponding results using $LiNbO_3$ SAW resonators is discussed.

II. WO_3 THIN FILM PROPERTIES FOR GAS DETECTION

The structural configuration of the WO_3 crystal lattice is the distorted rhenium trioxide (ReO_3) structure [1,2]. The crystal structure of tungsten trioxide is temperature dependent. The most common structure of WO_3 is monoclinic (P21/*n*). Based on the reversible changes in conductivity, WO_3 thin films have been used as sensitive layers towards O_3, NH_3, NO_x, CO, ethanol [3,4]. It was shown that the conductivity of WO_3 thin films changed in presence of NO_x gas with a dependence of temperature. At 375°C the resistance of WO_3 drop by a factor of 100 compared to its initial value at room temperature from 6.10^9 to 6.10^7 ohms respectively [5]. This behaviour can be explained by physisorptions and chemisorptions mechanisms and catalytic reactions between gases and material surface (phenomenon of adsorption and desorption) [6]. Due to its electrical properties, WO_3 is an ideal candidate for applications SAW gas sensors. Indeed, the interaction between gases molecules and tungsten trioxide causes a change in conductivity of thins films WO_3 resulting from in a variation of the velocity and propagation loss of the acoustic wave. By measuring the change in the frequency characteristics of the SAW sensor, it was possible to determinate different physical parameters of the sensitive layer WO_3 and sees the influence of the viscoelastic layer on the SAW device (dielectric loss, mass effect) [7,8]. To achieve this, it is imperative to have strong knowledge in the field of piezoelectricity and acoustic.

III. STRUCTURAL CHARACTERIZATION

A. Experimental

WO_3 thin films on the surface of a quartz substrate for SAW devices were prepared by reactive radio frequency magnetron sputtering at 13.56 MHz, using a 99.9% pure tungsten target. The synthesis setup and standard procedure have been described in more detail by previous work of the lab [6]. The obtained films were annealed at 400°C for 3 hours.

B. Characterization and results

The morphological analyses of WO_3 thin films were conducted by Atomic Force (AFM) and Transmission Microscopy (TEM, Philips TECNAI F20 FEG).

The structure properties of WO_3 films were determined by X-ray diffraction with Cu.Kα radiation (Siemens – Brucker D5000 diffractometer). X-ray patterns were compared with those of the Joint Committee on Powder Diffraction Standards (JCPDS). The DBWS Tools 2.16 software was used to perform Rietveld Refinement. Figure 1.a shown the state surface of the deposited WO_3 films on quartz substrates and reveals a weak roughness and a porous surface. This porosity varies from 10 nm to 100 nm and they extended in deep layers. The TEM image (fig 1.b) shows a cross section of the oxide layer deposited on Si substrate reference. For all studied thicknesses of WO_3: 50, 100, 200 and 300 nm, all films were homogenous.

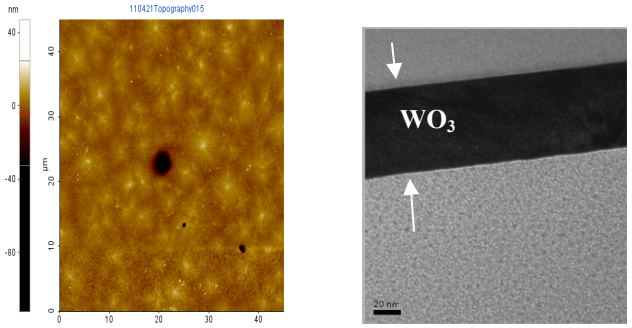

Figure 1. a) AFM image of WO_3 films on quartz substrate after annealing at 400°C for 3 hours; b) TEM cross section of WO_3 thin film thickness of 50 nm on Si substrate

The X-ray diffraction patterns and Rietveld refinement of trioxide tungsten are in good agreement (figure 2) showing a low crystallite size in accordance with TEM observation.

The XRD diagram show a polycrystalline structure identified as monoclinic phase and indexed from standard data sheet. The observed structural parameters are in good agreement with JCPDS (No. 83-0950) data [9].

From Rietveld refinement results, it is proved that WO_3 thin films have a monoclinic phase close to cubic one. The evaluated lattice parameter values of WO_3 are $a = 7.308$ Å, $b = 7.514$ Å, $c = 7.675$ Å, $\alpha = \gamma = 90°$, and $\beta = 90,632°$. This allows to hypothesize that WO_3 films behave as an isotropic system. All deposited layers (50 to 400 nm) were structured in the same phase and the calculated parameters remain unchanged.

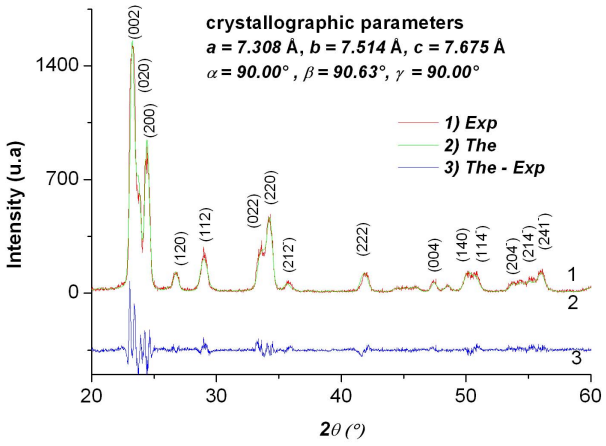

Figure 2. X-ray diffractogram (1.Exp) and theory Rietveld refinement (2.The) of WO_3 thin films with a thickness of 50 nm

IV. WO_3 Elastic constants characterization

In this section, the theoretical and experimental protocols for characterizing the WO_3 overlay properties are described, using Quartz SAW resonators (fig.3). The quality of the obtained physical paremeters is the assessed for $LiNbO_3$ (YZ) devices better suited for dielectric perturabtion detections.

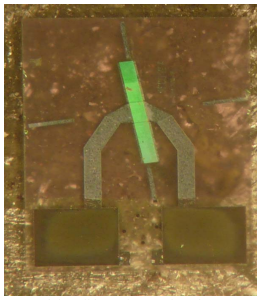

Figure 3. WO_3 thin film deposited on SAW devices

A. *Theoretical analysis*

As layered devices are concerned, with the WO_3 overlay covering the electrodes, one cannot make the economy for advanced simulation and analysis exploiting a combination of finite element and boundary element methods (FEM/BEM) developed in that purpose [10]. We here briefly recall the analysis approach, detailed description of the calculation fundamentals are reported in [11]. An harmonic admittance is derived from FEM computation of a single period of an infinitely long periodic transducer accounting for the inhomogeneous boundary conditions induced by the electrode/passivation surface conditioning. The acoustic contribution of the substrate is accounted for by Green's function based BEM. For an accurate simulation of the device behavior, one need a reliable set of physical constants, i.e. elasticity coefficients, mass density and dielectric parameters and associated intrinsic losses if available. Although some data can be found in the literature, providing a starting point for the simulation, a set of experiments has been achieved on SAW resonators of fig.1 built on a (ST,X+ψ) cut with ψ a small non zero propagation angle, therefore providing clear contributions at both edges of the stop-band and hence a direct evaluation of the reflection coefficient magnitude. This will be used for improving the theory/experiment agreement and consequently the accuracy of the above-mentioned constant determination.

B. *Experimental implementation*

As explained above, SAW resonators built on Quartz have been used first to determine the WO_3 overlay properties required for sign and analysis purposes. The asynchronous single-port resonators implemented in that purpose consist of one interdigited transducer (IDT) surrounded by two Bragg mirrors. They have been designed to operate at best in the 434-MHz centered ISM band. The IDT is composed of 82 Al electrode pairs with a mechanical period p of 3.627 µm and a metallisation ratio a/p of 0.8 to benefit for the reflection coefficient stabilitiy versus electrode width a. As suggested above, the mirror period differs from the IDT one, being fixed to 3.646 µm (same metallisation ratio) to force the resonance within the stopband of the mirrors and hence increasing their reflecvtion efficiency. The metal height h is 120 nm ($h/\lambda_{a\,c} \sim 1.5\%$). The acoustic apperture is 320µm (40 λ_{ac}) to avoid any possible diffraction effect. These devices have been then covered with WO_3 overlays of different thicknesses (50, 100, 200, 300 and 400 nm) to achieve the characterization discussed in the previous paragraph. Figure 4 shows the corresponding experimental electrical admittances compared with theoretical harmonic admittances derived with FEM/BEM. For each configuration, a set of material constants has been fitted to achieve the maximum agreement between both curves, reported in Table I. As one can easily see, the acoustic dissipation increases along the WO_3 thickness in such a way that above a 300 nm thick deposition, the experimental signal was no more exploitable (fig.5). Also the viscoelastic losses of the overlay has been fitted according to experimental observations, yielding an equivalent mechanical quality factor of 50 whatever was the WO_3 thickness.

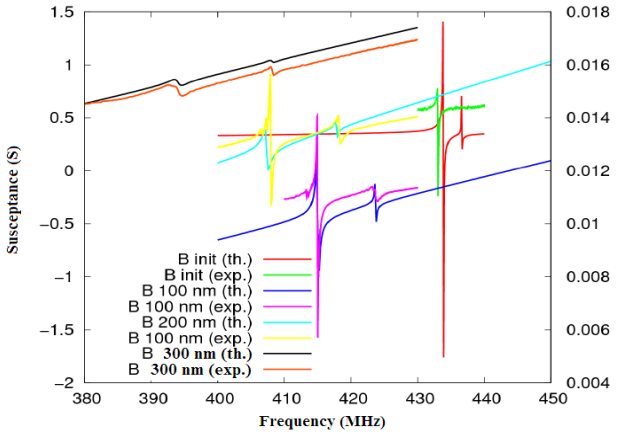

Figure 4. Theory/experiment assessment of SAW resonators on AT-Quartz cut for different WO_3 overlay thickness

In all the simulations, a relative dielectric constant of 230 has been fixed according to published material [12]. As shown by Table I, the mass density was changed along the WO_3 thickness for best fit purposes. Although one could also change the elastic constants in that matter, the reflection coefficient gave helpfull tracks for the fitting strategy, as it strongly depends on the combination of all the elastic constants. One could imagine keeping the mass density unchanged versus WO_3 thickness but the ratio between the elastic constants would then be kept unchanged. From a structural point of view, the film is assumed polycristalline and porous. This porosity vary with the deposition thickness. Within each grain, the elasticity behaviour is not changed but the overall of the layer actually reduces along the deposition height.

Materials	AT Quartz			(YX*l*)/128° $LiNbO_3$		
Physicals properties	***100nm***	***200nm***	***300nm***	***100nm***	***200nm***	***300nm***
Density ρ ($kg.m^{-3}$)	6500	4700	3900	6500	4700	3900
C_{11} (GPa)	14	15	12.5	14	15	15
C_{12} (GPa)	8	8	7	8	8	8
C_{44} (GPa)	2.5	2.5	2.5	2.5	2.5	2.5

Table I .Apparent elastic constants and density of the WO_3 versus overlay thickness. The initial value of the density was fixed to 7200 $kg.m^{-3}$ according to the literature and adjusted versus thickness for best fit purposes.

C. *Validation on $LiNbO_3$ SAW resonators*

The previous section has shown the way the physical parameters of the WO_3 overlay, more specifically the elastic constants and mass density, has been fitted. To confirm the reliability of these data, another set of experiments has been achieved using SAW resonators built on (YZ) $LiNbO_3$ cut with similar WO_3 deposition conditions and thickness (fig 3). As for Quartz resonators, a FEM/BEM analysis then was conducted using the fitted parameters to assess the experimental results. Figure 4 shows the corresponding experimental admittances compared with theory. For best fit purposes, slight changes have been applied to the elastic parameters but the overall behaviour of the device responses was well predicted using Quartz-resonator-derived data, yielding confidence in their physical meaning. Particularly, the frequency shift related to mass loading was found in good agreement here again and therefore, the above-proposed hypothesis concerning the porous surface and weak roughness was not infirmed. From a pragmatical point of view, these results show that the fitted apparent elastic constants and mass density can be used for the design of a next generation of sensors. This work is currently under development.

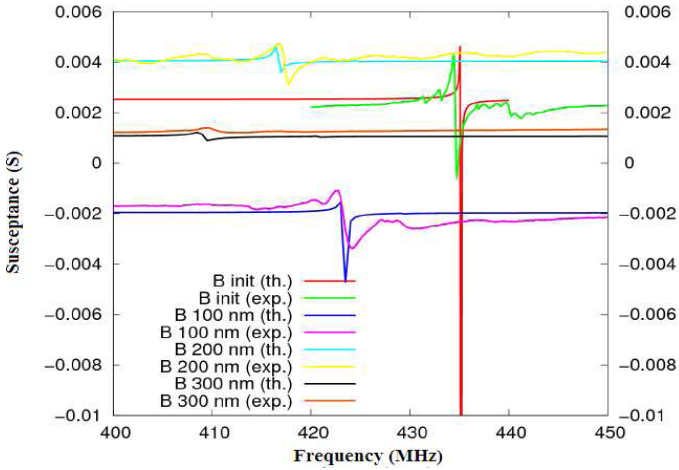

Figure 5. Theory/experiment assessment of SAW resonators on (YX*l*)/128° $LiNbO_3$ for same WO_3 overlay thickness

V. CONCLUSION

In this work, we investigated the design and the physical properties of WO_3 using SAW devices as a mean of characterzation. A pseudo cubic as isotropic system was identified for WO_3 sensitive films via structurals analysis. The measured reflection coefficient allowed to estimate the elastic properties and induced frequency shift on quartz/lithium niobate resonators as a function of the WO_3 layers thickness. Although mass density is found to change as a function of WO_3 thickness and their porosity, the apparent elastic constants reveal more stable. The max coating thickness actually is found near 300 nm, but it turns out that above 200 nm, the resonator response is too degraded to allow for any operation.

***Abstract*—We report here a langasite SAW device suitable for sensing temperature and oxygen concentration, with applications such as monitoring the exhaust of oxy-fuel combustion systems. In this paper we report on the observed temperature dependence of oxygen sensitivity, explain the mechanism for this behavior, and present a scheme for temperature compensation.**

I. Introduction

Langasite ($La_3Ga_5SiO_{14}$) surface acoustic wave (SAW) devices have potential applications in harsh-environment sensing. Important applications include exhaust gas oxygen sensors for the control of oxy-fuel combustion systems. In such combustors it is possible to achieve a nearly pure carbon dioxide exhaust suitable for geologic sequestration. In this application oxygen sensing in the temperature range from 500 to 1000 ºC is needed. Langasite SAW devices have been operated as resonators up to 1000 ºC [1]; langasite SAW sensors for H_2 and C_2H_2 gas have been operated up to 550 °C [2]; and wireless temperature sensing has been demonstrated up to 850 °C [3,4]. Here we report recent results obtained for langasite SAW oxygen sensors. We particularly focus on the temperature dependence of these sensors, and a method for reducing the impact of temperature flucuations on gas sensing.

II. Temperature and Gas Sensing

The SAW sensors considered here utilitze the electroacoustic effect, where a conducting layer near the piezoelectric surface influences the surface wave velocity. Gas sensing is achieved by using a layer with a conductivity that depends on the gas concentration. The most suitable conducting layers for this high-temperature application are metal oxides, which exhibit a semi-conducting behavior with conductivity dependent on the oxygen defect concentration. In metal oxides with predominant electron conduction, a reversible reaction occurs with gas-phase oxygen of the form

$$O_o^x \leftrightarrow V_{\ddot{o}} + 2e' + \tfrac{1}{2}O_2^{(g)} \qquad (1)$$

where O_o^x is the concentration of oxygen atoms on an oxygen site, $V_{\ddot{o}}$ is the concentration of doubly-negative oxygen vacancies, e' is an electron, and $O_2^{(g)}$ is an oxygen molecule in the gas phase. Higher oxygen partial pressure in the gas phase drives the reaction to the right, decreasing electron concentration and increasing the electrical conductivity. It can be shown that the conductivity is given by

$$\sigma = Ae^{-E_A/kT}P_{o_2}^{1/m} \qquad (2)$$

where E_A is the activation energy for conduction, kT is the thermal energy, and P_{O_2} is the oxygen partial pressure. Increasing conductivity of the sensing layer decreases the surface wave velocity, as the redistribution of charge in the sensing layer reduces the stored energy in the electic field above the surface, reducing the piezoelectric stiffening. The change in velocity can be predicted analytically; Figure 1 shows the calculated change of surface velocity for a (0, 138.5, 26.6) langasite SAW device.

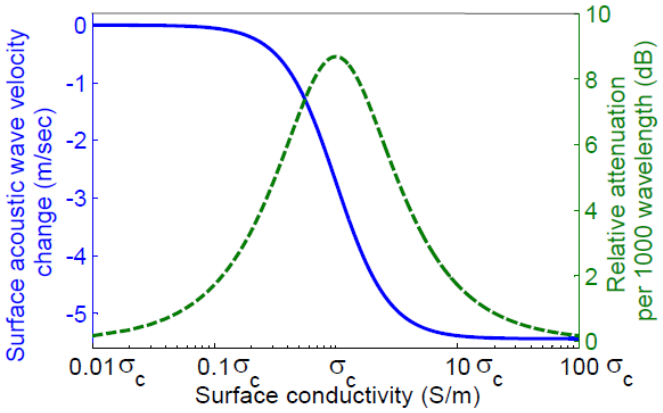

Figure 1. Calculated surface acoustic wave velocity changes (solid blue line) and relative attenuation (green dashed line) of langasite substrate with Euler angle (0, 138.5, 26.6) as a function of surface sensing film conductivity.

It is apparent from Figure 1 that significant velocity changes are only obtained for a limited range of sensing layer conductivity. As the conductivity is thermally activated according to (1), a particular sensing layer will have a limited temperature range where it exhibits useful response. Further, changes in temperature will also cause a change in surface wave velocity. We focus here are removing the impact of

small temperature changes on the surface wave velocity. We will also determine the temperature range over which on particular sensing layer is useful. In a practical sensor, the temperature and oxygen concentration need to be measured independently; this will be addressed in future work.

III. EXPERIMENTAL

SAW devices used in this work were fabricated on 76 mm diameter, 0.5 mm thick langasite wafers (Roditi International, UK) with Euler angles (0, 138.5, 27) using a lift-off technique. The metallization was e-beam deposited and consisted of 100 nm platinum with 10 nm titanium as an adhesion layer.

The SAW devices used in this work have the transmitter located in the center with open reflectors were located on two sides. The IDTs had 2 µm finger widths and gaps, yielding an 8 µm surface acoustic wavelength and a center frequency of 334 MHz at room temperature. For gas sensing, A 200 nm ZnO sensing film was deposited by reactive RF sputtering from a Zn target at a pressure of 4 mT and RF power 50 W, in 25% O_2/ 75% Ar. ZnO was masked from the IDT terminals using Mylar tape. The SAW device was then spin coated with polysiloxanes (IC1-200 and DC4-500 from Futurrex, Inc.). The polysiloxanes film was partially removed using a cotton tip with acetone and then annealed in air at 400 °C for 30 min to form a 100 nm SiO_2 insulating film on the IDT transmitter and terminals region.

XRD characterization of the sputtered ZnO film showed a wurtzite structure with a 30 nm grain size. In some experiments temperature sensing was performed at the same time using a second SAW device with longer path lengths, so that its reflections were not coincident with the first reflections of the gas-sensing device.

The SAW device(s) were placed in a furnace (Lindberg STF55433C) with computer-controlled gas flows. Connection to the measuring electronics was made using shielded thermocouple wire as a transmission line, connected to the SAW device using fine thermocouple wire and conductive ceramic paste. Measuring electronics consisting of a National Instruments (NI PXI-5670) and a vector signal analyzer (NI PXI 5661) [5] was used to measure the phase changes resulting from temperature and/ or gas concentration changes. Measurement of the phase changes requires a reference pulse; this reference pulse consisted of either another SAW reflection or the attenuated exciting pulse.

We first discuss separate measurements of temperature and gas concentration. Figure 2 shows the extracted effective velocity change as a function of temperature. The velocity decreases monotonically with temperature, consistent with previous reports [4,6,7].

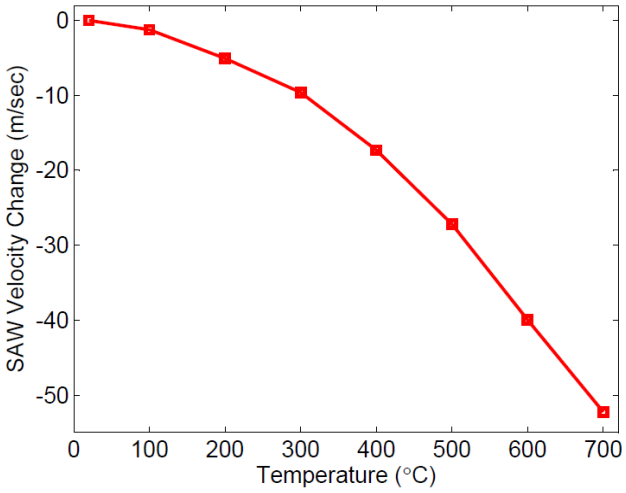

Figure 2. Extracted effective SAW velosity change as a function of temperature.

The effect of oxygen concentration was examined by measuring the phase change between \the exciting pulse and a reflection normalized for a 1 µs propagation time. The oxygen concentration was changed in a stepwise fashion with the balance of the gas being nitrogen. The oxygen concentration was varied by changing the mass flow controller setpoints while keeping the total mass flow constant. Figure 3 shows the results for three temperatures, where the phase changes consistent with *n* type conduction in the ZnO. While the phase changes are consistent with velocity changes due to the electroacoustic effect, they could also be caused by temperature variations in the furnace due to imbalanced gas flow. This is a particular concern at lower temperatures where the observed phase changes are small.

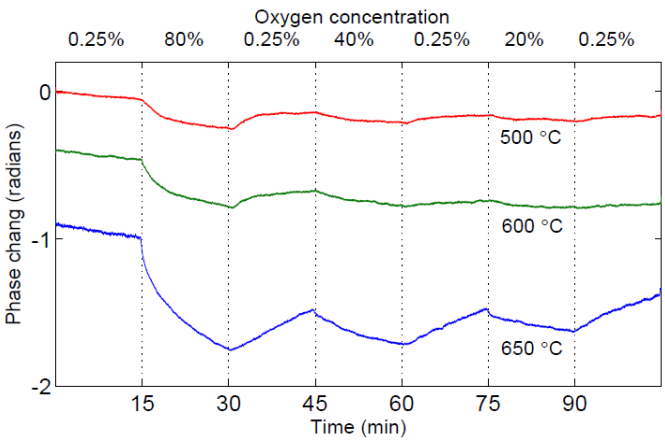

Figure 3. Phase change resulting from changes in the oxygen concentration.

The influence of small temperature variations can be removed by simultaneously measuring SAW reflections on two propagation paths, one with and one without without a ZnO sensing layer. This can be achieved by patterning the sensing layer so that some reflections are not influenced by the change in sensing layer resistivity. Alternatively, two separate SAW devices can be connected in parallel, one with and one without a ZnO sensing layer (Figure 4). In this case the SAW

devices must be different so that the reflections are distinguisable.

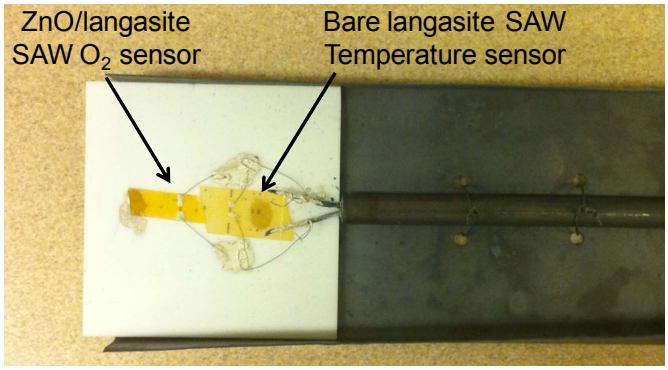

Figure 4. Two langasite SAW devices connected in parallel, one with and one without a ZnO sensing layer.

Figure 5 shows the observed reflections for two SAW devices connected in parallel at room temperature. Here the second series of reflections are from the temperature-sensing SAW device without a ZnO sensing layer. These reflections are strongest despite the longer path length; this is because the ZnO sensing layer causes additional attenuation [5].

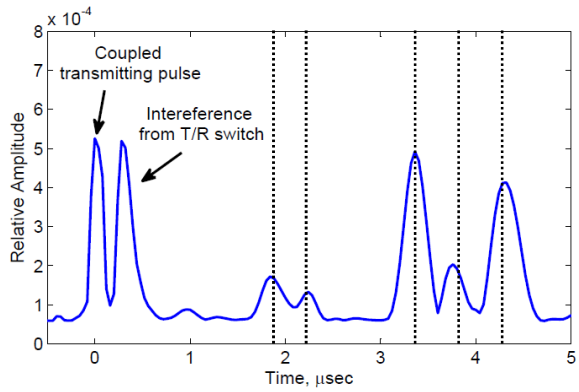

Figure 5. Reflections for two SAW devices wired in parallel at room temperature.

Figure 6 shows uncorrected phase measurements for the oxygen and temperature sensors (top two traces) and measurements compensated for temperature variations (bottom trace) at 650 ºC. Temperature compensation is achieved by subtracting the gas and temperature phase change measurements normalized for the propagation time. The data from the temperature sensor shows small perturbations (± 0.5 ºC) due to the gas flow switching. Removing these small perturbations shows that most of the phase change of the O_2 sensor was indeed resulting from the gas sensing layer.

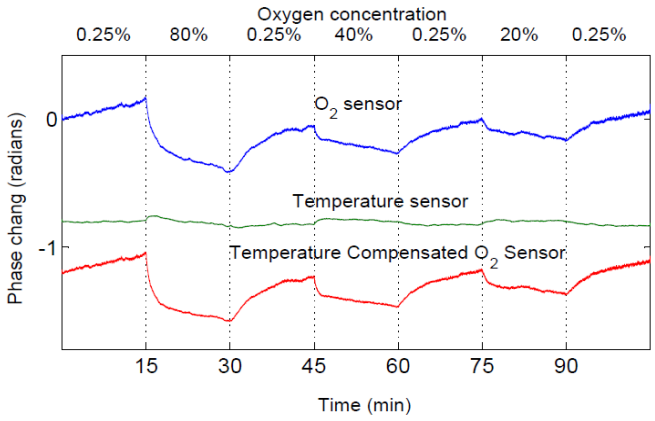

Figure 6. Compensation for temperature variations with a second SAW device.

Gas sensing performed over a wider range of temperature is presented in Figure 7. Data for 650 C and above has not been temperature-compensated due to failure of the temperature-sensing SAW device. Oxygen sensing however has been achieved up to 700 C.

This data shows clearly that sensing with a ZnO layer can only be performed over a limited temperature range. As shown in Figure 1, a significant change in propagation velocity is obtained only for a limited range of sensing layer conductivity. Due to the exponential dependence of conductivity on temperature, a peak in the sensitivity is expected at an intermediate temperature.

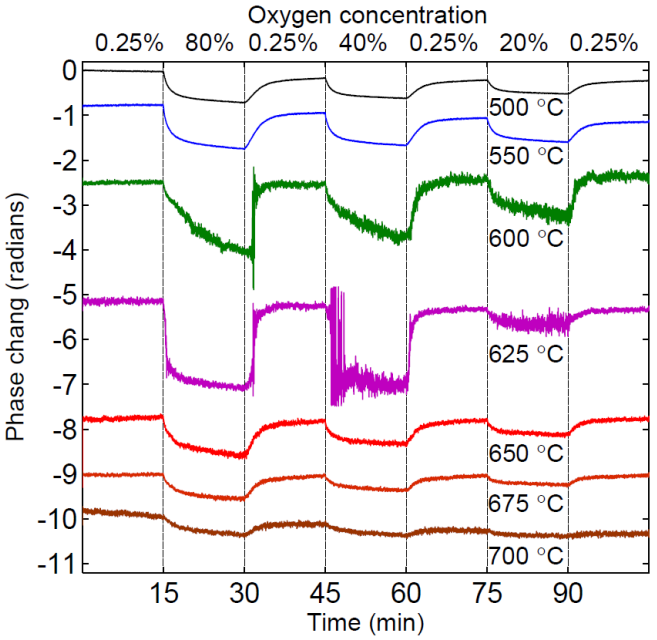

Figure 7. Oxygen sensing as a function of temperature.

The peaked behavior for the sensitivity as a function of temperature is an important issue in sensor design. In order to acheive accurate sensing over a range of temperature, sensing layers with little dependence on temperature are preferred. Recently some mixed-oxide sensing layers have been

investigated that have reduced temperature sensitivity [8]. Even in this case, the activitation energy is not exactly zero so simultaneous temperature measurement will still be needed.

Finally, we consider the issue of sensor stability. In early experiments, we evaluated the oxygen sensing as a function ot temperature at steadily increasing maximum temperatures of 630, 700, and 750 C. The total phase change resulting from an oxygen concentration change from 0.25% to 80% is plotted in Figure 8 for these three series of measurements. We see that the peak sensitivity shifts to lower temperatures with increasing temperature exposure. This change is consistent with increasing grain size in the ZnO layer, resulting in higher conductivity (increase in the factor A in equation (1)).

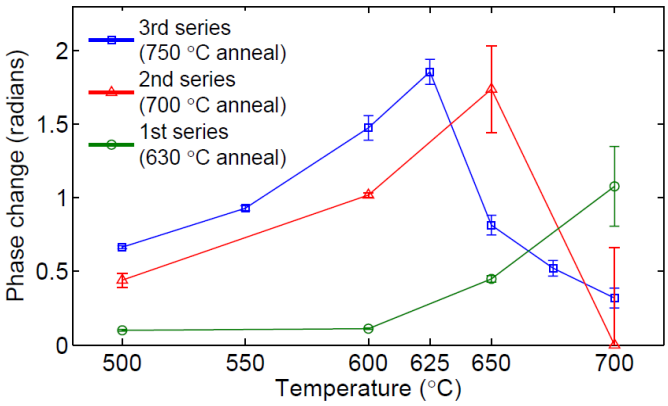

Figure 8. Measured phase change from 0.25% to 80% O_2 concentration at different temperature in three series of tests of the ZnO/langasite device.

In a subsequent series of experiments (not shown) closely similar results were obtained in three series of measurements. This suggests that the response of the sensing layer is stable when operated below the maximum anneal temperature.

IV. Conclusions

We have reported here on a langasite SAW sensor for simultaneous measurement of temperature and oxygen concentration. The sensitivity of the propagation velocity resulting to oxygen concentration depends on temperature because of the thermally activated conductivity of the sensing layer. As a result small perturbations in temperature will cause a change in the measured phase shift even if the oxygen concentration is constant. This effect can be minimized by using two SAW devices or two propagation paths, one with and one without a sensing layer.

We have also observed that the gas sensitivity can be influenced by aging of the sensing layer. This effect appears to be reduced when sensors are annealed at higher temperatures than used during operation.

***Abstract*—There has been little published data on spread spectrum SAW RFID correlator receiver performance, since most approaches published have used an FMCW system. The purpose of this paper is to discuss issues related specifically to correlator receiver performance parameters with respect to range, detection, and noise. The minimum detectable signal (MDS) at the ADC is used as the measure for prediction of the maximum range. The loop gain of the system, MDS, noise and processing gain bound the predicted achievable range for a correlator receiver. It will be shown that in a correlator receiver nano- to micro-joules of energy can obtain ranges greater than 50 meters, dependent on the key system parameters. A model is developed for prediction of the maximum range as a function of center frequency, output signal and power, MDS, synchronous interrogation, and loop gain. From the predictions, it appears feasible to have a sensor range of over 100 meters with modest interrogation energy in a pulsed correlator system.**

I. Introduction

The concept of using a correlator receiver for spread spectrum systems is well known. Results of a fully operational SAW orthogonal frequency coded (OFC) spread spectrum multi-sensor system have been recently reported [1]. The paper presented some of the important device and system considerations, such as the choice of operating frequency, device design, antenna size, loss, etc. The 915 MHz SAW temperature system presented was based on SAW OFC delay line devices that are interrogated with a pulsed RF signal. The temperature is extracted after signal reception through an analog-to-digital-converter (ADC) and the data points are post processed as in a correlator receiver, using an adaptive matched filter and associated software. The post processing is completely reconfigurable and is comparable to a software radio approach. Although an OFC SAW system will be used as an example, the correlator receiver analysis and approach should be applicable to any type of passive coded waveform system, SAW or others.

Surface acoustic wave (SAW) technology is beginning to seriously attract interest for a broad range of sensor applications, especially in aerospace and health monitoring applications [1] [2]. Many applications have very challenging requirements: zero maintenance (no battery), no external power (scavenging or external power source), reliable life-cycle (years in a wing structure or minutes in an engine exhaust), light and small, etc. A short list of system specifications may include simultaneous multi-sensor interrogation and reception, wireless, passive, radiation hard, and range of several centimeters to 10s of meters. The sensors should be small, rugged, provide RFID on chip, operate at cryogenic to high temperature, and differing embodiments should provide temperature, gas pressure, strain, chemo- or bio-detection and others.

Over the last 20 years there have been several proposed SAW embodiments for wireless, passive SAW RFID sensors, which include narrowband resonant devices, reflective delay line sensors, SAW chirp devices, external-sensor-SAW module, and CDMA [2]–[7]. Narrowband devices can provide an ID through differing resonant device frequency, while most delay line devices provide the coding through pulse position reflectors. The chirp sensor uses the correlation properties for enhanced sensor data extraction, but provides no effective multi-coding. Initial work on orthogonal frequency coded (OFC) SAW devices for RFID and communication began in 2000, and the first publication on SAW OFC was in 2004 [8] [9]. The research was begun to attempt to overcome the limitations of the previously described embodiments for device encoding, and then apply the approach to sensing.

II. OFC SAW Device Design

There have been a number of publications on the theory and approach to OFC based on communication theory, and then its application to SAW device embodiments [8] [9]. The basic embodiment for the OFC RFID tag and sensor is schematically shown in Fig. 1. A wideband transducer launches a SAW based on the interrogation signal, which is convolved with the OFC coded reflector array, and is re-radiated, via the transducer, to the receiver antenna. The chip orthogonality condition describes a relationship between the local chip frequencies and bandwidths, embodied in each SAW Bragg reflector. The reflector-chip frequency responses are a series of nearly ideal sampling functions with null bandwidths equal to $2 \cdot \tau^{-1}$. Each chip contains an integer number of carrier half cycles and the chip-Bragg center frequencies are separated by multiples of τ^{-1}. The key enabling technology is the fact that the nulls of adjacent Bragg reflectors align with all the peaks of the individual Bragg reflectors, indicating that the SAW signal

The authors acknowledge support from NASA STTR grants and the NASA Graduate Student Researchers Program (GSRP) Fellowship.

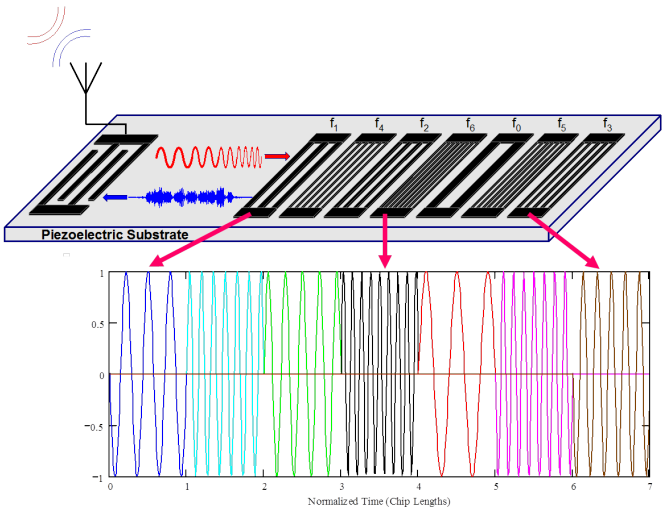

Fig. 1. Schematic of a 7 chip SAW OFC RFID tag which can be used as the platform for a sensor. The figure depicts a chirp input signal and the returned coded signal which is the convolution of the OFC code and chirp.

is nearly transparent to all Bragg reflectors, except near the center frequency and bandwidth of a single Bragg reflector. This allows the SAW to travel through the Bragg array without much attenuation, until a signal frequency coincides with the chip-Bragg reflector frequency. Coding is accomplished by shuffling the chips in time, which allows both frequency and time diversity. The OFC approach produces a wide or ultra-wide band spread spectrum device. The sensor information is encoded in the reflectors, time delay regions, or both. Dual tracks (in-line or parallel) can be used for enhanced coding or multiple sensor operations.

The OFC SAW devices used herein are at a center frequency of 915 MHz and used 5 chips per device with a bandwidth of approximately 92 MHz. This yields a device signal processing gain (PG) of 25.

III. Synchronous Transceiver Approach

The SAW OFC sensor device and system initial concept have been previously discussed [9]. The basic system concept, shown in Fig. 2 is composed of multiple SAW RFID-sensors (RFIDS) that can have various embodiments. The SAW and antenna compose the RFIDS. The transceiver, often called the reader for RFID systems, sends out an interrogation signal which is received by all the SAW sensors. The interrogation signal launches a SAW, which is encoded with the RFID and is appropriately modified to also encode the sensor information, and is rebroadcast to the receiver. The signal is demodulated and post processed to extract the RFID and the associated sensor information.

A conceptual diagram of the interrogation/receiver process is shown in Fig. 3, which uses a chirp interrogation signal and a correlator receiver. The chirp provides increased signal power over a single pulse and allows ultra wide band operation, if desired. The implementation of the actual reader hardware is more complex, but the operational principles remain the same. The near-baseband signal is post processed through an analog-to-digital converter and software.

An example of a 915 MHz pulsed synchronous, RF transceiver block diagram developed is shown in Fig. 4

IV. Signal and Noise Model

The system should attempt to maximize the detection probability, or minimize errors, as a function of system parameters. The system must overcome the signal path loss by amplifying the signal while minimizing all noise source effects .The following will define the signal-to-noise ratio based on the model parameters. From the model, with suitable approximations, the range for any synchronous correlator based system can be estimated.

The system critical operational parameters are:

- Center Frequency (f_o), Bandwidth (B)
- TxRx Antennas
- RFIDS Parameters
- Equivalent Isotropic Radiated Power ($EIRP$)
- Minimum Detectable Signal (MDS)
- Receiver Gain, Noise Figure, and Noise Sources

A. Parameter Definitions

The following elements within the model are defined. The elements do not consider details of implementation or optimization.

ADC	Ideal Analog-to-Digital Converter
MDS	Minimum Detectable Signal
S	Signal Power Measured at ADC
N	Noise Power Measured at ADC
kT	Thermal Noise Energy
$EIRP$	Equivalent Isotropic Radiated Power
G_{RFIDS}	RFIDS Gain (Less than unity for passive device)
G_{Rx-Ant}	Gain of Receiver Antenna
G_{Rx}	Receiver Gain from Antenna Output to ADC
PG	Signal Processing Gain of the System (τB)
PL	Path Loss
NF	Receiver Noise Figure
N_{ext}	External Noise Source at Antenna Output
N_{ADC}	ADC Equivalent Noise
N_{sum}	Number of Synchronous Integrations in ADC
PCG	Pulse Compression Gain

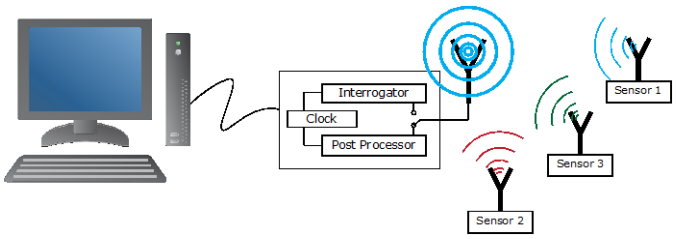

Fig. 2. Block diagram of a SAW wireless sensor system. The system will interrogate multiple sensors simultaneously. Receiving and identifying the RFID, the sensor information can be obtained via post processing of the received signal.

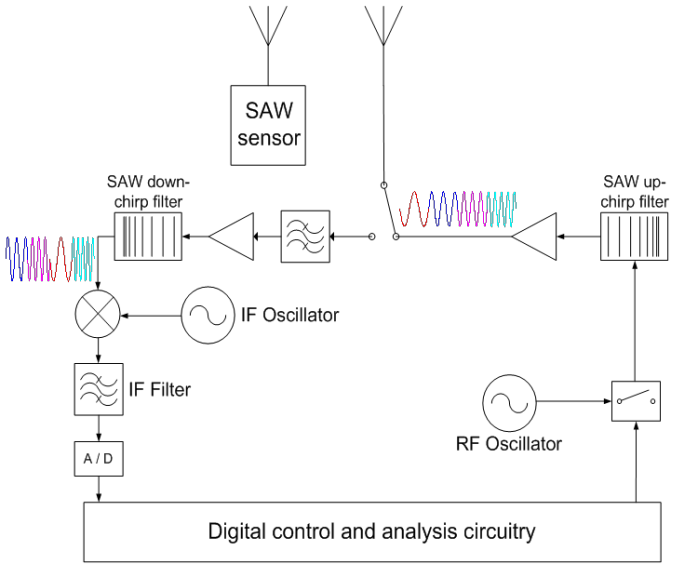

Fig. 3. A simple block diagram concept of the interrogation and correlator receiver approach as the sensor reader.

B. S/N Model

The signal is given as

$$S = EIRP \cdot G_{RFIDS} \cdot G_{Rx-Ant} \cdot PG \cdot PCG \cdot {N_{sum}}^2 \cdot PL. \quad (1)$$

The random noise is the summation of several possible sources, given as

$$N = [kTB \cdot G_{Rx} \cdot NF + N_{ext} \cdot G_{Rx} + N_{ADC}] \cdot N_{sum}. \quad (2)$$

To simplify the noise model and see the impact of excess noise compared to thermal noise, define a term

$$\gamma = [N_{ext} + (N_{ADC}/G_{Rx})]/kTB. \quad (3)$$

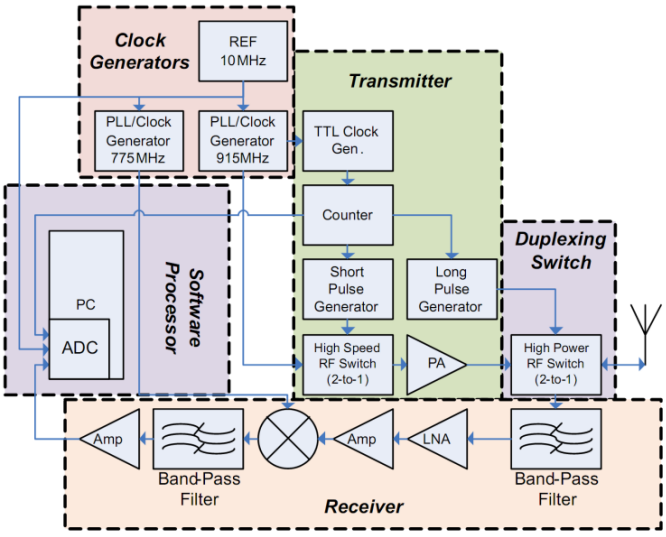

Fig. 4. A 915 MHz pulsed synchronous, RF transceiver block diagram developed for testing and analysis.

The noise can be rewritten as

$$N = [kTB \cdot G_{Rx} \cdot (NF + \gamma)] \cdot N_{sum} \quad (4)$$
$$= [kTB \cdot G_{Rx} \cdot NF^*] \cdot N_{sum}. \quad (5)$$

The signal to noise ratio at the ideal ADC, substituting, $PG = \tau \cdot B$ and regrouping, is given as

$$S/N = [EIRP/(NF^* \cdot kT/\tau) \cdot PCG \cdot PG] \cdot [(G_{RFIDS} \cdot G_{Rx-Ant})] \cdot [N_{sum} \cdot PL] \quad (6)$$

or

$$S/N = G_{PDL} \cdot PCG \cdot PG \cdot G_{sys} \cdot N_{sum} \cdot PL \quad (7)$$
$$= G_{loop} \cdot PL. \quad (8)$$

It is often convenient to write S/N in dB, which is given with dB terms in bold as

$$\mathbf{S/N_{dB}} = \mathbf{G_{PDL}} + \mathbf{PCG} + \mathbf{PG} + \mathbf{G_{sys}} + \mathbf{N_{sum}} + \mathbf{PL} = \mathbf{G_{loop}} + \mathbf{PL}. \quad (9)$$

The desired S/N establishes the required loop gain to overcome the path loss, in the presence of noise terms. Often, the MDS level is set at the noise power level and then

$$MDS = NF^* \cdot kT/\tau \quad (10)$$

and

$$G_{PDL} = EIRP/MDS \quad (11)$$

which represents a power gain.

As expected increasing the radiated power, reducing the thermal noise and noise figure, and increasing the encoded signal time length, all increase the S/N. For a passive sensor, such as a SAW device, the G_{RFIDS} is always less than unity. It is important to reduce the RFIDS loss as low as possible and to use as high gain antenna at the receiver as practical. Finally, coherent integration can, in theory, establish any desired S/N level, given a reduced RFIDS sampling rate. Interestingly, the receiver gain and the chip bandwidth do not impact the S/N, assuming a well designed receiver. The chip bandwidth does, however, impact the ability to code and detect, and therefore is an important variable for other system level considerations other than noise.

C. Range Prediction

For passive RFIDS, the range is given by Friis Equation as

$$Range = PL^{1/4}[v_{EM}/(4\pi f_o)] \quad (12)$$

where v_{EM} is the free space velocity.

A minimum S/N is determined for detection, and the maximum range, in meters, acheivable is obtained as

$$R_{max} = [(4\pi f_o)/v_{EM}]^{-1} \cdot [G_{PDL} \cdot PCG \cdot PG \cdot G_{sys} \cdot N_{sum}/(S/N_{min})]^{1/4} \quad (13)$$

or given in dB, dB terms in bold, as

$$\mathbf{R_{max-dB}} = (1/4) \cdot [\mathbf{G_{PDL}} + \mathbf{PCG} + \mathbf{PG} + \mathbf{G_{sys}} + \mathbf{N_{sum}} - \mathbf{S/N_{min}}] - 10 \cdot log[(4\pi f)/v_{EM}]. \quad (14)$$

V. System Design Considerations

The loop gain model developed predicts the maximum achievable range for the RFIDS synchronous correlator receiver system. The loop gain model components are separated into a series of terms that allow identification of important components for optimizing system range.

A. Path Loss

Assuming isotropic radiation, the received power from a transmitter decreases at 40 dB per decade as a function of increasing frequency and operational range. The thermal noise floor is constant with range but increases with bandwidth. The plots of Fig. 5 point to the use of the lowest operational frequency to minimize path loss and increase operational range. If target size is not a primary consideration, then operation at 250-500 MHz might be a good solution to increase operational range.

B. RFIDS-SAW and Antenna Target

However, to make the target (SAW plus antenna) small, it is desirable to work at relatively high frequencies. As operational frequencies increase, the SAW size typically decreases, the absolute operational bandwidth increases (for a given fractional bandwidth), the propagation losses increase, and the photolithographic resolution requirements increase. High velocity materials relax manufacturing process requirements, but constraints on fabrication and propagation loss have currently limited SAW operational frequencies to below 3 GHz. High coupling materials can provide low loss operation over wide bandwidths, but typically have large temperature coefficients of frequency. The SAW OFC devices developed thus far have used YZ-LiNbO3 since the material provides high coupling, broad bandwidths and minimal diffraction. A key parameter is the frequency dependent propagation loss constant, for YZ-LiNbO3 given as [10]

$$\alpha(f) = 0.19f + 0.88f^2 \quad (dB/\mu s), \quad (15)$$

with f in GHz.

The loss increases rapidly above 1 GHz, and it would be desirable to operate where the loss is not a dominant factor. Also, this loss term is optimistic, since thin films and other effects often increase expected device and material loss even greater with frequency. Antenna gain and achievable fractional bandwidths increase for a given volume for electrically small antennas (ESA) as frequency increases. The antenna gain and bandwidth can be estimated for an ESA given in Fig. 6, and shows that higher frequencies provide better performance with respect to both gain and bandwidth.

At 1 GHz, gain greater than 0 dB can be achieved for an antenna radius of an inch. Higher frequencies can further increase antenna gain and bandwidth, but the SAW device propagation loss counters the advantage, and the overall target performance will be optimized in the 850-1.5 GHz range, depending on other parameter factors.

Based on the previous arguments, the SAW OFC system currently under development has an operational frequency of 915 MHz; since many of the applications being considered have few or no restrictions on center frequencies and bandwidths. Regulatory constraints require consideration if operated in a restricted environment; placing additional constraints on the operating parameters. The 915 MHz frequency was chosen to balance the conflicting parameters of RFIDS small size, low loss, wide bandwidth, and fabrication process control. The devices at 915 MHz have a $\lambda/4$ line width of approximately 0.8 um on YZ-LiNbO3. The SAW OFC device results presented used 5 chips, with a processing gain (PG) of 25 and a device bandwidth of approximately 92 MHz. The surface mounted RFIDS was soldered to a PC board, open sleeve dipole antenna. The antenna, with the soldered SAW device, was 125 mm x 55 mm on a 32 mil FR4 copper clad PC board. The measured antenna gain, in a 50 ohm system, is approximately 1.8 dB and had a bandwidth of approximately 200 MHz [11]. The RFIDS had a loss of approximately 23 dB.

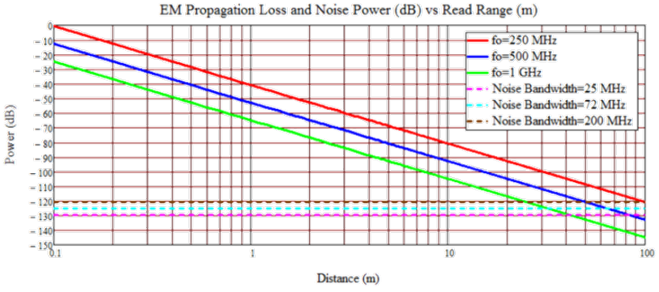

Fig. 5. Ratio of receive to transmit power, in dB, as a function of range, in meters, for a passive target for 3 differing operational frequencies, 0.25, 0.5 and 1 GHz - solid lines. The dotted traces are the thermal noise power levels (dBW) at 3 differing bandwidths, 25, 75, and 200 MHz.

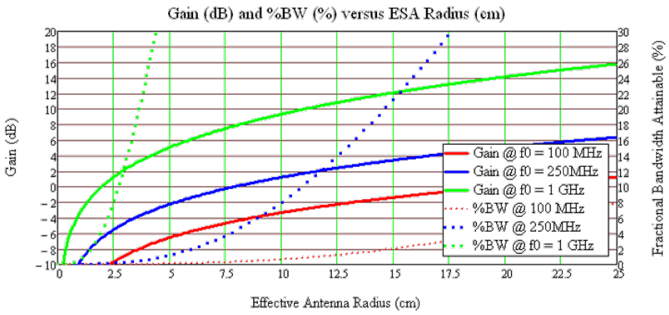

Fig. 6. Plots of the approximate gain and fractional bandwidth versus effective antenna radius for an electrically small antenna, from the analysis of Wheeler [11,12].

C. Transceiver

The following section presents results of measurements for two differing temperature SAW OFC systems at 915 MHz. The systems use an adaptive filter in a correlator based receiver to identify the SAW sensor and to extract temperature. Measurements are for a single sensor operation.

1) RF Pulsed Transceiver Parameters:

- f_0 = 915 MHz, $BW_{IF} > 100$ MHz
- Peak RMS Power = 30 dBm
- Pulse-Length = 10 ns
- PCG = -1 dB
- Antenna Gain = 9 dBi
- Bandwidth = 82 MHz
- G_{Rx} = 47 dB
- NF* = 18 dB
- N_{ext} = -22 dBm
- P_{FoM} = 30 - 1 - (-22) = 51 dB

The RF pulsed format is quite simple, but the radiated energy is small. For the pulsed system developed, a pulse length of 10 nsec gated a 915 MHz RF carrier. The peak power was 30 dBm and fed to a 9 dBi gain Yagi antenna, yielding an equivalent isotropic radiated power (EIRP) of 39 dBm. The radiated energy per pulse is approximately 79 nano-joules. Pulse compression gain in this case is approximately -1 dB, due to the bandwidth of the IF filter. Power figure of merit (P_{FoM}) can be expressed as sum of peak power to the antenna and PCG less noise floor of the system or the environment (N_{ext}).

Fig. 7 illustrates the range capabilities of an RF pulsed transceiver with the above parameters. Measurements were conducted of a single OFC sensor for identification of the code, as well as extraction of temperature. The brown line with markers is a plot of the fractional error in temperature to the range of the RFIDS. A false identification is indicated by a fractional error of 0.1 and occurs at a range of 3 meters. The red and black dot-dashed plots compare the predicted reflected RMS power measured at the ADC vs. range, and agree well until a large fractional error of temperature is measured.

2) Chirped Transceiver Parameters:

- Power to Antenna = 28 dBm
- Pulse-Length = 700 ns
- PCG = 17 dB
- Antenna Gain = 9 dBi
- Bandwidth = 78 MHz
- G_{Rx} = 45 dB
- NF* = 15 dB
- N_{ext} = -22 dBm
- P_{FoM} = 28 +17 - (-22) = 67 dB

Measurements were also made with a transceiver utilizing a chirped interrogation with the above parameters. The receiver IF bandwidth was 74 MHz, which reduced the apparent PG to 20. Pulse compression gain in this case is 15dB. The increase in P_{FoM} from pulsed to chirped system is 16dB. The range of the chirped transceiver is shown in Fig. 8, and the increase in range from 3 to 7.3 meters correlates well to the improvement

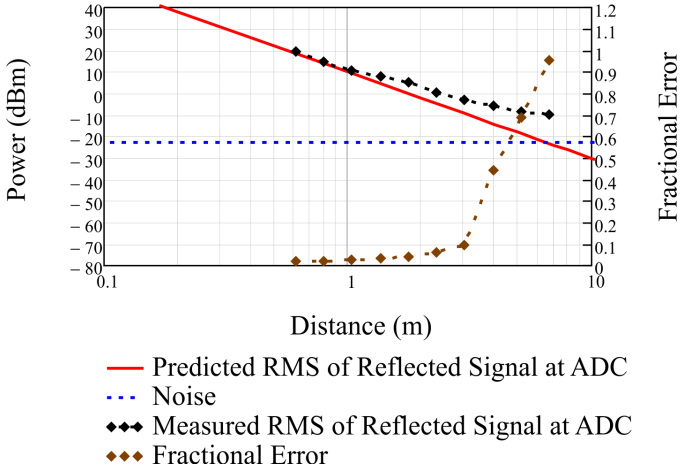

Fig. 7. Range measurement for RF pulsed system: RMS power reflected and received at ADC (red solid), noise floor (blue dashed), actual received reflection at ADC as measured using adaptive matched filter (black dot-dashed with markers), and fractional reading error (brown with markers)

in P_{FoM}. Similar to the pulsed system, the measured vs. predicted reflected RMS power strongly agree and validates the outlined range model given previously.

VI. Discussion

Major operational parameters of the correlator based interrogator have been established and a loop gain model has been developed for predictions of range. It has been shown that for certain key parameters, terms containing bandwidth of the system and the receivers gain drop out of the model. A power figure of merit has been defined. Two demonstrated systems implemented two different receiver architectures (RF pulse and chirp) with a maximum interrogatable range (for a single sensor) of 3m and 7.3m respectively, which correlates well with their P_{FoM}, which are 51 DB and 67 dB respectively.

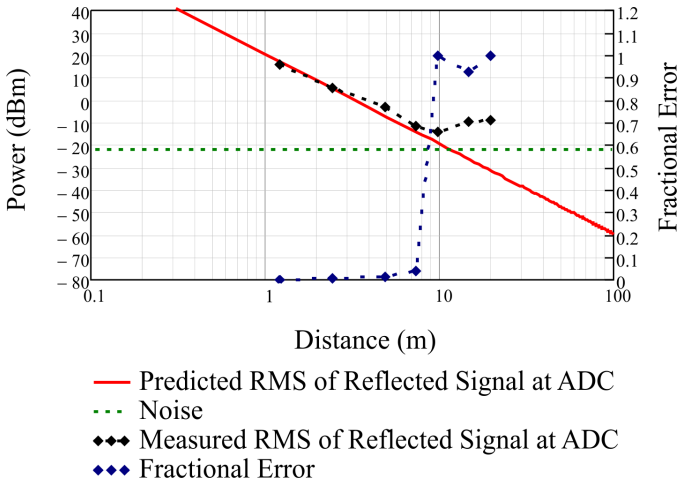

Fig. 8. Range measurement for chirped system: RMS power reflected and received at ADC (red solid), noise floor (blue dashed), actual received reflection at ADC as measured using adaptive matched filter (black dot-dashed with markers), and fractional reading error (brown with markers)

Based on practical improvements in the following system parameters:

- $\mathsf{NF}^* =$ -22 dB $\rightarrow$ -32 dB ($\Delta\mathsf{G} = 10$ dB)
- $\mathsf{G}_{\mathsf{RFIDS}} =$ -23 dB $\rightarrow$ -10 dB ($\Delta\mathsf{G} = 13$ dB)
- $\mathsf{PG}_{\mathsf{dB}} + \mathsf{N}_{\mathsf{sum-dB}} = 12$ dB $\rightarrow 22$ dB ($\Delta\mathsf{G} = 10$ dB)
- $\mathsf{PCG} = 17$ dB $\rightarrow 19$ dB ($\Delta\mathsf{G} = 2$ dB)
- Overall Gain Improvement: 35 dB

an increase in range of up to 80m is expected when using 10 synchronous averages or 40m with a single ping.

ACKNOWLEDGMENT

The authors wish to thank continuing support from NASA, and especially Dr. Robert Youngquist of Kennedy Space Center (KSC), for his encouragement. The authors are also grateful to Joni Richards, NASA-KSC, for her efforts in supporting a NASA Wireless SAW Workshop. The authors express thanks to all of the current and past students for their varied contributions to this research.

***Abstract*- Oxyborate single crystals, $ReCa_4O(BO_3)_3$ (Re=La, Pr, Nd, Y. Gd), have recently been demonstrated to offer superior dielectric, piezoelectric and electromechanical properties to quartz, langasite and other commonly used piezoelectric crystals. Of particular significance is the ability to function at temperatures > 1000°C, offering the potential for SAW, BAW and related sensors operational in harsh environments. In this work, the elasto-acoustic properties of oxyborate crystals were investigated as a function of rare earth cation. Crystallographic relationships were determined to be related to bond length and dependence of cation ordering, which was also reflected in the mechanical loss. Parameters related to high temperature operation, including electrical resistivity, dielectric loss, together with temperature dependent electromechanical and elastic properties were determined and discussed in relation to various applications.**

I. INTRODUCTION

Piezoelectric crystals, including quartz (α-SiO_2), lithium tetraborate ($Li_2B_4O_7$, LBO), gallium orthophosphate ($GaPO_4$), lithium niobate ($LiNbO_3$) and langasites ($La_3Ga_5SiO_{14}$, LGS), have been investigated for bulk acoustic wave (BAW) resonators, surface acoustic wave (SAW) devices and various sensors, including accelerometer(s) [1-2]. Recently, oxyborate crystals, $ReCa_4O(BO_3)_3$ (Re: rare-earth cation) have attracted considerable attention for various piezoelectric applications. As summarized in Table I, ReCOB borate crystals exhibit higher piezoelectric properties to that of quartz and $GaPO_4$, while offering the highest levels of electrical resistivity. Together with no temperature limiting phase transformation(s) prior to their melting points (Tm=~1500°C), borate crystals offer potential usage at temperatures exceeding 1000°C [3-8].

In this work, the elasto-acoustic properties of ReCOB crystals were investigated as a function of rare-earth cation. Crystal structure property relationships based on cation radii and structural disorder were established, leading to the identification of new borate crystals with enhanced piezoelectric properties. Parameters pertaining to high temperature operation, including electrical resistivity, dielectric loss, together with temperature independent electromechanical coupling and elastic properties were determined to establish the potential of borate crystals for piezoelectric resonators and sensors in harsh environments.

Table I Comparison of various high temperature piezoelectric crystals

Crystals	Symmetry	d_{eff} (pC/N)	Coupling k_{eff}	Resistivity (ρ) @500°C(Ω-cm)	Temperature usage range	Crystal growth method
Quartz[1]	32	2~3	~13.7%	~1×10^9	<350°C	Hydrothermal
LBO[2]	4mm	~20	~40%	/	<230°C	Bridgman
$GaPO_4$	32	~4	~18%	~1×10^{10}	<970°C	Hydrothermal
$LiNbO_3$[1,3]	3m	~21	~60%	~1×10^6	<600°C	Czochralski
LGS	32	6~7	~16%	~1×10^7	<800°C	Czochralski
Borates	m	5~7	~30%	~$\times10^{11}$	>1000°C	Czochralski

II. STURECTURE PROPERTY RELATIONSHIPS

$ReCa_4O(BO_3)_3$ crystals belongs to the point group '*m*'. For the determination of the complete set of elasto-acoustic related parameters, numerous sample geometries are required, as shown in Figure 1 [9].

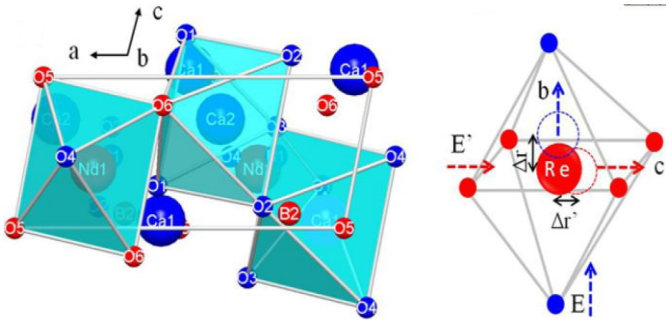

Figure 2 Crystal structure of NdCOB (left) and the schematic of Re- ion displacement movement (right) [9-10].

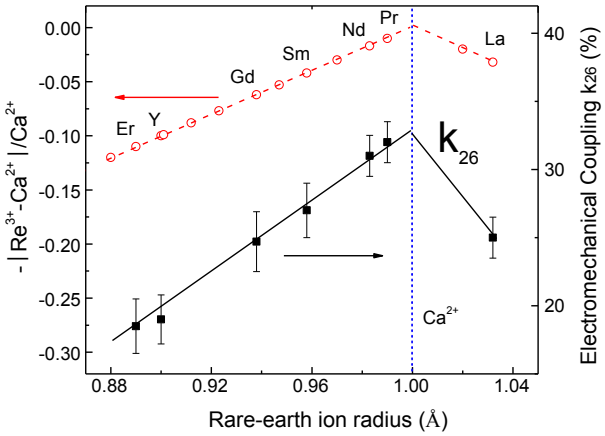

Figure 3 Variation of electromechanical coupling factor k_{26} as a function of Re-cation radius [10].

A schematic of the crystal structure showing the Re-cation is exhibited in Figure 2 [9-10]. Analogous to the langasite family ($R_3Ga_5SiO_{14}$, R= rare-earth elements) of crystals, where the electromechanical coupling factor was found to be related to the lattice parameter '*a*'[11], the elasto-acoustic properties of borates were found to be dependent on the Re-cation radii.

Figure 3 presents the piezoelectric shear properties as a function of Re-cation radii, revealing a maximum value in coupling k_{26} for ReCOB single crystals. The observed relationship was determined to be related to the Re-cation radii and the level of cation disorder. From observations, new borate crystals, including Nd and Pr borates were grown and optimum piezoelectric properties confirmed [10].

The level of cation disorder in the oxyborate crystals was reflected in the mechanical Q, as shown in Figure 4. Due to increased phonon scattering, the electrical resistivity was also found to decrease with increasing Re-cation radii, with the exception of LaCOB. The resistivity values for different ReCOB crystals at 1000°C were determined to be 1.0×10^6~1.0×10^8 Ohm·cm, as shown in Figure 5, where the small inset gives the extrapolated room temperature resistivities [8].

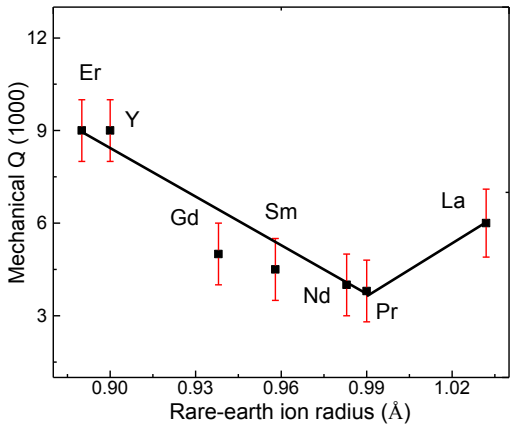

Figure 4 Variation of mechanical Q as a function of Re^{3+} radius in oxyborate crystals.

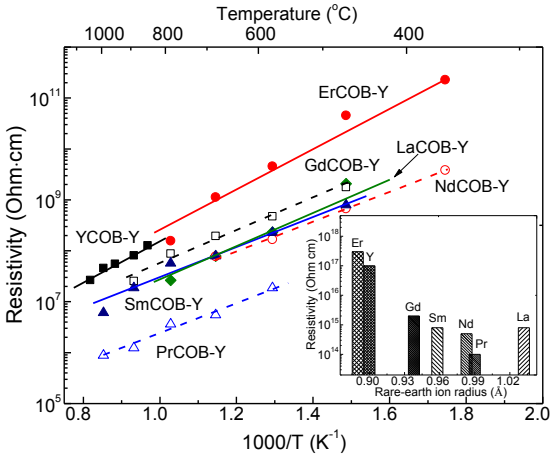

Figure 5 Variation of electrical resistivity for different ReCOB crystals along the Y-axis (after [8]).

III. HIGH TEMPERATURE PROPERTIES

Figure 6 shows the electromechanical coupling factor k_{26} for (ZXw)-θ cut YCOB as a function of temperature up to 950 °C. The largest k_{26} value was obtained in the (ZXw)-30°-cut sample, being 22% at room temperature, maintaining the same value till 950°C [7, 12]. Figure 7 presents the variation of resonance frequency f_r for (ZXw)θ (θ = –60°, 0°, 33°) YCOB crystal cuts. As can be seen, the resonance frequency shifts downward with increasing temperature, exhibiting linear temperature/ frequency characteristics over a wide temperature range of 20–950 °C. The highest first order TCF was found to be on the order of –91 ppm/K for the (ZXw)-33° cut. The impedance modulus for (ZXw)-0° cut samples as a function of temperature is shown in the inset of Fig. 7, indicating that the resonance and antiresonance peaks shift to lower frequencies with increasing temperature. Generally, sharp and narrow resonance frequency peaks reflect high

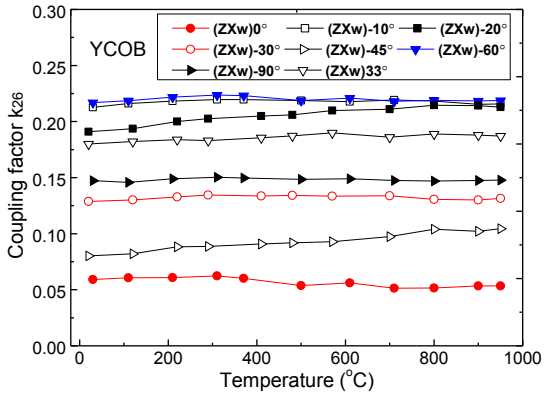

Figure 6 Variation of electromechanical coupling k_{26} for YCOB crystals as a function of temperature and crystal cut.

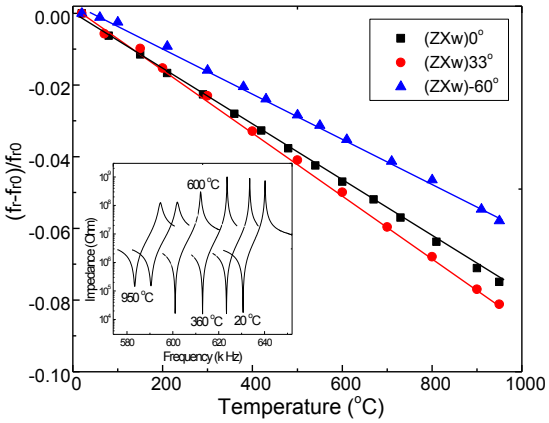

Figure 7 Frequency shift of YCOB crystals as a function of temperature and crystal cut. Inset is the impedance modulus for (ZXw)-0° cut YCOB as a function of temperature.

mechanical quality factors, Q. From the impedance modulus, the mechanical quality factors in air were calculated and found to be on the order of 16,000 at 20 °C and 2,000 at 950°C [7].

IV. HIGH TEMPERTURE APPLICATIONS

Potential high temperature applications of single crystals in the oxyborate family have been explored. As shown in Figure 7, the (ZXw)θ –cut YCOB crystals were found to possess linear frequency -temperature characteristics, with TCF on the order of -60 ~-90ppm/K, which are promising for temperature sensing applications at elevated temperatures. In contrast, bulk acoustic wave (BAW) resonators require temperature stability of the resonance frequency. In order to further investigate the potential of zero TCF crystal cut(s), NdCOB samples with different orientations as a function of rotation angle were prepared, as shown in the inset of Figure 8. The shear mode resonance frequency in the temperature range –140 to 200 °C for different crystal cuts (ZXw)θ (θ = –18°, –15°, 0°, 5°, 15°,

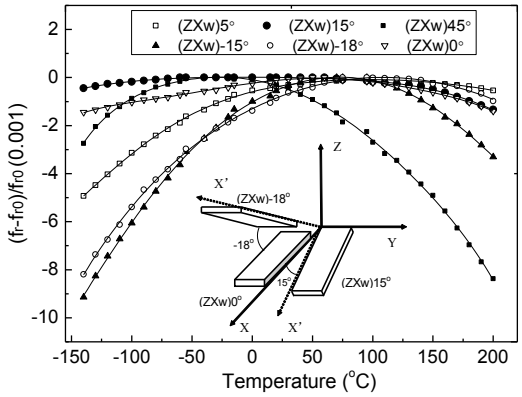

Figure 8 Resonance frequency shift of (ZXw)θ (θ = -18°, -15°, 0°, 5°, 15°, 45°) crystal cuts as a function of temperature for NdCOB crystals (after [13]).

Table II. Principle properties of NdCOB and PrCOB crystals, compared to commercial piezoelectric crystals used in frequency control devices [13-14].

Crystals	Cuts	Temperature range (°C)	TCF(1)*	TCF(2)*	d_{eff} (Pc/N)	k_{eff}
Quartz	AT-cut	-60~120	0	0	3~4	<8.8%
LBO	(YXl)51°	-30~110	0	-260	/	26%
$GaPO_4$	(YXl)-15.77°	-50~150	0	-10	4~5	13%
LGS	Y-cut	5~80	0	-58.9	~7	16%
CTGS	(YXl)-22.5°	-60~200	0	-39	~11	17%
PrCOB	(YXt)-1.5°	-140~200	0	-40	15.8	30.2%
NdCOB	(YXt) 15°	-140~200	0	-12	15.0	29.0%

* TCF (1): ppm/°C; TCF (2): ppb/°C²

45°) were measured, in which the (ZXw)15° crystal cut exhibited stable temperature frequency characteristics [13].

Table II lists the fitted first and second order TCF parameters for (YXt) θ-cut NdCOB and PrCOB single crystals, compared to commercial piezoelectric crystals. The piezoelectric d_{eff} and electromechanical k_{eff} are also listed in the table for comparison. The first order TCF reached zero for NdCOB crystals when the cut angle θ was 15°, while the crystal cut angle θ =-1.5° for PrCOB crystals was found to possess a zero TCF. Of particular significance is that both NdCOB and PrCOB single crystals have the highest piezoelectric coefficients d_{eff} ~ 15-16pC/N, with electromechanical coupling k_{eff} being on the order of 19-30%, higher when compared to other single crystals [13-14].

Other applications, such as vibration sensors (accelerometers) were also demonstrated with sensitivities being on the order of 2.5pC/g in a wide temperature range of 30-1000°C, achieved in a monolithic compression mode accelerometer, indicating high stability and reliability in the harsh environment [6].

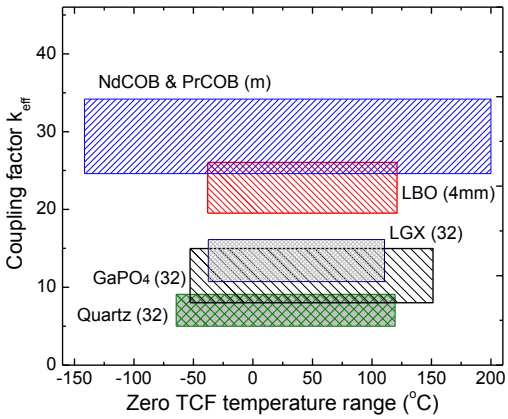

Figure 9 Comparison of NdCOB and PrCOB with commercial piezoelectric crystals used in BAW resonators (after [14]).

V. CONCLUSION

The electromechanical properties of piezoelectric crystals in the rare earth oxyborate family, including YCOB, GdCOB, ErCOB, SmCOB, NdCOB and PrCOB, were explored as a function of the rare earth cation radius, with maximum values observed for PrCOB crystals. The relationship between crystal structure and electromechanical properties for ReCOB crystals were believed to be related to the Re^{3+} ion radius and/or Re-O bond length and disorder distribution of Re^{3+} and Ca^{2+} cations. A consequence of increased disorder was the reduced electrical resistivity and mechanical Q, as confirmed in PrCOB crystals. YCOB crystals were found to possess linear characteristics of the frequency temperature behavior up to 1000°C, promising for temperature sensor applications, while NdCOB and PrCOB crystals exhibited nonlinear behavior in the temperature range of -140 ~200°C, leading to zero TCF characteristics for the potential in BAW resonator applications. Figure 9 summarizes the main properties of NdCOB and PrCOB crystals, compared to other commercial piezoelectric crystals with zero TCF and turnover temperature at 20°C. As shown, NdCOB and PrCOB offer significantly higher electromechanical coupling factors, together with the wide temperature usage range, make them candidates for BAW resonator applications [14].

Modeling Phase Noise in Multifunction Subassemblies

Michael M. Driscoll*

Abstract – **Obtaining requisite phase noise performance in hardware containing multifunction circuitry requires accurate modeling of the phase noise characteristics of each signal path component, including both absolute (oscillator) and residual (non-oscillator) circuit contributors. This includes prediction of both static and vibration-induced phase noise. The model (usually in spreadsheet form) is usually refined as critical components are received and evaluated. Additive (KTBF) phase noise data can be reasonably estimated, based on device drive level and noise figure. However, accurate determination of component near-carrier (multiplicative) and vibration-induced noise usually needs to be determined via measurement. The model should also include the effects noise introduced by IC voltage regulators and discriminate between common vs. independent signal path residual noise contributors.**

I. INTRODUCTION

Accurate prediction of the spectral characteristics of signal generation and reception circuitry early in the hardware design phase is essential as it quickly identifies those circuit elements that are major noise contributors and performance limiters. Simplified, pre-design modeling is also helpful during proposal development in terms of identifying technology tradeoffs and making realistic assessments of attainable performance, risk, cost, etc. As oscillator noise reduction techniques and resonator characteristics have progressed, it can no longer be safely assumed that the phase noise contribution of the non-oscillator components can be largely ignored, especially in the presence of significant vibration and acoustic stress [1-5]. Modeling should include all possible or suspected major noise contributors in signal path circuitry and is time-consuming from both the standpoint of gathering data and entering it into the model. Nevertheless, it is considered a very necessary and worthwhile effort - one that is far less expensive in the long run, compared to the consequences fabricated hardware exceeding phase noise specification limits. The proposed model treats absolute (oscillator) phase noise separately from total residual (non-oscillator) signal path noise, with the two contributors added together at the hardware output signal ports.

*Written while employed by Sycom Services, a subsidiary of Ameriforce Craft Services, under contract to Northrop Grumman Electronic Systems, Baltimore, MD.

II. ABSOLUTE PHASE NOISE

Oscillator output signal phase noise can be inserted into the model as measured, vendor-advertised, or formulated data. Figure 1 shows a simplified block diagram of an oscillator incorporating a modular amplifier sustaining stage [5-6].

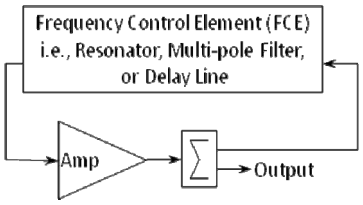

Figure 1. Feedback Oscillator Block Diagram

The data entered into the spreadsheet includes the amplifier open loop power input, noise figure, and multiplicative (usually 1/f) noise, and frequency control element (FCE) in-circuit group delay, and short-term frequency stability (self-noise). In a well-designed crystal or SAW oscillator, the FCE self-noise is usually the primary contributor to output signal near-carrier phase noise [6-9]. Amplifier multiplicative noise may be entered as a 1Hz intercept value or as measured data. Similarly, the white phase noise (floor) level may be computed from the noise figure and input drive level, with a "fudge factor" sometimes included to account for noise floor degradation with amplifier in-compression operation [10]. FCE self- noise may be entered, based on measured data or past experience. Sustaining stage measured data should be gathered at the actual amplifier operating point and powered from the intended voltage regulator, with the noise measurement system self noise accounted for. The output signal phase noise single sideband level can be calculated from these parameters as:

$$10 \log[((1/2\pi\tau f)^2+1)(K_1/f+K_2) + K_3/f^3] \qquad (1)$$

The numeric inside the outer brackets represents one half of the power spectral density (PSD) of the phase fluctuations. The $K_1/f+K_2$ terms represent the open loop PM noise of the non-resonator portion of the oscillator (the sustaining stage amplifier and other functional sub-circuits). K_1/f is the amplifier 1/f PM component. If the measured open loop 1/f PM noise at f=1Hz is –140dBc/Hz, then K_1=can be entered as 10^{-14}. K_2 is the white noise component. $K_2=10^{XX}/10$ where "XX" is the additive (i.e., KTBF) phase noise level in dBc/Hz = –177dBm/Hz-Pin(dB)+NF(dB). K_3 is a term that

accounts for the FCE self-noise that, in acoustic resonators and delay lines most often occurs as flicker-of-frequency noise in the oscillator. When measured in a phase bridge using an external signal generator, this type of instability induces flicker-of-phase (10dB/decade) noise onto the carrier signal. In oscillators comprising discrete component sustaining stages, the model must take into account the effect of the FCE frequency-selective impedance characteristics on the active device noise contributors [11-13].

IV. RESIDUAL PHASE NOISE

Like absolute noise, non-oscillator component, residual noise can be inserted into the model as measured, vendor-advertised, or formulated data. Usually the residual phase noise PSD contains a flicker-of-phase (K_1/f) component and a white noise (K_2) component as described in section II [1].

Measured data should be obtained with the UUT operated at the intended drive level and operated from the intended DC supply or voltage regulator. If/when the device phase shift is influenced by DC supply voltage fluctuations, the phase noise PSD characteristic may be degraded and deviate from the $K_1/f+K_2$ type characteristic, depending on the DC supply/voltage regular noise characteristics and internal device design (feedback control loop peaking, etc.)

V. COMMON vs. INDEPENDENT SIGNAL PATH NOISE

When more than one signal drives a signal path device like a mixer, accurate phase noise modeling requires that a distinction be made between phase noise that is common to the device input signals and that which is not. For example, consider the simplified block diagram shown in figure 2.

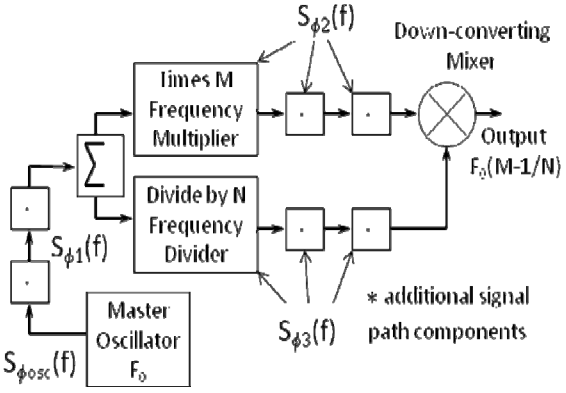

Figure 2. Common vs. Independent Signal Path Noise

$S_{\phi osc}(f)$ represents the oscillator *absolute* phase noise, $S_{\phi 1}(f)$ the *common* signal path *residual* phase noise, and $S_{\phi 2}(f)$, $S_{\phi 3}(f)$ represent the *independent* signal path *residual* phase noise, including the residual noise of the multiplier and divider, referenced to the device outputs. The phase noise PSD at the mixer output is:

$$(M\text{-}1/N)^2 S_{\phi osc}(f) + (M\text{-}1/N)^2 S_{\phi 1}(f) + S_{\phi 2}(f) + S_{\phi 3}(f) \qquad (5)$$

III. PHASE-LOCKED OSCILLATORS

The use of a phase-locked loop (PLL) is a widely used technique for imparting the near-carrier phase noise and long-term frequency stability of the PLL reference input signal to the locked oscillator (VCO), while retaining phase noise characteristics of the VCO at carrier offset frequencies in excess of the loop bandwidth [14-15]. In addition, the PLL is also used in indirect frequency synthesizers in order to provide frequency agility. Often, the entire PLL is available in integrated circuit chip form where the loop frequency/phase detector and frequency dividers are digital logic level devices. Figure 3 shows a simplified block diagram of a phase-lock loop.

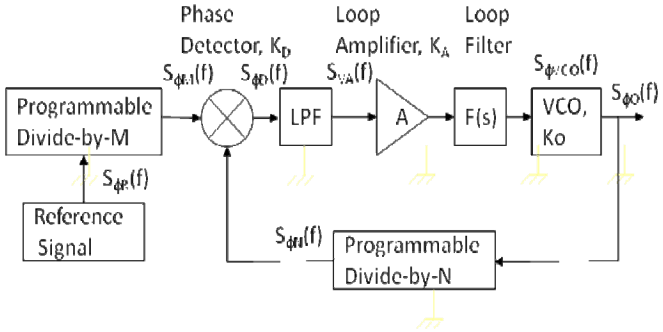

Figure 3. Phase-lock Loop Functional Elements

When the PLL is configured in discrete component form, classic formulas apply for modeling the output signal phase noise. In Figure 3, $S_{\phi R}(f)$, $S_{\phi VCO}(f)$, $S_{\phi M}(f)$, $S_{\phi N}(f)$, and $S_{VA}(f)/2K_D^2$ are the phase noise PSDs of the reference signal, VCO, frequency dividers (at the divider output), phase detector, and loop amplifier. The amplifier equivalent input noise voltage (volts^2/Hz) divided by two (50% AM, 50% PM) times the detector constant squared yields the equivalent amplifier phase noise, and includes input current noise flowing through the external input resistance. The open-loop gain is:

$$G_{OL} = (K_D)(K_A)(F(s))(K_O/s)(1/N) \qquad (2)$$

The phase noise PSD of the phase-locked VCO is:

$$(S_{\phi R}(f)/M^2 + S_{\phi M}(f) + S_{\phi N}(f) + S_{VN}(f)/2K_D^2) \text{ times } ((N)(G_{OL})/(1+G_{OL}))^2 \text{ plus } S_{\phi VCO}(f)/((1+G_{OL})^2) \qquad (3)$$

The phase noise of the components depicted in figure 3 can be modeled as described in sections II and III. From a phase noise standpoint, the optimum PLL bandwidth is usually at/near the frequency where the free-running VCO phase noise level is equal to that of all the non-VCO noise contributors times N^2. In phase lock loops incorporating logic level frequency dividers with high N divide ratios, the divider noise often limits output signal

phase noise performance. Manufacturers of PLL ICs often specify PLL phase noise performance in terms of a "normalized phase noise floor" or Figure of Merit (FOM). The FOM has been defined in the literature as:

$$L_{1Hz} = L_{floor} - 20\log(N) - 10\log(F_c) \quad (4)$$

L_{floor} is the "in-band" (inside the PLL bandwidth) single sideband, white phase noise level, N is the loop feedback division ratio, and F_c is the phase (detector) comparison frequency [16].

VI. VIBRATION-INDUCED NOISE

Vibration-induced phase noise is very often the dominant contributor to hardware output signal phase noise in the frequency offset region where vibration is impinging on sensitive components. Although this region often does not extend beyond 1-2kHz, the resulting phase noise degradation can extend to many times that frequency if when mechanical non-linearities exist. Examples of non-linearities include: loose particles from machining or galling, loose parts from assembly i.e. washers), lightly sprung electromechanical relays, and improperly secured electrical components, wires, cables, covers, and inner enclosed subassemblies. Even a slight amount of scraping between parts can cause a problem, as well as lack of flatness between large area enclosure surfaces. Mechanical resonances will cause amplification of the vibration level at the resonance frequency, where the vibration PSD level increase is proportional to the resonant Q factor squared [3].

Oscillator vibration induces changes in the oscillator loop phase shift and/or resonator resonant frequency that induces *frequency modulation* (FM) onto the oscillator output signal. Since the oscillator FCE represents the highest group delay component in the oscillator, it's vibration sensitivity is the dominant source of vibration-induced FM. Oscillator and oscillator resonator vibration sensitivity (Γ_f) is usually expressed on a fractional frequency basis, with $\Gamma_f = \delta f/f_0$ per g. The "f" subscript is used here to denote fractional frequency sensitivity to vibration. If the oscillator FCE is a delay line whose phase shift at the operating frequency varies according to a *phase* sensitivity to vibration (Γ_ϕ) in units of radians per g, the resultant oscillator fractional frequency vibration sensitivity can be expressed as:

$$\Gamma_f = 2\pi\tau\Gamma_\phi/f_0 \quad (6)$$

where τ equals the delay line delay or multipole filter group delay in seconds [3]. If the vibration is random, the vibration PSD is usually denoted as $S_g(f)$, and the vibration-induced, oscillator phase noise PSD is given by:

$$S_\phi(f) = S_g(f)((\Gamma_f f_0/f)^2) \quad (7)$$

where f is the carrier offset (vibration) frequency.

Unlike oscillator vibration, vibration in non-oscillator, signal path components induces *phase modulation* onto the carrier signal. Sensitive signal path components include narrow band (high group delay) filters and other narrowband circuits used for impedance matching, etc. Also included are broadband components like coaxial cables, optical fibers, and connectors [3, 17]. Cables are sensitive because they are usually free to move between points where they are secured and can scrape or hit against printed boards and enclosures and because their movement can induce changes in effective length and characteristic impedance, and can also induce motion in coaxial connectors – especially bayonet and "push-on" styles. When vibration results in signal PM, the use of Γ_ϕ is recommended for use in noise modeling, and the vibration-induced phase noise is:

$$S_\phi(f) = S_g(f)(\Gamma_\phi^2) \quad (8)$$

For coaxial cables, Γ_ϕ is usually varies with the vibration frequency. Filter vibration sensitivity can be represented in fractional (center) frequency or phase sensitivity form. If represented as a fractional frequency term, the vibration-induced phase noise is:

$$S_\phi(f) = S_g(f)((2\pi\tau\,\Gamma_f f_0)^2) \quad (8)$$

where τ is the filter pass-band group delay. Band-pass filter vibration-induced phase noise is subject to the filter transmission selectivity response, and vibrating filter resonators can induce a non-uniform effect on vibration-induced filter PM [18].

The most common method for reducing the spectrally-degrading effects of vibration is the use of passive, mechanical vibration isolators. These devices attenuate vibration levels at frequencies above their resonant frequency, amplify vibration at the resonant frequency, and exhibit unity transmission below the resonant frequency. The expression defining the transmission response of a mechanical isolation system is:

$$T=\mathrm{sqrt}((1+((f/(Qf_n))^2))/(((1-((f/f_n)^2))^2)+((f/(Qf_n))^2))) \quad (9)$$

where Q and f_n are the Q-factor and resonant frequency of the isolation system or vibration isolators. Figure 4 shows the theoretical vs. "realistic" isolator transmission response characteristics. For random vibration, the output vibration PSD is equal to the input vibration PSD times Γ^2. The dashed line in figure 4 is in recognition that most isolation systems do not provide attenuation in excess to 20 to 30dB. Figure 5, which shows the measured transmissibility of a low frequency isolation system, clearly demonstrates this effect [19].

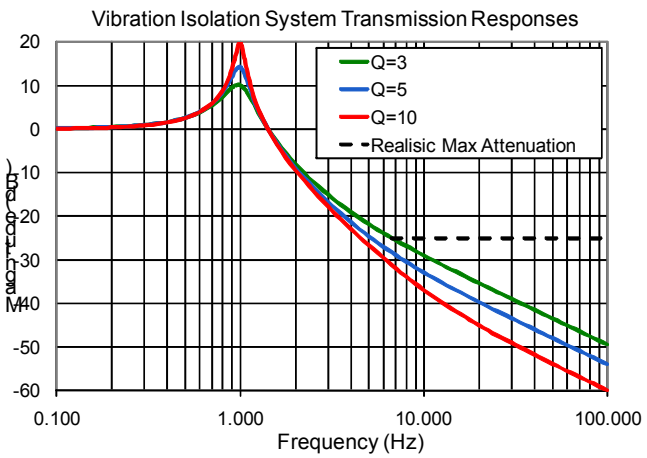

Figure 4. Theoretical Mechanical Isolation System Responses

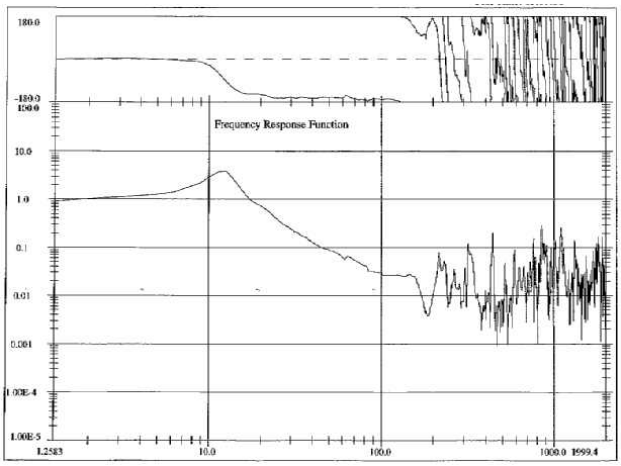

Figure 5. Measured Isolation System Response

VII. STATISTICAL VARIATION

When modeling both absolute and residual noise, variations in individual device or subassembly signal path noise levels (especially near-carrier phase noise) must be taken into account. Typical variability must usually be gleaned from measured data. Although some suppliers do provide typical vs. guaranteed levels, statistical data is usually not supplied. For example, short-term stability variations on the order of 10dB or more are typically observed for "identically" fabricated, VHF quartz crystal resonators [20]. Figure 6 shows the results of measurement of identical part number, tape and reel HBT amplifiers operated at UHF.

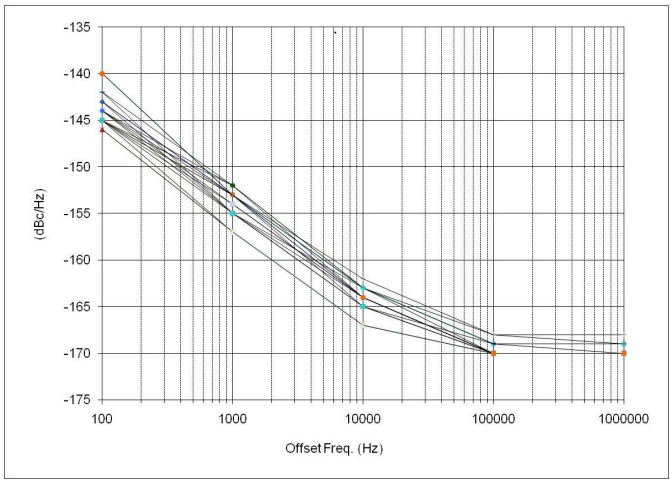

Figure 6. Measured PM Noise for Identical Part Number, UHF HBT Amplifiers

VIII. SPREADSHEET EXAMPLES

Examples of noise modeling spreadsheets are shown in the Appendix.

IX. CONCLUSIONS

Obtaining requisite phase noise performance in hardware containing multifunction circuitry requires accurate modeling of the phase noise characteristics of each signal path component.

Accurate prediction of spectral characteristics early in the hardware design phase quickly identifies those circuit elements that are major noise contributors and performance limiters.

It cannot be assumed that the phase noise contribution of non-oscillator components can be ignored, especially in the presence of significant vibration and acoustic stress.

Modeling is time-consuming, but is far less expensive in the long run, compared to the consequences fabricated hardware exceeding phase noise specification limits.

Vibration Isolation of Acceleration Sensitive Devices

Joseph B. Donovan
Electronic Systems
Northrop Grumman Corporation
Linthicum, Maryland, USA

Abstract— **Significant vibration exists in many applications such as aircraft, ground vehicles, ships, and even in the laboratory due to cooling fans, footsteps, etc. The acceleration sensitivity of frequency control devices often requires that they be isolated from their vibration environment in order to maintain the required stability. Even the latest advances in acceleration compensation of oscillators require high-performance vibration isolation systems to reach their full potential. This paper presents an approach to the design of vibration isolation systems tailored to the needs of the package designer for an acceleration-sensitive device. The approach starts with the vibration environment, the maximum allowable device acceleration, and the space available and arrives at sufficient information to select candidate off-the-shelf isolators or specify custom ones. Limitations and trade-offs inherent in practical isolation systems are presented as well as common pitfalls awaiting the designer.**

I. INTRODUCTION

The designer responsible for packaging of an acceleration-sensitive device will likely find that the required stability cannot be achieved without taking additional measures. Reference [1] describes in detail how to perform the calculation of the maximum allowable level of vibration for the device whether its sensitivity is best characterized by fractional frequency sensitivity or phase sensitivity and whether the noise generated is broadband or discrete in nature. Broadband noise places an upper limit on the power spectral density of acceleration, S_g, in units of g^2/Hz, whereas discrete noise places an upper limit on the peak acceleration, G, in units of g or multiples of the acceleration of earth's gravity. Both S_g and G may vary with frequency offset from carrier, corresponding to the modulation, or vibration, frequency. For the purposes of this paper, only broadband noise will be considered. However, the approach is similar, and somewhat simpler, for discrete noise.

Once the allowable level of vibration has been determined, it must be compared to the vibration environment to determine whether additional measures need be taken. Knowledge of the applicable vibration environment may come from design specifications or it may be inferred from what is known about the intended end-use environment.

II. VIBRATION ENVIRONMENT

Example vibration levels associated with a few end-use environments are shown in Fig. 1. The appropriate level, combined with any influence of intervening structure, forms the excitation power spectral density, S_e. Thus, additional measures are required if $S_e > S_g$. The transmissibility, T, or ratio of output to input motion needed, is given by

$$T = \sqrt{\frac{S_g}{S_e}} \tag{1}$$

such that the attenuation required corresponds to $T < 1$ and the amplification permitted corresponds to $T > 1$.

III. ATTENUATION

If required, attenuation is most often achieved through vibration isolation. A vibration isolation system consists of several passive isolators, each having sufficiently low stiffness to produce the desired attenuation at frequencies of interest.

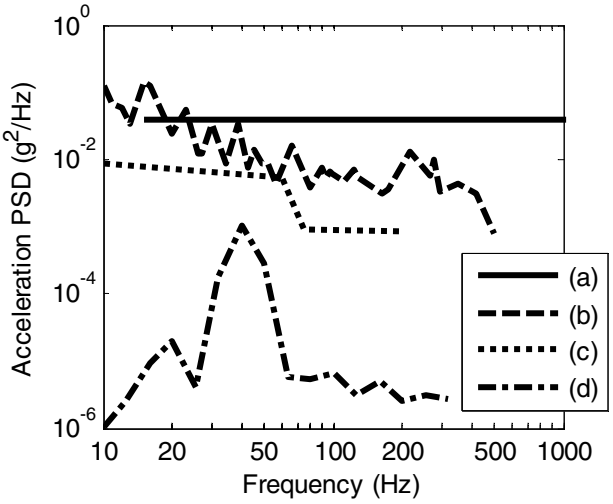

Figure 1. Example vibration levels for (a) aircraft[1], (b) wheeled vehicles[2], (c) ships[3], and (d) the laboratory of an orbiting space station[4].

Note that a passive isolation system will amplify vibration at frequencies below those of primary interest. Thus it is critical to properly define the minimum frequency of interest or, at least, provide for a range of frequencies over which amplification is permitted.

Some of the unique aspects of isolation system design when its purpose is primarily to provide for adequate frequency or phase stability are

- Device fragility is usually not a driving consideration.
- Individual isolator size is of greater concern than the number of isolators.
- The isolation system design is just one of several inter-related inter-disciplinary systems which must be optimized simultaneously, such as electrical design and mechanical packaging.

The first aspect focuses the approach on the attenuation characteristics of the system with transmitted acceleration a lesser concern. The second aspect permits isolator size to be driven by displacement requirements and not the force due to gravity, etc. The third aspect places an emphasis on designation of isolator stiffness, size, and sway space as dependant variables more so than the design of isolation systems for other purposes.

The fundamental characteristics of a vibration isolation system are its natural frequency, f_n, and sharpness of resonance, Q. These characteristics can be determined by assuming the isolation system behaves as a single degree-of-freedom under-damped system. This is a simplification of realistic isolation systems such as the one diagramed in Fig. 2.

The transmissibility of such a system is given by [1]

$$T = \sqrt{\frac{1+\left(\frac{f}{f_n Q}\right)^2}{\left[1-\left(\frac{f}{f_n}\right)^2\right]^2+\left(\frac{f}{f_n Q}\right)^2}} \qquad (2)$$

A plot of (2) is shown in Fig. 3 for Q=3, a typical value for isolators.

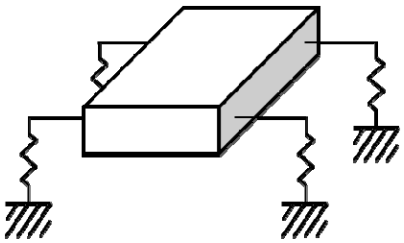

Figure 2. Diagram of an isolation system.

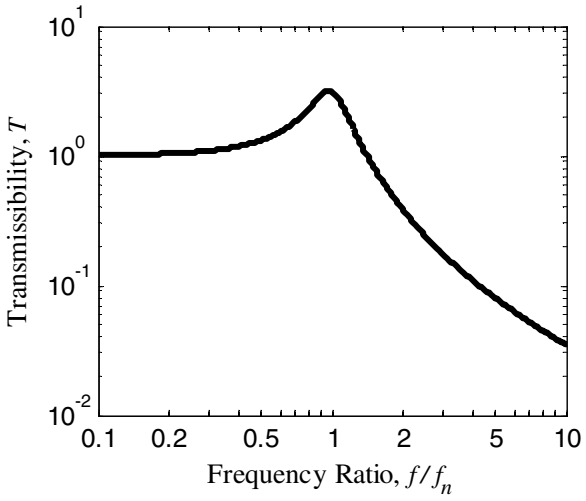

Figure 3. Transmissibility of a single degree-of-freedom system for Q=3.

Solution of (2) for the upper limit on natural frequency yields

$$f_{nul} = \sqrt{\frac{-b-\sqrt{b^2-4ac}}{2a}} \qquad (3)$$

where

$$a = T^2 - 1$$

$$b = \left(\frac{T^2-1}{Q^2} - 2T^2\right) f^2$$

$$c = T^2 f^4 .$$

Equation (3) is plotted in Fig. 4, again for Q=3, for several values of T.

Anticipation of T<0.1 is not realistic due to the inevitable presence of multiple degree-of-freedom behavior [1]. If such attenuation is required, multiple cascaded stages of isolation must be considered. If there are several offset frequencies for which attenuation is required, (3) can be used to determine the lowest value of f_{nul}. This is the upper limit on natural frequency under conditions where performance is required. However, as will be shown in the following section, there is a lower limit on natural frequency as well, dictated by the need for the isolators to survive.

Given f_{nul} and the isolated weight, w, the upper limit on system stiffness, k_{ul}, is obtained from [5]

$$k_{ul} = \frac{w}{g}\left(2\pi f_{nul}\right)^2 \qquad (4)$$

where g is the acceleration of earth's gravity.

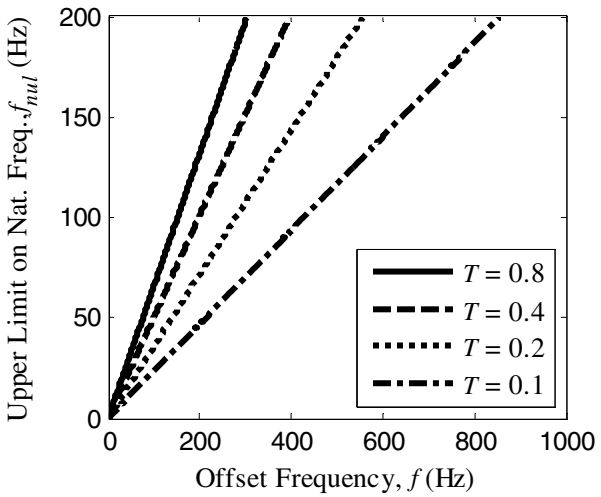

Figure 4. Relationship of the upper limit on natural frequency to the transmissibility required at a particular offset frequency for Q=3.

Given the isolated mass, the upper limit on system stiffness rules out combinations of isolator stiffness and number of isolators which result in a greater system stiffness. For this to be true, the center-of-gravity (CG) and center-of-elasticity (CE) must be coincident or very nearly so. The CG is, of course, the point on which the mass will balance without rotation. Conversely, the CE is the point on which a force can be applied resulting in equal deflection of all isolators. If the CG and CE are not coincident, so called "coupling" will occur and it becomes necessary to consider rotational response to translational excitation. Furthermore, device sensitivity to rotational acceleration is a relatively unexplored area. Substitution yields

$$k_{ul} = \frac{w}{g}(2\pi f)^2 \left[\frac{\left(2T^2 - \frac{T^2-1}{Q^2}\right) - \sqrt{\left(2T^2 - \frac{T^2-1}{Q^2}\right)^2 - 4T^2\left(T^2-1\right)}}{2\left(T^2-1\right)} \right] \quad (5)$$

IV. Producibility

It is unrealistic to expect an isolation system to exhibit the same natural frequency over time and from unit-to-unit. Thus, the upper limit on natural frequency, f_{nul}, will be accompanied by a lower limit on natural frequency, f_{nll}, separated from the upper limit to some extent. The separation may be defined by a factor F as follows

$$f_{nll} \le \frac{f_{nul}}{F} \quad (6)$$

The actual value of F is a result of at least

- Unit-to-unit variability due to manufacturing tolerances on natural frequency of up to 30% [6].
- Temperature sensitivity exhibited by elastomers resulting in natural frequencies varying by 15% to 60% depending on material and temperature range [7].
- Anisotropy, especially for wire rope, resulting in natural frequencies varying by 60% to 200% depending on the configuration and direction of displacement [8].
- Strain sensitivity exhibited by both elastomers and wire rope result in natural frequencies varying by 30% to 70% depending on strain amplitude [7].

The values of F in Table I are appropriate for rough sizing of isolators to help ensure that they are producible.

TABLE I. Practical Separation of Natural Frequency Limits

Type of Isolators	*F*
Off-the-shelf isolators	3.0
Custom isolators	2.0
Custom isolators operating under limited conditions	1.2

V. Isolation System Size

A. Sway Space

The lower limit on natural frequency typically defines the sway space required. Damage to the device could occur if the sway space were not adequate for the deflection, resulting in a collision. Assuming single degree-of-freedom behavior, the rms displacement of the isolation system is

$$d_{rms} = \frac{g}{(2\pi f_n)^2} G_{rms} \quad (7)$$

where G_{rms} is the rms acceleration response. In general

$$G_{rms} = \sqrt{\int \left(T^2 S_e\right) df} \ . \quad (8)$$

It can be shown that the rms acceleration, when S_e is reasonably flat (white), is [9]

$$G_{rms} \cong \sqrt{\frac{\pi}{2} f_n Q S_e\left(f_n\right)} \quad (9)$$

where $S_e(f_n)$ is the excitation PSD evaluated at the isolation system natural frequency. A common assumption is that the

sway space, s, needed to accommodate the maximum displacement is

$$s = 3d_{rms}\,. \tag{10}$$

This assumption is based on the fact that due to Gaussian random vibration, displacements which exceed three times the rms value occur less than 0.3% of the time and can be ignored. Thus, the sway space needed to equal the maximum displacement of the isolation system is

$$s = \frac{3gF^{\frac{3}{2}}}{(2\pi)^2 f_{nul}^{\frac{3}{2}}}\sqrt{\frac{\pi}{2}QS_e\left(\frac{f_{nul}}{F}\right)}\,. \tag{11}$$

It is apparent that the lower the natural frequency, the larger the sway space required. The mechanical package, then, must leave sufficient room to include the sway space plus any desired clearance.

B. Isolator Size

The lower limit on natural frequency also defines the size of the isolator required. An isolator not large enough to accommodate the maximum displacement would be damaged even if the sway space were available. Thus, any isolator considered must have its maximum permissible displacement compared to the maximum displacement calculated in the previous section. Even isolators large enough to accommodate the maximum displacement could be damaged if the displacements were repeatedly applied, eventually resulting in fatigue failure. A useful assumption is that the relationship between displacement and the number of cycles to failure at that displacement follows the so-called "power law" [10]

$$N = \left(\frac{d_0}{d_{CA}}\right)^{2m} \tag{12}$$

where d_{CA} is the constant amplitude displacement and N is the number of cycles to failure which generally occur at the rate dictated by the system natural frequency, f_n, such that

$$N = f_n t \tag{13}$$

where t is the time to failure in seconds. The constants d_0 and m depend on the make-up of the isolator.

The exponent, m, determines the relative damage done by displacements of differing amplitudes. Published values of m range from approximately 1.6 to 2.0 for elastomers [9, 11, 12] and similar values can be found for wire rope in bending [13, 14]. A value of m=1.6 is a conservative value useful for rough sizing.

The factor, d_0, is the value of d_{CA} that corresponds to $N=10^0=1$ when extrapolated from much larger numbers of cycles. However, this is not literally the displacement that would cause failure in one cycle. The maximum permissible displacement of the isolator can be quite different than d_0. Published values of d_0 indicate that it is roughly proportional to the height of the resilient portion of the isolator, h, for the most compact isolator types. That is

$$d_0 = Ch \tag{14}$$

where the constant of proportionality C, ranges from approximately 20 to 40 for elastomers [9, 11, 12]. Similar values can be found for wire rope in bending [13, 14]. A value of C=20 is a conservative value useful for rough sizing. A plot of the power law relationship is shown in Fig. 5.

The data that is available for determining these constants are based on tests of isolators conducted with constant amplitude displacement as indicated by the definition of d_{CA}. To meet our needs it is necessary to determine the constant amplitude displacement which is equivalent to the random displacement experienced by isolators subjected to broadband random vibration.

Miner's rule provides a means of accumulating the damage due to displacement at various amplitudes [9]. By accumulating the damage due to Gaussian distributed amplitudes using the value of m given above, it can easily be shown that a constant amplitude displacement of approximately two times the rms displacement produces equivalent damage. Thus

$$d_{CA} = 2d_{rms}\,. \tag{15}$$

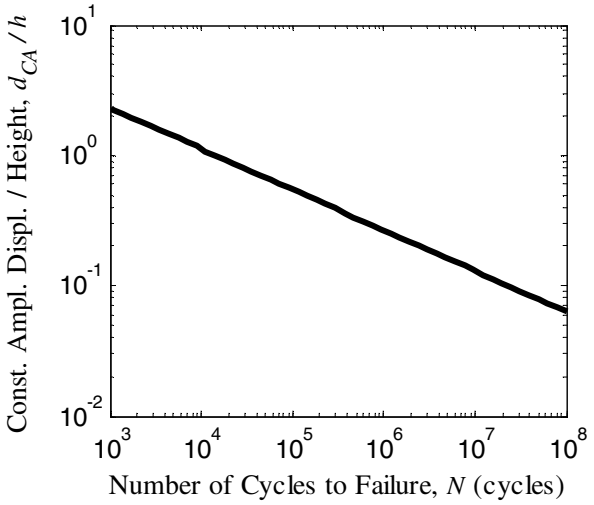

Figure 5. "Power law" relationship between displacement and number of cycles to failure.

Making substitutions and solving for *h* gives

$$h = \frac{2gt^{\frac{1}{2m}} F^{\left(\frac{3}{2}-\frac{1}{2m}\right)} \sqrt{\frac{\pi}{2} Q S_e \left(\frac{f_{nul}}{F}\right)}}{(2\pi)^2 C f_{nul}^{\left(\frac{3}{2}-\frac{1}{2m}\right)}}. \quad (16)$$

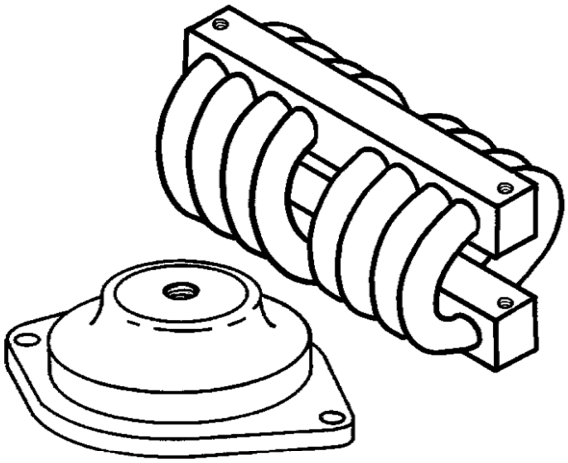
Using (16), it is possible to roughly estimate the size of each isolator required to meet the durability requirements.

VI. Isolator Selection

Examples of vibration isolators for use with acceleration sensitive devices are shown in Fig. 6. The typical resilient part is an elastomer or wire rope. Examples of elastomers used are natural rubber and silicone rubber. Wire rope is typically corrosion resistant steel. In either case, metal flanges or other features are incorporated which permit the isolator to be mechanically attached to both the isolated mass and the supporting structure.

A. Off-the-Shelf Isolators

Off-the-shelf isolator selection begins with the height determined from (16). From among all candidate isolators, only those whose resilient portion has a height in excess of h need be considered. Next, comparison of the required sway space from (11) with the maximum permissible deflection will rule out more. Finally, determine the number of isolators of each type which results in the total stiffness which is close to, but does not exceed, the stiffness obtained from (5). From the remaining candidates, choose the one that has an agreeable number of isolators (typically four, six, eight, or more) as well as maximizes design margin in other areas.



(a) (b)

Figure 6. Typical vibration isolators for used with acceleration sensitive devices. The resilient element is often (a) an elastomer or (b) wire rope.

B. Custom Isolators

There are often gaps between series of isolators which can be filled with custom designs. Isolators with resilient parts made of elastomer lend themselves to customization in more ways than wire rope. With either type of isolator the dimensions of the resilient part and of the attachment features can be customized. With elastomers, the material properties can be adjusted. Wire rope can be exercised and/or lubricated to adjust its properties.

VII. Common Pitfalls

There are several pitfalls that the package designer for an acceleration sensitive device is likely to encounter. First, there are a number of assumptions inherent in the method shown or ones like it.

- Although the sharpness of resonance, Q=3, has been assumed, it can vary between 2 and 10 depending on the resilient material, strain, temperature, and chemical exposure.
- The stiffness indicated here must be the dominant stiffness. "Shorting" stiffness in parallel with the isolators, such as from wires or cooling air ducts, must be much less.
- Applications which have significant constant acceleration or shock levels, have survival vibration levels which exceed the performance vibration levels, or must endure conditions which cause significant creep, will require more sway space than indicated here. However, it is possible to include bumpers which limit sway to that indicated here with the penalty of higher transmitted acceleration.
- Estimates of fatigue life are extremely rough. They do not consider the cumulative damage from vibration in multiple directions. At best they are a prediction for the median of the population. In order to account for scatter in the data, a safety factor 3 to 10 on life may be appropriate depending on the criticality of the application [14].

Second, for the reasons given above and others, it is absolutely necessary to confirm all conclusions formed by this approach with the isolator supplier. The intent of this method is to get the isolation system design in the right "ball-park" so that major re-design is unnecessary at later stages of the design process.

Finally, creative packaging engineers often fall prey to the temptation to design their own vibration isolators. This almost always ends in disappointment as the lessons learned by experienced designer/manufacturers cannot be leveraged. If even just one of the several inter-related design constraints is ignored, performance, durability, and/or producibility will suffer.

VIII. EXAMPLE

Consider the design of packaging for an acceleration sensitive device weighing 1 lb which has an upper limit on power spectral density of acceleration of 4×10^{-4} g^2/Hz at 300 Hz offset. The device is to be deployed on the aircraft of Fig. 1 (S_e=4×10^{-2} g^2/Hz) for 10 hours. The required transmissibility from (1) is

$$T = \sqrt{\frac{4\times10^{-4}}{4\times10^{-2}}} = 0.1 .$$

Assuming Q=3, (3) provides the upper limit on natural frequency f_{nul}=70 Hz and (4) limits the system stiffness to be no greater than

$$k_{ul} = \frac{1}{386}(2\pi 70)^2 = 501 \text{ lb/in.}$$

or 125 lb/in. each for a four isolator system.

Assuming off-the-shelf isolators are desired (F=3.0) the sway space from (11) is

$$s = \frac{3\cdot 386\cdot 3.0^{\frac{3}{2}}}{(2\pi)^2 70^{\frac{3}{2}}}\sqrt{\frac{\pi}{2}\cdot 3\cdot 0.04} = 0.11 \text{ in.}$$

Furthermore, from (16), in order to have sufficient durability, the resilient portion of the isolator must have a height at least

$$h = \frac{2\cdot 386\cdot (10\cdot 3600)^{\frac{1}{2\cdot 1.6}} 3.0^{\left(\frac{3}{2}-\frac{1}{2\cdot 1.6}\right)}\sqrt{\frac{\pi}{2}3\cdot 0.04}}{(2\pi)^2\cdot 20\cdot 70^{\left(\frac{3}{2}-\frac{1}{2\cdot 1.6}\right)}}$$

$$= 0.27 \text{ in.}$$

Examination of isolator catalogs, following the steps outlined in section VI of this paper, readily leads to candidate isolators employing either elastomers or wire rope. These candidates can form the basis for packaging concepts.

IX. CONCLUSION

This paper presents an approach to the design of vibration isolation systems tailored to the needs of the package designer for an acceleration-sensitive device. This approach is not rigorous or all-inclusive but it does establish realistic expectations for the size and performance of the isolation system early in the mechanical design process. Armed with only the required stability and vibration environment, one can perform rough sizing of the sway space and isolators. The resulting stiffness can be used to identify candidate off-the-shelf isolators or to begin the process of specifying custom ones. The approach respects limitations imposed by producibility while warning of common pitfalls.

Limited Live-time Measurements of Frequency Spectra

D. A. Howe, N. Ashby, D. Lirette, A. Hati, and C. Nelson
Time and Frequency Division
National Institute of Standards and Technology
Boulder, CO 80305

***Abstract*—Frequency-difference-of-arrival (FDOA) can be used to monitor and track an emitter's location by observing Doppler frequency shifts of the carrier during short pulsed transmissions. This specific application needs to consider two frequency-stability levels: the short τ_{on}-average frequency measurements and the sampling time interval between measurements, denoted by τ_s. We show the advantage of using "dynamic" ThêoH for τ_{on} frequency measurements. Between τ_{on} transmissions while powered off, the emitter's reference-oscillator frequency will change due to power-start thermal variations, vibration, stress, and other frequency disturbances. If we regard long-term frequency instability as an uncertainty on an oscillator's expected or designated frequency, then the dominant error of frequency prediction is likely to be the error due to frequency drift and/or random walk FM, indicating the non-stationary behavior or disturbances. A two-sample variance is devised, called "Psi-variance," that has desirable statistical properties similar to those of the Allan variance. From this, we compute the power spectral density of frequency fluctuations, $S_y(f)$, from which phase noise, L(f), can be derived.**

I. Introduction and Summary

We characterize an oscillating signal for applications in which the oscillator itself is either only "on" or measured for short times (τ_{on}) between long, periodic or "stride" intervals (τ_s), during which the oscillator is off for $\tau_s - \tau_{on}$ seconds. A statistic called Psi-deviation, $\Psi(\tau_{on},\tau_s)$, is created that estimates the frequency-prediction error from the last frequency measurement. The variance of the prediction is $\Psi^2(\tau_{on},\tau_s)$, which is a time-averaged, two-sample variance and provides desirable properties similar to the Allan variance. The application is the tracking of an emitter, transmitting only for short periods of time, by means of frequency difference of arrival (FDOA). While the emitter's oscillating signal is on and transmitting (or being measured), receivers calculate tracks based on Doppler shifts, that in turn provide a navigation solution. On a two-dimensional plane, circular error probability (CEP) due to the emitter's oscillator noise is minimized, given low enough phase noise and frequency error during the interval τ_{on}. Because τ_{on} is short and we want to optimally characterize frequency stability, we compute ThêoH [1]. Using 10 sequential segments of τ_{on}, we display each segment's ThêoH in a "waterfall" or surface plot, to characterize the oscillator's turn-on transient. Dubbed "Dynamic ThêoH", or DThêoH, it allows us to compare the time taken by different oscillators to obtain consistent ThêoH. Oscillators having low enough cost, size, weight, and power appropriate for power cycling are OCXOs and TCXOs or oven and temperature compensated MEMs oscillators, respectively. Section II details the measurement setup and an example of DThêoH for an OCXO. Section III motivates and develops frequency prediction error $\Psi(\tau_{on},\tau_s)$. Section IV derives the relationship between Ψ-variance in the time domain and spectral density $S_y(f)$. Sections V and VI show time-domain and frequency-domain measurements, respectively, comparing an OCXO and a TCXO in limited live-time operation.

II. Dynamic ThêoH while Oscillator is On

We want to capture oscillator turn-on frequency stability and establish dynamic ADEV as a useful format [2]. ThêoH is preferred rather than ADEV since an oscillator is on for only a short time compared to its off-time. ThêoH is a hybrid (hence the "H") of ADEV for short-term averaging times plotted with a bias-removed version of Thêo1, called ThêoBR [3] for long-term. The Thêo portion characterizes to 75 % of a data run, whereas straight ADEV characterizes to only 20 % [1]. To illustrate, ThêoH plots are generated from measurements of oscillators powered on for a data run of only 3 s. Fig. 1 shows the measurement setup. Dynamic ThêoH is a waterfall graph where each 3 s run is parsed into ten sequential time segments, then ThêoH is computed for each segment and displayed as another waterfall plot, as shown in Fig. 2.

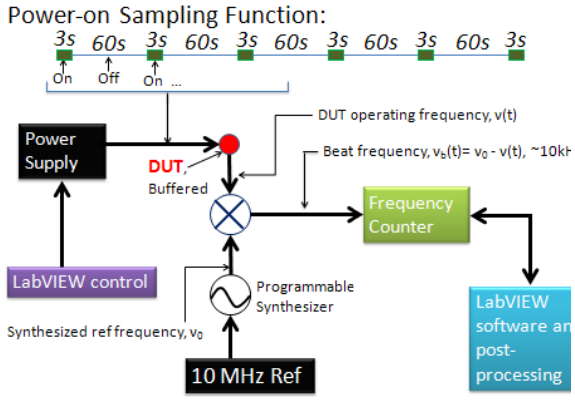

Figure 1. The device-under-test (DUT) is a temperature-compensated or oven-controlled oscillator with quartz or MEMs

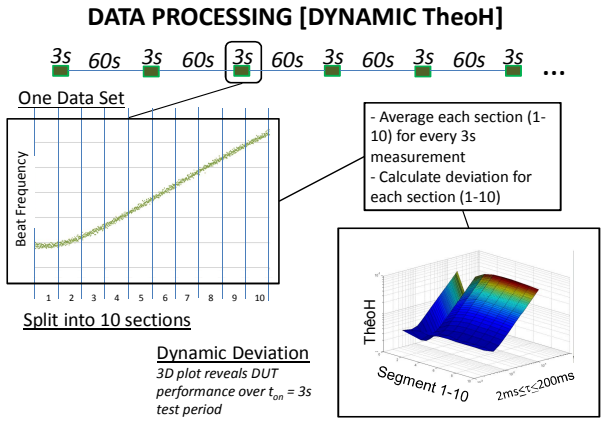

Figure 2. Dynamic ThêoH plot. Surface smoothness is a general measure that the test oscillator has attained steady-state operation after having been powered on.

Such plots provide a quick assessment of how long, and to what degree, it takes an oscillator to settle down to a consistent stability after being turned on.

We will use an example in which the emitter is repeatedly turned on for τ_{on} = 3 s every τ_s = 60 s. In addition to the frequency that is traced during start-up, discussed above, an important criteria is the start-up frequency reproducibility and its characterization, described next.

III. Frequency Prediction Error for Multiples of τ_S

We wish to estimate an oscillator's frequency at its next turn-on. While there are any number of different ways to make this estimate based on a history of actual measurements [4], we construct a two-sample frequency prediction to mimic the desirable properties of noise identification, convergence, convenience, and acceptance provided by the two-sample standard variance, better known as the Allan variance, and its square root, ADEV [5]. The two-sample, no dead-time Allan variance has widely accepted statistical properties, however, limited-live applications have substantial dead-time.

Fractional-frequency error $y_{on}(t)$ and its prediction at $y_{on}(t+\tau_s)$ is based on the reasonable assumption that (or one expects that) any given manufacturer wants $y_{on}(t+\tau_s)$ to be the same value as measured values of $y_{on}(t)$. If we write $y_{on}(t+\tau_s) = (1+\varepsilon)y_{on}(t)$, where ε is a random variable, we also expect average $\frac{1}{N}\sum_{n=1}^{N} y_{on}(t-n\tau_s)$ to be dependent on N, i.e. nonstationary, without a central limit, rendering this average of little or no practical use in the estimate of the frequency error designated as $\hat{y}_{on}(t+\tau_s)$. The efficient predictor in the presence of random walk noise is $\hat{y}_{on}(t+\tau_s) = y_{on}(t)$, the last measured value of y_{on}. The variance of this expectation can be written as a first difference

$$\Psi^2(\tau_{on},\tau_s) = \left\langle \left[\hat{y}_{on}(t+\tau_s) - y_{on}(t)\right]^2 \right\rangle, \quad (1)$$

where $\langle\cdot\rangle$ denotes an ensemble average. Like AVAR, (1) is the variance of an increment that converges in the limit.

DEFINITION: Samples of the fractional frequency-error function *y(t)* occur at a rate f_0 having an interval $\tau_0 = \frac{1}{f_0}$ (setup shown in Fig. 1). Given a sequence of fractional frequency errors $\{y_n : n=1,\ldots,M\}$ with a sampling period between adjacent measurements given by τ_0, we define the $m\tau_0$-average fractional-frequency deviate as

$$^{m}\bar{y}(t) \equiv \frac{1}{m}\sum_{j=0}^{m-1} y_{n-j},$$

where $y_n = y(t)$ with $n = t/\tau_0$ starting from a designated origin $t_0 = 0$. We also define psi-variance from the space of all possible two-sample increments as:

$$\Psi_y^2(\tau_{on},\tau_s) \equiv \left\langle \left[{}^{\tau_{on}}\bar{y}(t) - {}^{\tau_{on}}\bar{y}(t-\tau_s)\right]^2 \right\rangle \quad (2)$$

where $\langle\cdot\rangle$ denotes an ensemble average and ${}^{\tau_{on}}\bar{y}(t)$ is the mean frequency over duration $\tau_{on}=m\tau_0$. Fig. 1, top, shows the sampling function associated with $\Psi^2(\tau_{on}, \tau_s)$ acting on $\{y_n\}$, where τ_{on} is called the averaging or live interval and τ_s - τ_{on} is the oscillator's dead time. Note that $\Psi^2(\tau_{on}, \tau_s)$ becomes twice the two-point standard (Allan) variance $\sigma_y^2(\tau_s)$ if $\tau_{on} = \tau_s$.

IV. Relationship of $S_y(f)$ to Ψ–variance

For computing the usual power spectrum, we start with Parceval's theorem:

$$\Psi^2(\tau_{on},\tau_s) = 4\int_{\frac{1}{2\tau_s}}^{f_h} |H(f)|^2 S_y(f)\,df \quad (3)$$

where *H(f)* is the frequency-domain response of the time-domain sampling function of $\Psi^2(\tau_{on}, \tau_s)$ shown at the top of Fig. 1. $S_y(f)$ of the emitter is multiplied by the FT squared of the sampling function to obtain $|H(f)|^2$. We obtain:

$$\Psi^2(r,\tau_{on},\tau_s) = 4\int_{\frac{1}{2\tau_s}}^{f_h} \frac{S_y(f)\,df}{\pi^2\tau_{on}^{\,2} f^2}\left(\sin(\pi\tau_{on}f)\sin(\pi r\tau_s f)\right)^2 \quad (4)$$

where r = t/τ_s (starting from origin t_0) is a counting index r=1,2,3… representing the r^{th} data run of 3 s duration.

The f-domain response function $|H(f)|^2$ is shown in Fig. 3. This response is +20dB/decade like the Allan variance for low frequencies up to the peak at $f\tau_s$=½. There is insufficient roll off above this peak, so white and flicker of phase noise types will cause the level of $\Psi^2(\tau_{on},\tau_s)$ to depend on f_h in (4). This kind of dependence, though, is not a concern as of yet, since DUT random walk FM (and drift) are likely to dominate limited-live applications, as discussed in Section III, while white FM can occur from the measurement system at short- term.

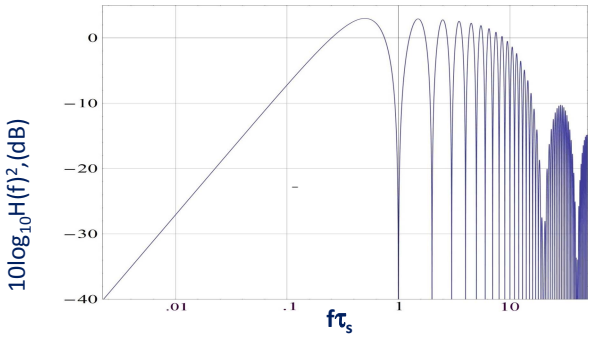

Figure 3. Frequency response $|H(f)|^2$ of $\Psi^2(\tau_{on},\tau_s)$ in (3), $\tau_{on} = (\tau_s)/20$, r=1.

Table 1 compares the transform to frequency spectrum $S_y(f)$ of $\frac{1}{2}\Psi^2(\tau_{on}, \tau_s)$ and $\sigma_y^2(\tau_s)$. We use the scaling factor "1/2" in $\frac{1}{2}\Psi^2(\tau_{on}, \tau_s)$ to normalize its result to equal $\sigma_y^2(\tau_s)$ if $\tau_{on}=\tau_s$, i.e., zero dead-time. Furthermore, the zero-dead time Allan and $\frac{1}{2}\Psi^2(\tau_{on}, \tau_s)$ respond identically to white FM noise having equal frequency-spectral coefficient h_o [6]. Flicker noise is given in terms of $\sigma_y^2(\tau_s)$ to simplify the formula. The Table evidences the bias on $\sigma_y^2(\tau_s)$ due to limited-live operation of the DUT.

We now observe the intrinsic level of random walk or drift that properly characterizes the DUT as τ approaches its maximum around 2 s, using ThêoH. Since fast-frequency measurements mask or are not sensitive to DUT-based PM-noise types that would appear as "super white" FM-noise in y(t) raw data, $\frac{1}{2}\Psi^2(\tau_{on}, \tau_s)$ is never biased by this noise when compared to AVAR. Since the bias never occurs, the unbiased white-FM-transform coefficient h_0 used for $S_y(f)$ does not depend on a high-cutoff, $f_c=1/(2\tau_{on})$, as indicated in Table 1. Random walk (and drift) are slightly biased (depends on $r = \tau_s/\tau_{on}$ [7]) and the positive τ-slope is the same for $\Psi^2(\tau_{on}, \tau_s)$ and $\sigma_y^2(\tau)$. It is important to note that flicker-FM noise using dead-time AVAR (here $\Psi^2(\tau_{on}=const., \tau_s=\tau)$) will appear as white-FM noise [8].

TABLE I. TABLE OF TRANSFORMS

Noise Type	Allan $\sigma_y^2(\tau)$	Psi Variance $\frac{1}{2}\Psi^2(\tau_{on},\tau_s)$
White FM	$\frac{h_0}{2\tau}$	$\frac{h_0}{2\tau}$
Flicker FM	$2h_{-1}\log 2$	$\frac{h_{-1}}{2\tau_{on}^2}\left(\begin{array}{l} 4\tau_s\tau_{on}\tanh^{-1}\frac{\tau_{on}}{\tau_s} \\ +2\tau_{on}^2\ln\frac{\tau_s}{\tau_{on}}+ \\ (\tau_s^2+\tau_{on}^2)\ln\left(1-\frac{\tau_{on}^2}{\tau_s^2}\right)\end{array}\right)$
Random Walk FM	$\frac{2\pi^2 h_{-2}}{3}\tau$	$\frac{\pi^2 h_{-2}}{3}(3\tau_s-\tau_{on})$

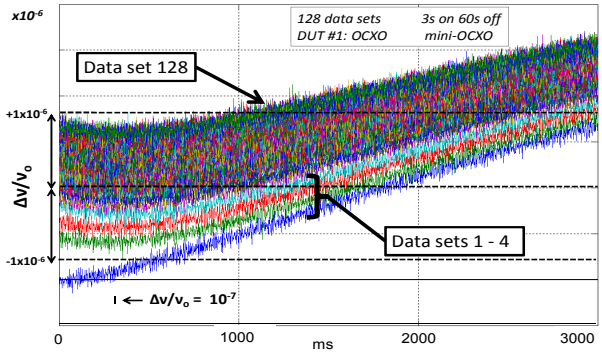

Figure 4. 128 sets of raw fractional frequency measurements. Set 1 is the first series of y(t), and the oscillator is first turned on from a "cold" start. Each trace is 3 s worth of data repeating every 60 s during which the oscillator is turned off. ν_o = 16.384MHz.

It remains to be seen if flicker-FM can be reliably detected by unraveling Ψ-variance to obtain AVAR. However, this distinction is usually unimportant to Doppler-relevant applications.

V. TIME DOMAIN MEASUREMENTS OF OSCILLATORS

We use a commercial miniature OCXO and TCXO at 16.384 and 26 MHz, respectively, as DUTs for an example. Fig. 4 shows 128 raw $y(\tau_{on})$ data runs of 2 ms sampled measurements on top of each other. At the very bottom, data set #1 starts the test oscillator. One can see that the first four sets capture a larger set-to-set overall variation than the remaining 124. In real applications, the oscillators are not cold-started but are in process, so the initialization sets such as 1 to 4 can generally be ignored. We process individual runs of Fig. 4 with dynamic ThêoH as described in Section II. This is shown in Fig. 5 along with averages of ThêoH. One can see that a consistent level of stability (drift+white FM) is reached after about 60 ms. Measurements are an equispaced sequence of fast-frequency errors, y(t), and are not time-errors, x(t). Thus, measurement noise is white FM and not typified by PM noise during runs of τ_{on}. Fig. 5 shows measurement white FM in short-term, i.e., $\sigma_y(\tau_0)\propto\tau^{-1/2}$.

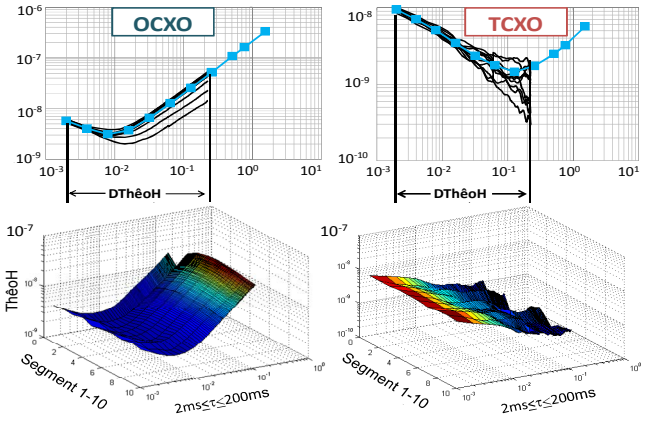

Figure 5. ThêoH deviation (top) and dynamic ThêoH (DThêoH) deviation (bottom) for the OCXO and TCXO. Note that the longest τ for DThêoH corresponds to 1/10 of the longest τ for ThêoH.

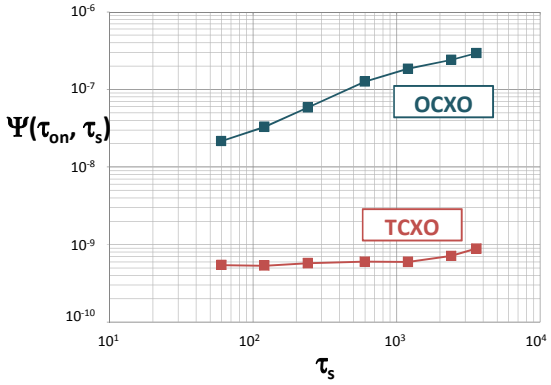

Figure 6. Ψ-deviation for the OCXO and TCXO. The minimum averaging time is τ_s = 60 s. τ_{on} = 3 s.

With the average of each data run, $^{\tau_{on}=3s}\overline{y}(t)$, we compute $\Psi^2(\tau_{on}, \tau_s)$ using all runs. Results are shown in Fig. 6, where we observe the level and rate of frequency reproducibility as a function of $n\tau_s$ for each time that the DUT is powered on. This level and rate may or may not limit other application-specific goals. Likewise, with a given level and rate, one may be forced to use application strategies or improve emitter reproducibility to achieve goals. Our finding is that there is no reliable method for estimating $\Psi(\tau_{on}, \tau_s)$ from $\sigma_y(\tau)$.

VI. Frequency Domain Measurements of Oscillators

Phase noise L(f) is important during limited-live Doppler tracking. L(f) is a convenient standard used to determine the error vs. range in offset-f, proportional to emitter velocity, as set by the emitter. L(f) is computed from the fast-frequency measurements obtained using Fig. 1. For a given τ_{on} data run sampled at t_0, the fractional-frequency spectrum $S_y(f)$ is obtained from the discrete FT of the series [6]:

$$Y(m\Delta f) = \frac{1}{N}\sum_{k=1}^{N} y(k\tau_0)e^{-2\pi i m\Delta f k\tau_0} \qquad (5)$$

where $\Delta f = 1/(N\tau_0)$. The one-sided spectral density of y(t) is computed by adding the squares of the real and imaginary components of Y and dividing by the RBW of the data run:

$$S_y(m\Delta f) = 2\frac{\left\{\mathrm{Re}\left[Y(m\Delta f)\right]\right\}^2 + \left\{\mathrm{Im}\left[Y(m\Delta f)\right]\right\}^2}{\Delta f} \qquad (6)$$

with BW = 1 Hz and RBW = Δf. Converting to L(f), we use [6]:

$$L(m\Delta f) = \frac{1}{2}S_\varphi(m\Delta f) = \frac{1}{2}\frac{\nu_0^2}{(m\Delta f)^2}S_y(m\Delta f) \qquad (7)$$

and obtain L(f) plotted on log-log scales in Fig 7.

In practice, the noise of each limited-live spectrum affects Doppler-track error. Averages of limited-live estimates of L(mΔf) are shown in Fig. 7 for TCXOs #1 and #2. A word of caution — L(f) derived from fast-frequency measurements in

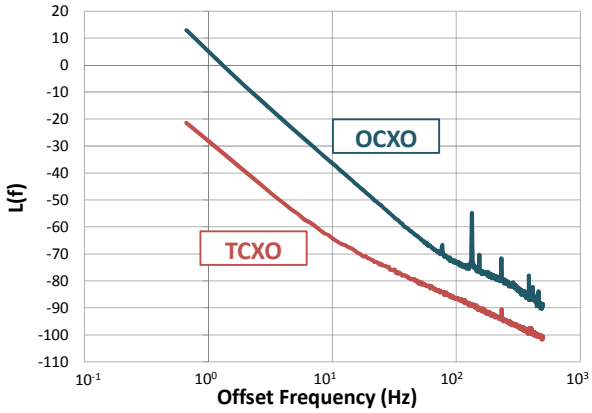

Figure 7. L(f) for the OCXO and TCXO from dead-time measurements.

Fig. 1 will not be sensitive to white and flicker PM noise, as mentioned earlier. This is not problematic to most limited-live characterizations, since the measurement high frequency cutoff (BW) is $f_c = 1/(2\tau_0)$ and τ_0 is of the order 10^{-3} in this case. Thus, L(f) is not computed beyond f of several hundred hertz, even in the best case.

For future studies, characterization of limited-live oscillators in this paper will be used while such oscillators are subject to temperature and vibration stresses.

ACKNOWLEDGMENT

The authors wish to thank Kyle Byrnes for setting up the preliminary phase of this experiment and writing initial computer code.

Simplified Phase Noise Model for Negative Resistance Oscillators

Jeremy Everard and Min Xi
Department of Electronics
University of York,
Heslington, York,UK

***Abstract*— This paper describes a greatly simplified model for the prediction of phase noise in oscillators which use a negative resistance as the active element. It is based on a simple circuit consisting of the parallel addition of a noise current, a negative admittance/resistance and a parallel (Q limited) resonant circuit. The transfer function is calculated as a forward trans-resistance (V_{OUT}/I_{IN}) and then converted to power. The effect of limiting is incorporated by assuming that the phase noise element of the noise floor is KT/2 ie -177dBm/Hz at room temperature.. The answer is the same as more complex analyses but enables a simple clear insight into the operation of oscillators. The phase noise for a given power in the resonator in the resonator appears to be lower than in feedback oscillators. The reasons for this are explained.**

I. INTRODUCTION

The phase noise in oscillators often sets the ultimate limit in communications and RADAR systems. It is therefore useful to develop simple accurate linear theories which both highlight the underlying operating principles and is simple to use.

Oscillator phase noise for feedback oscillators was first described by Leeson [1] and the spectral density function was shown. This equation was manipulated and shown to have an optimum coupling coefficient between the resonator and the feedback amplifier for minimum phase noise as presented by Parker [2].

It is useful to develop simple linear theories from first principles and a simple accurate linear theory was developed by Everard at Philips Research Laboratories, UK in 1983 and published in [3] [4] [5]. At that time a similar theory for negative resistance oscillators was developed although some of the noise aspects were not completely clear.

II. FEEDBACK OSCILLATORS

The linear theory for feedback oscillators is based on the model shown in Figure 1 where the single input is modelled as two inputs which are added together. One of these is for noise injection and the other for the feedback path. A transfer function $V_{OUT(node2}/V_{IN2}$ can therefore be calculated, converted to power and a phase noise equation derived. The LCR circuit is used to model the resonator (and can be used for most types of resonators. Any coupling transformers can be incorporated by varying the values of L, C and R_{LOSS}.

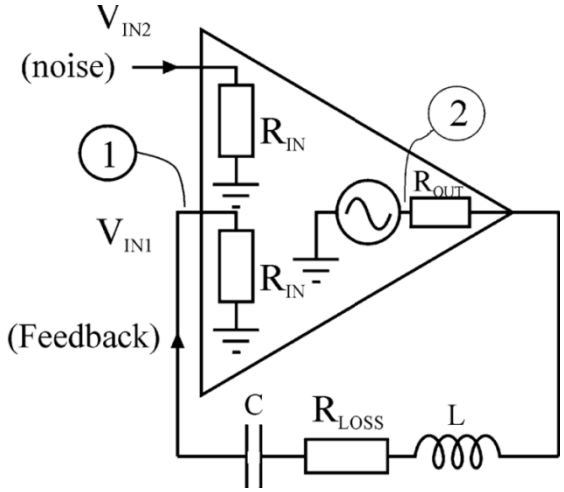

Figure 1 Simple Phase Noise Model for Feedback Oscillators

An equation for phase noise based on this model is shown in the following equation [5]:

$$L(f) = A \cdot \frac{FkT}{8\,(Q_0)^2\,(Q_L/Q_0)^2\,(1-Q_L/Q_0)^N\,P}\left(\frac{f_0}{f}\right)^2$$

Where:

1. N = 1 and A = 1 if P is defined as PRF and ROUT = zero
2. N = 1 and A = 2 if P is defined as PRF and ROUT = RIN
3. N = 2 and A = 1 if P is defined as PAVO and ROUT = RIN

If we take assumption 3, this equation becomes:

$$L(f) = 1 \cdot \frac{FkT}{8\,(Q_0)^2\,(Q_L/Q_0)^2\,(1-Q_L/Q_0)^2\,P_{AVO}}\left(\frac{f_0}{f}\right)^2$$

It is interesting to note the equation is very similar to the equation for power dissipated in a resonator (P_{RLOSS}) as a function of P_{AVO}

$$P_{RLOSS} = 2\frac{Q_L}{Q_0}\left(1 - \frac{Q_L}{Q_0}\right)P_{AVO}$$

The power in the resonator is (P_{RLOSS}) is maximum and hence phase noise is minimum when Q_L/Q_0 = ½. At this point, half the power is dissipated in the resonator, ¼ is transmitted and ¼ is reflected.

This therefore means that the phase noise is minimum when maximum power is dissipated in the resonator. This is also discussed in [6].

The phase noise equation for minimum noise is therefore:

$$L(f) = \frac{2FkT}{P_{AVO}}\left(\frac{f_0}{f}\right)^2$$

It should be noted that this equation is half the value of Leeson's equation when the optimum Q_L/Q_0 is included.. Leeson realised the factor of two shortly after he published his famous paper (private communication from Prof Leeson).

This will be compared later with the phase noise equation for negative resistance oscillators. This equation has been found to produce very accurate modelling of the phase noise of feedback oscillators (0 to 1dB) It also gives a clear insight into the operation of oscillators.

III. Negative Resistance Oscillators

A number of models have been produced for negative resistance oscillators [7-9]. A simple model for a negative resistance oscillator is shown in figure 2. This consists of the parallel addition of a noise current, a negative admittance/resistance and a parallel (Q limited) resonant circuit. The noise current is generated by R_{LOSS} and for this calculation the load resistance and noise figure are ignored. This is similar to the model shown in a paper by Hajimiri and Lee [9] although in their paper the calculation was performed in a different way and the emphasis was on the impulse sensitivity function.

The transfer function is calculated as a forward trans-resistance (Vout/Iin) and then converted to power. The effect of limiting is incorporated by assuming that the phase noise element of the noise floor is KT/2 ie -177dBm/Hz at room temperature

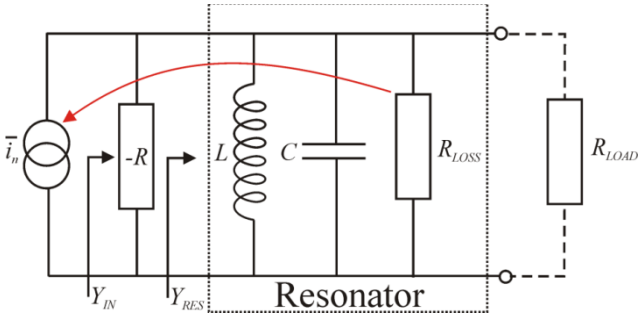

Figure 2 Simple Model for a Negative Resistance Oscillator

A. Calculation of the resonator Admittance

The admittance of the resonator is:

$$Y_{RES} = \frac{1}{j\omega L} + j\omega C + \frac{1}{R_{LOSS}}$$

If we now look at ω as the sum of a centre angular frequency and offset frequency ($\omega_0 + \Delta\omega$) where $\Delta\omega$ is the offset frequency:

$$Y_{RES} = \frac{-j}{(\omega_0 \pm \Delta\omega)L} + j(\omega_0 \pm \Delta\omega)C + \frac{1}{R_{LOSS}}$$

$$Y_{RES} = \frac{-j}{\omega_0\left(1 \pm \frac{\Delta\omega}{\omega_0}\right)L} + j\omega_0\left(1 \pm \frac{\Delta\omega}{\omega_0}\right)C + \frac{1}{R_{LOSS}}$$

At resonance: $\omega_0 L = 1/\omega_0 C$ Therefore

$$Y_{RES} = \frac{-j\omega_0 C}{\left(1 \pm \frac{\Delta f}{f_0}\right)} + j\omega_0\left(1 \pm \frac{\Delta f}{f_0}\right)C + \frac{1}{R_{LOSS}}$$

Where ω is the angular frequency.

Assuming that: $\Delta f << f_0$, then as:

$$Y_{RES} = j\omega_0 C\left(-\left(1 \mp \frac{\Delta f}{f_0}\right) + \left(1 \pm \frac{\Delta f}{f_0}\right)\right) + \frac{1}{R_{LOSS}}$$

$$Y_{RES} = 2j\omega_0 C\left(\frac{\Delta f}{f_0}\right) + \frac{1}{R_{LOSS}}$$

As $Q_0 = R_{LOSS}\omega_0 C \quad \therefore \omega_0 C = \frac{Q_0}{R_{LOSS}}$

$$Y_{RES} = \frac{1}{R_{LOSS}}\left[1 \pm 2jQ_0\left(\frac{\Delta f}{f_0}\right)\right]$$

This equation also describes the resonant response around the carrier for most other forms of parallel resonant circuits.

IV. Oscillation Conditions

If we now complete the oscillator by incorporating the negative resistance, the input admittance becomes

$$Y_{IN} = \frac{1}{R_{LOSS}}\left[1 \pm 2jQ_0\left(\frac{\Delta f}{f_0}\right)\right] - \frac{1}{R}$$

Under oscillating conditions the negative resistance cancels the positive resistance and therefore:

$$Y_{IN} = \left[\frac{\pm 2jQ_0}{R_{LOSS}}\left(\frac{\Delta f}{f_0}\right)\right]$$

We can now calculate the transfer function in terms of the forward trans-resistance and therefore calculate V_{OUT} in terms of i_n:

$$V_{OUT} = \frac{i_n}{Y_{IN}} = i_n \frac{R_{LOSS}}{2jQ_0}\left(\frac{f_0}{\Delta f}\right)$$

At resonance, Δf is zero and V_{OUT} becomes infinite whereas in reality it is actually just finite. However the

sideband noise is still significantly lower than the carrier for offset < 1Hz for most oscillators.

If we assume the noise is produced by the loss resistance in the amplifier then we can calculate the noise current as:

$$\left(\frac{i_n}{2}\right)^2 R_{Loss} = kTB$$

Therefore:

$$i_n = \sqrt{\frac{4kTB}{R_{LOSS}}}$$

The output voltage is now therefore

$$V_{OUT}(\Delta f) = \sqrt{\frac{4kTB}{R_{LOSS}}}\frac{R_{LOSS}}{2jQ_0}\left(\frac{f_0}{\Delta f}\right)$$

For noise, it is usually necessary to deal in terms of power the output power at an offset (not including zero) is therefore:

$$\frac{\left(V_{OUT}(\Delta f)\right)^2}{R_{LOSS}} = \frac{kTB}{{Q_0}^2}\left(\frac{f_0}{\Delta f}\right)^2$$

As this theory is a linear theory, the sideband noise is effectively amplified narrow band noise passed through a Q multiplication filter. Note the Q multiplication is approximately the ratio of the output voltage over the input voltage.

This is huge! It occurs because the voltage transfer function increases by $1/\Delta f$ as power is proportional to $1/\Delta f^2$.

The 3dB point in the resonator now becomes the 3dB above the noise floor!

To represent this as an ideal carrier plus sideband noise, the signal can be thought of as a carrier with a small perturbation rotating around it.

Note that there are two vectors rotating in opposite directions, one for the upper and one for the lower sideband. The sum of these vectors can be thought of as containing both amplitude modulation (AM) and phase modulation (PM). The component along the axis of the carrier vector being AM noise and the component orthogonal to the carrier vector being phase noise. PM can be thought of as a linear modulation as long as the phase deviation is considerably less than 0.1 rad.

Although linear, this theory can incorporate the non-linearities, i.e. limiting in the amplifier, by modifying the absolute value of the noise. If the output signal amplitude is limited with a 'hard' limiter, the AM component would disappear and the phase component would be half of the total value. This is because the input noise is effectively halved. This assumes that the limiting does not cause extra components due to mixing. Limiting also introduces a form of coherence between the upper and the lower sideband which has been defined as conformability by Robins [10]. The phase noise sideband output power is therefore

$$\frac{\left(V_{OUT}(\Delta f)\right)^2}{R_{LOSS}} = \frac{kTB}{2{Q_0}^2}\left(\frac{f_0}{\Delta f}\right)^2$$

To obtain $L(f)$ we now just need to divide by the output power of the oscillator (P) and therefore

$$L(f) = \frac{kTB}{2{Q_0}^2 P}\left(\frac{f_0}{\Delta f}\right)^2$$

This equation is very similar to that shown by Edson [7], Grebennikov [8] and Hajimiri and Lee [9]

V. Comparison of Feedback and Negative Resistance Oscillator Phase Noise Equations

It is interesting to compare this with the equation for phase noise for a feedback oscillator

$$L(f) = \frac{2kTB}{{Q_0}^2 P_{AVO}}\left(\frac{f_0}{\Delta f}\right)^2$$

This is 4 times larger. A factor of 2 can be explained by the fact that P in the negative resistance is the power dissipated in the resonator whereas PAVO is twice the value of the power dissipated in the resonator under optimum operating conditions. The other factor of two is probably due to the fact that the S/N ratio is set by the power at the input of the amplifier which is a ¼ in the feedback oscillator. Never the less it may still be important in some circumstances when the power in the resonator needs to be kept low that for the same power in the resonator the negative resistance amplifier offers a factor of two improvement in the phase noise.

VI. Evaluation of Negative Resistance Amplifiers

The easiest way to evaluate the performance of a negative resistance amplifier in terms of its noise figure and transposed flicker noise is to turn it into a two port amplifier to enable conventional measurement of noise figure and transposed flicker noise. A system is shown if figure 3 which uses a circulator to turn negative resistance into a conventional two power amplifier. The diplexer is added to try and ensure near 50 termination both inside and outside the band as illustrated in Figure 4, The diplexer has the additional requirement to incorporate the change of out of band impedance caused by the circulator. The S parameters for the circulator are measured and the filter response adjusted to take this into account. A plot of an example operating at 1 GHz is shown in Figure 5

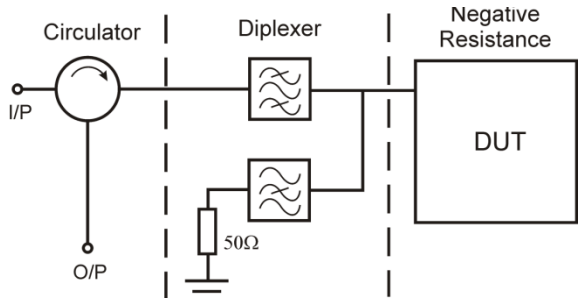

Figure 3 Technique to Evaluate Negative Resistance

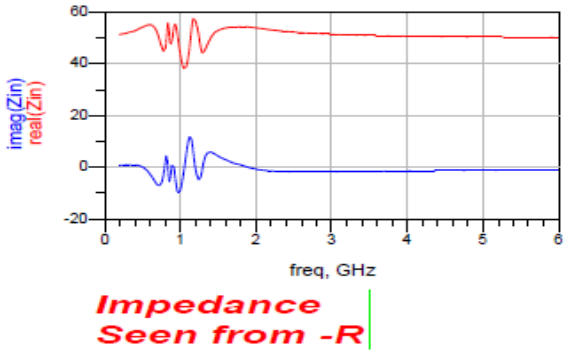

Figure 4 Variation in impedance see from –T (DUT)

An implementation for a typical circuit was implemented for this and tested in ADS harmonic balance software. The noise figure for the simulated negative resistance amplifier was measured in simulation and a phase noise plot is shown in Figure 5 and compared with theory. It is seen that the two plots are very similar.

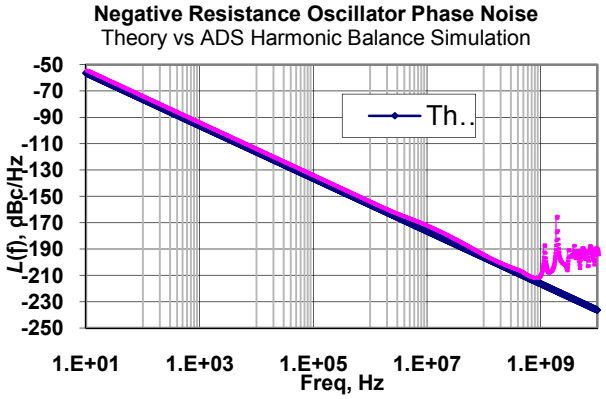

Figure 5 Comparison of theoretical and simulated Phase Noise

VII. Noise Floor Reduction

It is interesting to note that low noise floors appear to be available in the simulatation. A discussion of reduced noise floors is presented in an Agilent Patent by John R Burgoon in 1981.

VIII. Transposed Flicker Noise Reduction

A further justification for using a linear theory is if that transposed flicker noise corners can be significantly reduced. A number of authors have been working on this [11-15]. This group has recently shown that both series and parallel feedback can be used to reduce flicker noise significantly [16][17] Figure 6 and demonstrated some amplifiers with between 1 to 2 order magnitudes of flicker noise reduction. Typical phase noise plots are shown in figures 7 and 8. These phase noise plots were downconverted from 100MHz to enable them to be measured on this particular all digital phase noise measurement system.

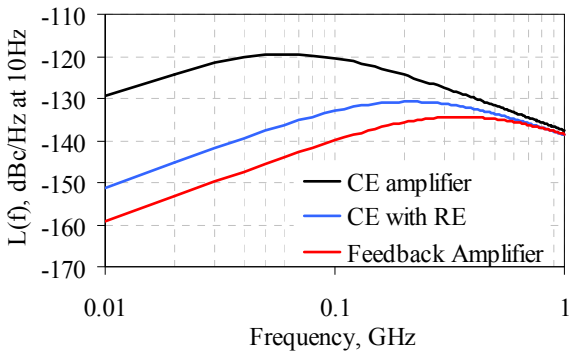

Figure 6 Transposed Flicker Noise Reduction for Series and Parallel Feedback Amplifiers

This group has recently shown that both series and parallel feedback can be used to reduce flicker noise and demonstrated some amplifiers with between 1 to 2 order magnitudes of flicker noise reduction. A typical phase noise plot is shown in figures 5 and 6.

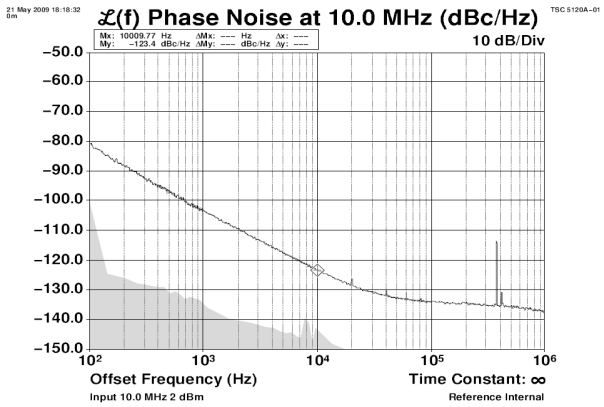

Figure 7 Phase Noise Plot for 100MHz Oscillator

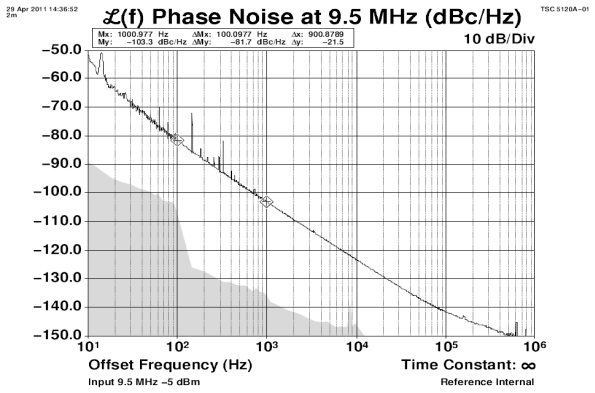

Figure 8 Phase Noise Plot for 100MHz Oscillator

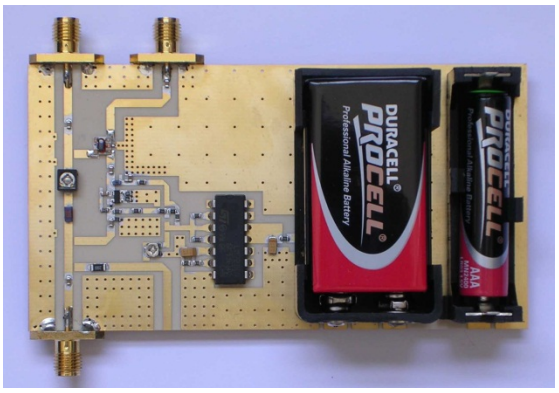
These circuits have been used in a battery powered labkit for the one day courses on 'Low Phase Noise Oscillators: Theory and Laboratory run at the IEEE International

Microwave Symposium:- IMS 2009, 2010 and 2011. This labkit is shown in Figure 8 and enables five experiments to be performed.



IX. CONCLUSIONS

A simple linear theory for phase noise in negative resistance oscillators has been presented. A comparison between the phase noise equations for feedband and negative resiatantce amplifiers has been discussed.

X. ACKNOWLEDGEMENTS

J Everard would like to thank BAE Systems and the Royal Academy of Engineering for supporting him and this work. He would also like to acknowledge Philips Research Laboratories where very similar calculations were recorded in his work lab book in 1983 although the noise modelling for negative resistances was not presented clearly there. Min Xu would like to thank SEMTECH for their support during her studies towards a PhD.

***Abstract* : A phase noise measurement bench is integrated on a 3.6 mm^2 silicon chip. The bench includes a splitter with quadrature outputs, a phase detector, a low noise baseband amplifier and, if necessary, a synthesized source. Applications to the characterization of frequency sources and BAW resonators are discussed.**

***Index terms* : Phase noise, Built-in-self-test (BIST), integrated circuit, phase detection, SMR resonator**

I. INTRODUCTION

A phase noise measurement bench is generally a costly laboratory equipment, based on active references or long delay lines, including low noise amplifiers and phase detectors. The ability to include on a single silicon chip the elements of such a measurement bench allows the measurement and the monitoring of this critical parameter in small size systems, and probably also the correction of the sources phase noise using active loops. The device under test may either be a frequency source (ex : a VCO) or a two port system, such as an amplifier, a digital circuit… In the first case, the phase noise measurement bench must include a frequency reference element, either passive (resonator, delay line) or active (reference source). In the second case, it is mainly based on a low noise phase detection process.

A special case of two ports devices characterization is the measurement of piezoelectric resonators noise, which is very difficult to perform using conventional phase noise measurement techniques on 50 Ω load. Indeed, these devices need different impedances conditions to take benefit of their series or parallel resonances. While realized on a chip, the input and output impedances can be controlled and the resonator is characterized in the same conditions it experiences when it is included in a circuit.

Such an approach can be part of a Built-In-Self Test system [1-4], and used for reliability applications. As an example, the ability to measure the phase noise degradation in an embedded system allows to switch from the noise degraded device (oscillator, amplifier…) to another device, thus maintaining the system performance at its best.

Various elements of a phase noise bridge have thus been designed using an integrated circuit foundry (ST Microelectronics, BiCMOS7RF 0.25 µm). The system has been firstly designed to measure the phase noise of integrated BAW resonators using an SMR technology (CEA-LETI). However, the replacement of one of the resonators by a short line results in an enhancement of the detection of the frequency fluctuations of the source, and thus in the realization of a narrow bandwidth frequency discriminator. This discriminator is able to measure the phase noise spectrum of any type of LC resonator based VCOs.

II. PHASE NOISE MEASUREMENT SYSTEM

Figure 1 represents the typical circuit topology of such a phase noise measurement bench. The main device is a phase detector, generally realized with a mixer with the two signals (LO and RF) maintained close to the phase quadrature (±90°). The phase detector is followed by a baseband amplifier, which should feature an equivalent input low frequency noise lower than the output noise of the phase detector.

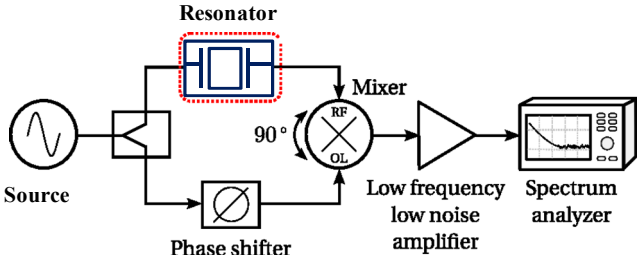

Figure 1 : Typical topology of a phase noise measurement bench, in the configuration for source measurement (frequency discriminator). The residual phase noise measurement system is the same, with the resonator substituted by the device under test

If the purpose of the measurement bench is to characterize the frequency source, the resonator is used as the frequency reference element, and is part of the measurement bench. It allows, thanks to its large phase to frequency slope (dϕ/df), the conversion of the frequency fluctuations of the source into phase fluctuations, which are then detected by the phase detector.

If the purpose of the measurement bench is to measure the residual phase noise of two ports devices, such an amplifier, the device under test (DUT) replaces the resonator, but a frequency source should be available in the system. This oscillator must be tunable and, above all, must feature low AM and FM noise. The AM noise is the most critical specification in this case [5], because the FM noise is simply removed by equilibrating the delay in the two arms of the phase detector. In the case of a resonator measurement, the problem of the parasitic FM noise detection of the source is solved by measuring two identical resonators, one in each arm of the phase detector, thus canceling the delay caused by one resonator. The resulting phase noise is the addition of the phase noise of the two resonators, i.e. a phase noise increased of 3 dB compared to a single resonator, if the resonators are identical. Finally, in the case of the measurement of frequency conversion devices (frequency dividers, multipliers…), once again two identical devices must be used, in order to reach the same frequency on the RF and LO ports of the mixer.

One of the devices depicted in Figure 1 is very difficult to integrate : the phase shifter. It is realized on a macroscopic phase noise measurement system with a stretched line, which allows phase rotations of generally more than 180° at all the frequencies of interest. Such a wide control of the phase is difficult to get on integrated circuits. However, in the integrated world, the phase is generally well known and does not shift too much on the small lines used in a silicon chip. We thus propose a solution to this problem which avoids the realization of this phase control.

Finally, the output signal is analyzed on a low frequency spectrum analyzer. We have not integrated on a chip such a complex system, although it would be possible to do it. In our case, the final analysis is still performed out of the chip. However, it would be easy to integrate a power measurement on a given frequency bandwidth, which would allow to get an estimate of the phase noise at a given frequency offset carefully chosen for the application foreseen.

We will now describe all the elements of this system and the way they have been effectively integrated on silicon, starting with the input stages and ending with the phase detector stage.

A. Synthesized frequency source

An integrated synthesizer has been realized, and is depicted in Figure 2. It is based on a LC differential VCO, which features a phase noise of -80 dBc/Hz at 10 kHz offset from a 7.5 GHz carrier, and on a PLL realized with a digital prescaler. The PLL allows the locking of the VCO on a low frequency reference source (30 MHz) and the generation of stable signals with a 30 MHz step on the whole VCO locking range (6.8 GHz to 8 GHz). Only the reference source (quartz oscillator) is maintained outside the chip.

B. Input stage : splitter and quadrature output

The problem of the phase quadrature at the mixer input can be solved very easily in an integrated circuit approach with a power divider delivering signals already in quadrature. If the phase shift in the DUT is small, or if it can be compensated using two identical devices, the phase quadrature is maintained down to the mixer stage, and the phase detection is performed at its maximum sensitivity.

To realize this function, a digital frequency divider by two has been used. This circuit, depicted in Figure 3, is based on D flip-flop cells and generates four output signals which are all in phase quadrature (0°, 90°, 180° and 270°). However, such a digital circuit located at a critical stage of the phase bridge can be the main noise source of the system. Our goal has thus been to optimize the phase noise of this circuit [6], in order to get a very low residual phase noise divider. This has been performed using the phase noise simulation capabilities of Cadence™, and particularly the ability of this software to isolate the main noise source of the circuit. An important optimization work has been focused on the D flip-flop topology, and more precisely on the current source of this differential element. More details on this process can be found in reference [6].

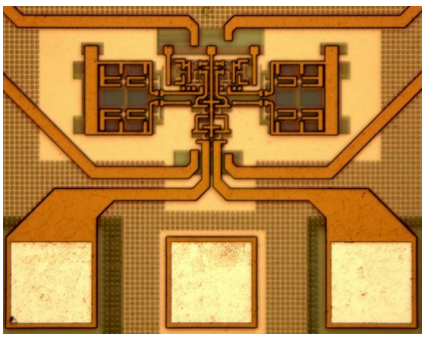

Figure 3 : Input power divider and frequency divider by two, featuring four outputs in phase quadrature

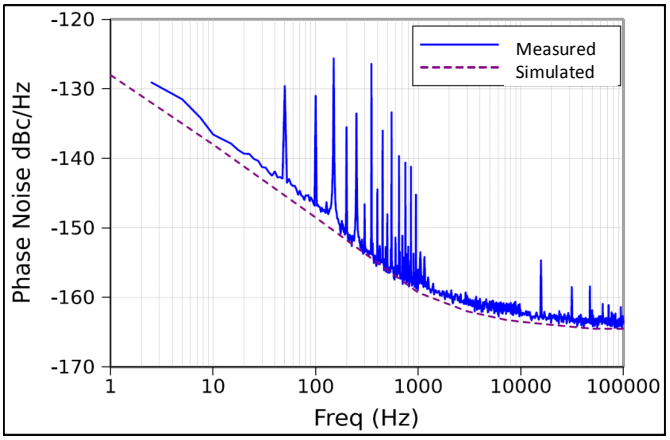

Figure 4 : Measured and simulated phase noise of the input frequency divider by two

Figure 3 represents the realized circuit, and Figure 4 its residual phase noise simulated using Cadence™ and measured on a conventional (macroscopic) phase noise measurement set-up. The agreement between simulated and measured data is excellent, and the phase noise floor effectively reached is as low as -164 dBc/Hz at 100 kHz offset from an input frequency of 3.5 GHz.

C. *Phase detector*

Phase detectors are classically realized with four balanced diodes mixers. Such phase detectors are very reliable and can work on a large frequency range. However, the main drawback of this approach lies in the need for a sufficient LO power to drive the mixer (typically 7 dBm) and on the conversion losses of passive mixers. It is therefore interesting to investigate on active mixers for phase detection. The residual phase noise of some bipolar transistor, when loaded and biased properly, is as low as the residual phase noise of schottky diodes silicon mixers, and these devices can lead to a substantial improvement of the phase detection coefficient.

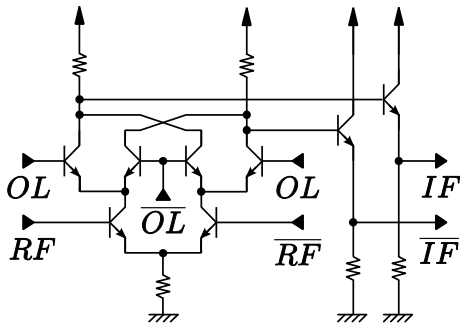

Figure 5 : Active phase detector, with resistive loads

Various active phase detectors have thus been designed, based on Gilbert cell mixer and using bipolar devices. Two versions of this circuit have been realized, one based on resistive loads (Figure 5) and featuring a phase detection coefficient of 350 mV/rad, and another one based on active loads and featuring a phase detection coefficient of 970 mV/rad. Up to now, only the first circuit has been measured and used in the integrated phase noise bench, although the other circuit features a better simulated phase noise performance. When this second mixer will have been fully characterized, it will be the purpose of a dedicated publication. However, the resistive loads mixer is already particularly interesting because it features a phase detection coefficient higher than passive mixers and works on much lower level signals. Moreover, its phase noise is low, as it can be deduced from the overall system phase noise measurement presented in section III (Figure 9).

D. *Low noise amplifier*

The low noise amplifier must feature an equivalent input noise level lower than the output noise of the phase detector. Using the resistive loads mixer, the phase detection coefficient is (a little higher but) close to the phase detection coefficient of a passive mixer, and the amplifier performance should be as close as possible as the one of the best operational amplifiers. Such metrological amplifiers feature an equivalent voltage noise floor in the range of 1 nV/√Hz, and a 1/f noise corner frequency lower than 1 kHz. Our goal has thus been to integrate an amplifier with similar performances.

Our first attempt with a conventional differential topology first stage has led us to noise performances in the range of 20 nV/√Hz or more at the amplifier input. The strategy to improve the amplifier performance has been based on the duplication of the bipolar transistors involved in the first differential stage and, also, in the gain stage. Indeed, setting in parallel many transistors reduces the equivalent noise (at a cost of an input impedance reduction, which is not mandatory here) because the noise sources of each device are added incoherently meanwhile the current (the information) is added coherently. The result of this study has been the realization of a state of the art low noise amplifier, featuring a noise floor of 1.05 nV/√Hz and a noise corner frequency in the kHz range. This is particularly interesting, taking into account the small size (640 µm X 227 µm) and, above all, the low power consumption of this circuit : 2.5 V, 18 mA (45 mW).

Figure 6 represents the circuit realized, and Figure 7 the measured low frequency noise of this amplifier. The noise measurement is in perfect agreement with the simulated noise, and demonstrates that the design goals have been fulfilled. More details on the noise optimization process for this circuit can be found in reference [7].

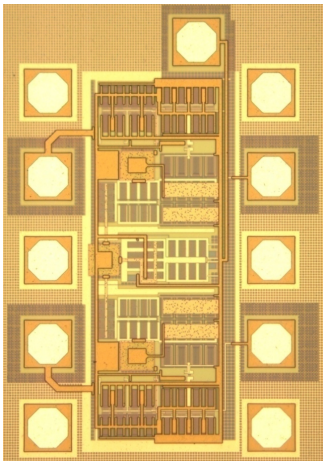

Figure 6 : Photograph of the low noise output amplifier

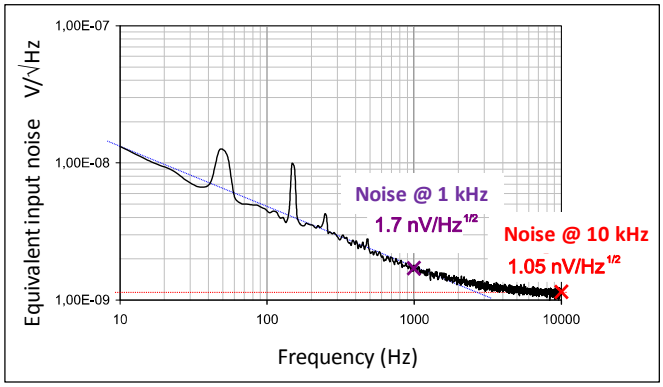

Figure 7 : Measured equivalent input voltage noise of the amplifier

E. Overview of the whole integrated circuit

These elements of the circuit are then put together on a single silicon chip. The final circuit is represented in Figure 8, and its size is in the range of 1.67 mm X 2.17 mm. The central part is dedicated to the DUT (case of residual phase noise measurement) or the resonators (BAW) and lines, which are reported on the circuit using a flip-chip technology. As the input stage provides four outputs in quadrature, we use these four outputs in order not to lose power, and the mixer is also designed with four inputs. The signal at the output of the low noise amplifier is then analysed on a FFT spectrum analyser. The system noise floor is measured using four identical short lines in place of the resonators.

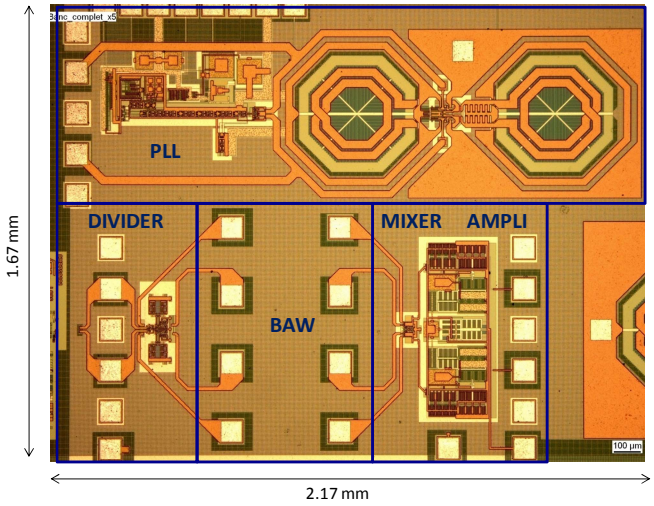

Figure 8 : Overview of the integrated phase noise bench

III. Application to the Characterization of Integrated BAW Resonators Phase Noise

Unlike many passive microwave resonators, BAW resonators may induce a 1/f noise component in the circuit. As an example, we have measured some years ago on a conventional phase noise bridge a 1/f phase noise component in FBAR resonators [8], and the measured phase noise level in these devices was sufficient to be the main noise contribution to an oscillator realized with one of these resonators. However, the same measurements performed in the same conditions on some new SMR resonators have given results much too close from the measurement noise floor to conclude on the noise contribution of these devices. This is due not only to the absolute level of phase noise (or more precisely to the fluctuation of the resonator centre frequency) but also to the fact that a proper impedance must be used to get an observable resonance with these devices.

We have thus used our integrated phase noise bench to measure the residual phase noise of those SMR resonators, the resonators being realized at CEA-LETI in Grenoble (France). More details on these resonators and their applications can be found in reference [9]. Four identical resonators have thus been mounted using flip-chip technology on the silicon circuit. Unfortunately, some contacts problems due to differences in metals pads between the two devices have prevented the measurement of this integrated circuit. We have thus used the separated elements to assemble a partially integrated phase noise test bench, and we have obtained the data depicted in Figure 9. The measured noise is the one of the four devices (incoherent addition of the noise of each device), which is effectively higher than the noise floor. The phase noise of a single resonator can be deduced from this plot by subtracting 6 dB to this curve.

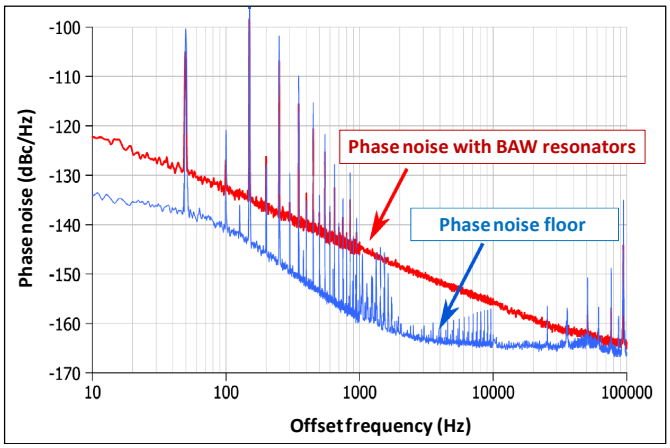

Figure 9 : Measured phase noise of the four SMR resonators, and phase noise floor of the measurement bench

Apart from the resonators residual phase noise, this measurement demonstrates a relatively good phase noise floor for our system. The phase noise floor is close to the measured phase noise of the input stage (frequency divider by two), with a bump on the spectrum added around 100 Hz offset, which is probably due to a contribution from the phase detector noise.

IV. Conclusion

A phase noise measurement bench integrated on a silicon chip has been presented. This bench may be used either for residual phase noise measurements, or for oscillator phase noise measurement in the frequency discriminator configuration, with a BAW resonator as frequency reference. Some of the elements of this bench are at the state of the art for integrated circuits functions in terms of noise performance (low noise amplifier, frequency divider). An application to the

measurement of the noise properties of some BAW-SMR resonators is also presented.

ACKNOWLEDGMENTS

We would like to thank A. Reinhardt and J.B. David from CEA-LETI for integrated resonator realization. This work has been performed in the frame of the contract "MOBILIS" which was part of the European FP6-IST program.

Abstract -**The miniaturization of crystal resonators and filters towards the MEMS (Micro-Electro-Mechanical Systems) and nano-structured scales demands improvement of nonlinear piez oelectricity theory and a better understanding of th e nonlinear b ehavior of new crystal materials. The nonlin earities affect the quality factor and acousti c behavior of MEMS and nano-structured resonators and filters. Among these nonlinear effects, drive level dependence (DLD), which describes the instability of the resonator frequency due to voltage level and/or power density, is an urgent problem for miniaturized resonators. Langasite, a new promising piezoelectric material, is of recent interest for a variety of applications because of its good temperature behavior, good piezoelectric coupling, low acoustic loss and high Q factor. It has been recently used to make high temperature MEMS. In this article, experimental measurements of drive level dependence of langasite resonators with different configurations (plano-plano, single bevel, and double bevel) are reporte d. The results show that the resonator configuration affects the DL D of the l angasite resonator. The drive sensitivity of resonators with different configurations is determined.**

I. Introduction

The miniaturization of crystal resonators and filters towards the MEMS and nano-structured scales demands better understanding and modeling of the nonlinear behavior of crystal materials. The nonlinearities affect the quality factor and acoustic behavior of the MEMS (Micro-Electro-Mechanical Systems) and nano-structured resonators and filters. These effects include force-frequency effect, electroelastic effect, mode coupling and activity dip, acceleration sensitivity, intermodulation and drive level dependence. Among these nonlinear effects, drive level dependence (DLD), which describes the instability of the resonator frequency due to voltage level and/or power density, is an urgent problem for miniaturized resonators. This behavior is of current interest due to the increasing importance of low phase noise oscillators, because there is a direct relationship between resonator drive level and oscillator phase noise [1]. Except for the influence on the frequency, drive level dependence could also worsen the activity dip problem [2], [3].

Langasite, a new promising piezoelectric material, combines many of the advantages of quartz, barium titanate and lithium niobate -- having high electromechanical coupling and good frequency-temperature characteristics. It is a potential material to substitute for current applications dominated by quartz. One of the most important advantages of langasite is that it will not undergo phase transitions up to its melting temperature of 1473 deg C, which makes it very promising to make high temperature MEMS sensors. Common piezoelectric devices made by quartz and lithium niobate are limited to an operation temperature of 520 deg C or 400-500 deg C; MEMS made by langasite will be able to operate at least 1050 deg C. Recently, several attempts have been made to use langasite as the material to make high temperature MEMS sensors [4] and nano devices [5], [6], [7]. Investigation of nonlinearities of langasite is critical for the real application and optimal design of these devices, and research on DLD is especially important for these miniaturized devices. The measurement of drive level dependence for Y-cut langatate and langanite resonators has been performed by Kim [8]; however, measurements for doubly rotated langasite resonators have not been performed yet. In this article, we show that the different configurations of the resonators also affect the drive level sensitivity of doubly rotated langasite resonators. Experimental measurements of drive level dependence of langasite resonators with different configurations (plano-plano, single bevel, and double bevel) are reported. The drive sensitivity of resonators with different configurations is determined.

II. Sample preparation

There are three langasite resonator samples under test. Their diameter, thickness and cut angle are the same. All other parameters are different. The detailed design parameters for these three resonators are listed in Table I.

Table I: Resonator design parameters.

Resonator configuration	Plano-plano	Plano convex with double bevel	Plano convex with single bevel
Material orientation	YXlw $\Theta=45^0/\Phi=65^0$	YXlw $\Theta=45^0/\Phi=65^0$	YXlw $\Theta=45^0/\Phi=65^0$
Plate diameter (mm)	13.0	13.0	13.0
Thickness (mm)	0.65	0.65	0.65
Electrode diameter (mm)	5.50	5.61	5.61
Radius of curvature (diopter)		4	4
Abrasive size to grid the bevels (micron)		1	1
Fundamental resonant frequency (Hz)	2,577,150	2,752,600	2,409,750

III. Experiment setup

The experiment setup is shown schematically in Fig. 1. An Agilent 33220A function generator is used to excite the crystal; the function generator is connected to and controlled by a computer with Labview. The signal from the function generator is fed into the crystal resonator through a PI network shown in Fig. 2. The resistance values in the PI network are shown in Table II. The response signal from the crystal resonator is collected by a Tektronix TDS 3054 C oscilloscope, which is subsequently connected to and controlled by the same computer with Labview.

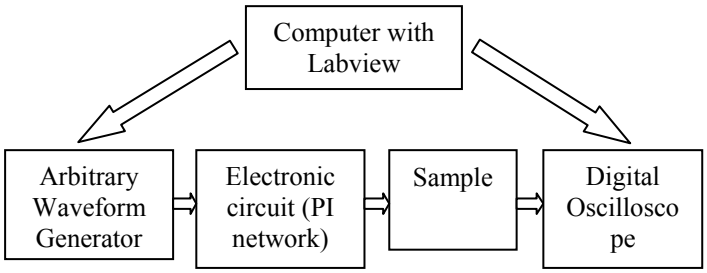

Fig. 1. The experiment setup.

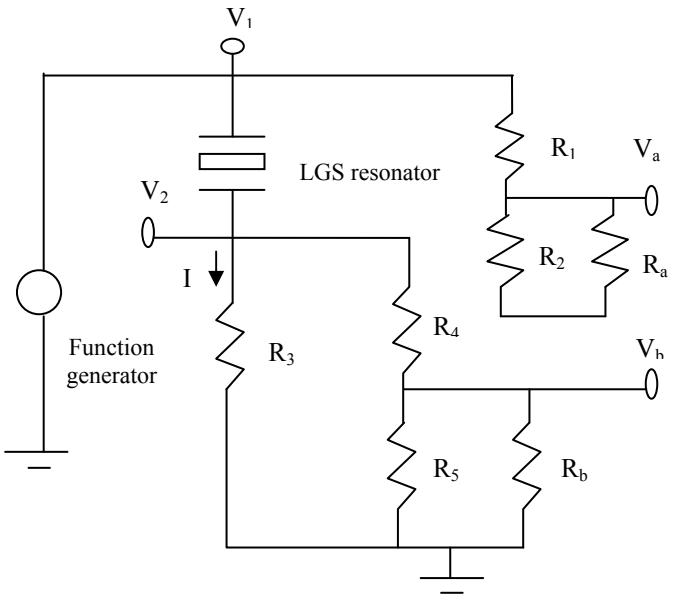

Fig. 2. The PI network circuit diagram.

Table II. The list of resistance values in the PI network.

R_1	R_2	R_3	R_4
1210 OHMS	51 OHMS	51 OHMS	1210 OHMS
R_5	R_a	R_b	I
51 OHMS	50 OHMS	50 OHMS	1.14Vb

IV. Measurement results

The relation between the resonator current and frequency is measured and shown in Figs. 3, 4, and 5 as a function of the magnitude (Volt) of the sinusoidal excitation signal from the function generator. As expected, the resonance curves shift towards a lower frequency as the voltage increases, which is a "softening" behavior. This is contrary to the DLD of SC cut quartz resonators in [9], as the resonance curves for SC cut quartz resonators bend towards higher frequency, which is a "hardening" behavior. The relative drive sensitivity D defined in [9] is extracted in Figs. 6, 7 and 8. The results are listed in Tables III and IV; Table III compares the D for the LGS resonators and SC cut quartz resonators with different

curvatures. It is apparent that the drive sensitivity of the tested LGS resonators exceeds SC cut quartz resonators. Table IV compares the D for LGS resonators and LGN, LGT resonators. It seems that the drive sensitivity of LGS resonators in fundamental mode is smaller than LGN and LGT resonators. Higher overtones of the tested LGS resonators could not be measured due to undesired mode interference.

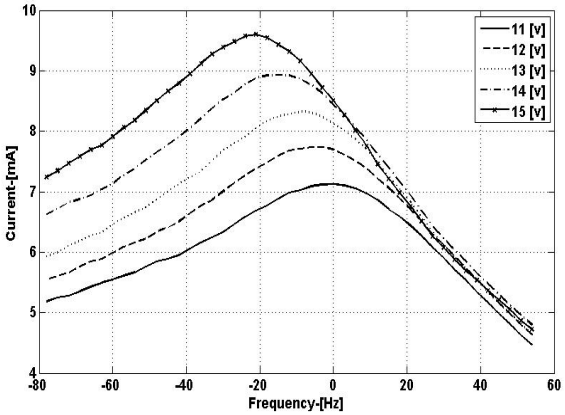

Fig. 3. Drive level dependence of LGS resonator with plano-plano configuration.

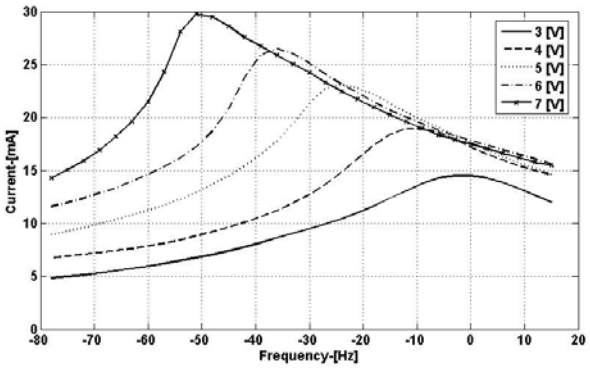

Fig. 4. Drive level dependence of LGS resonator with bevel-bevel configuration.

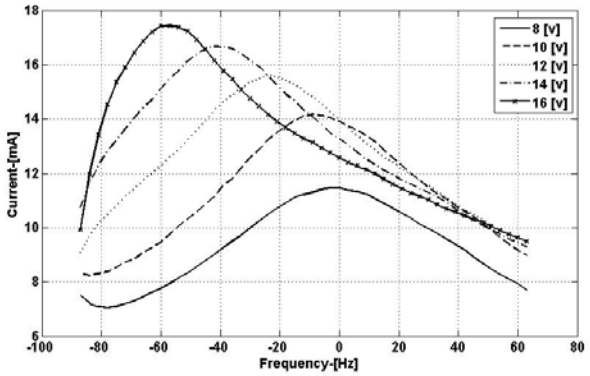

Fig. 5. Drive level dependence of LGS resonator with plano-bevel configuration.

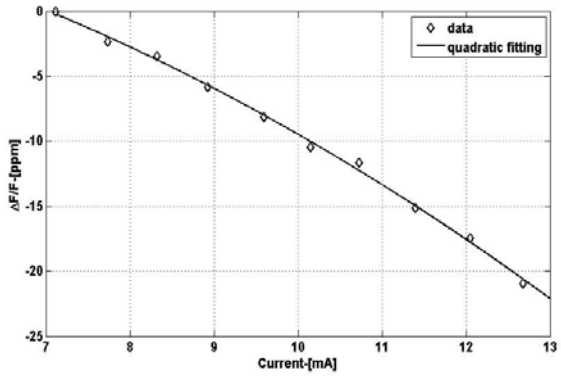

Fig. 6. Drive sensitivity of LGS resonator with plano-plano configuration.

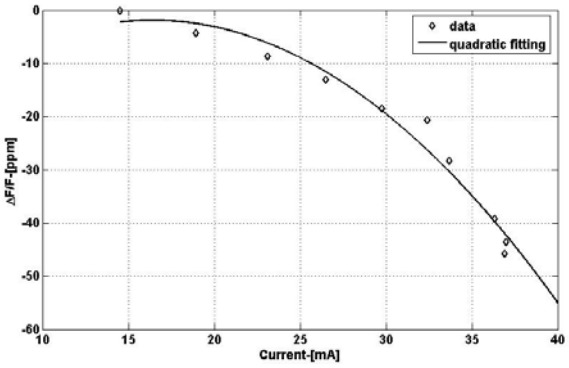

Fig. 7. Drive sensitivity of LGS resonator with bevel-bevel configuration.

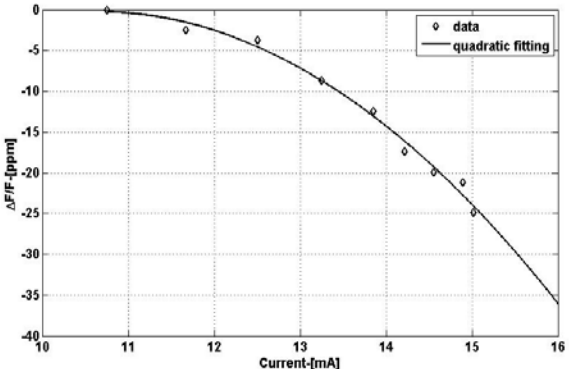

Fig. 8. Drive sensitivity of LGS resonator with plano-bevel configuration.

Table III: Comparison with SC-cut Quartz Resonators

Drive Sensitivity D [ppm/mA^2]		**Drive Sensitivity D [ppm/mA^2] for a SC cut r esonators at 5.115 MHz fundamental mode**	
LGS double bevel	-0.0954	Diopter 1.00	0.0076
LGS plano-plano	-0.1741	Diopter 1.25	0.0116
LGS single bevel	-1.2460	Diopter 1.5	0.0127

Table IV: Comparison with Langatate and Langanite Resonators

Drive level Sensitivity D [ppm/mA^2]	
LGS double bevel	-0.0954
LGS plano-plano	-0.1714
LGS single bevel	-1.2460
LGN	-3.34 (3rd OT)
LGT	-1.63 (3rd OT)

V. Conclusion

The drive level dependence of doubly rotated langasite resonators show softening behavior, which is contrary to the hardening behavior a SC cut quartz resonator exhibits. The change of resonator configuration has altered the drive level sensitivity. The resonator with single bevel configuration has the largest drive sensitivity coefficient; the resonator with double bevel configuration has the least drive sensitivity. Compared with SC-cut quartz resonators, the langasite resonator has generally larger drive level dependence. Compared with langatate and langanite resonators, langasite resonators show smaller drive level dependence.

***Abstract*—Boundary conditions for a layered piezoelectric structure under the influence of a uniform dc electric field have been obtained. Dispersive dependences and anisotropy of phase velocities, electromechanical coupling coefficients, power flow angle, and controlling coefficients of dc electric field influence as a functions of h×f product for the Rayleigh and Love modes in bismuth germanium oxide/fused silica and langasite/fused silica layered structures have been calculated.**

I. INTRODUCTION

Development of acoustoelectronics (AE) is now concerned with the design of complicated structures such as layered piezoelectric devices [1, 2]. For example, by this way there is opened an attractive possibility to include the non-piezoelectic substrate with good acoustical properties into device meanwhile the acoustic wave can be excited using the piezoelectric film/plate. However, to extend the class of devices it is desirable to obtain the ability to control their parameters during the wave propagation process. On the other side the choice of optimal film/crystalline layer thickness h is important to obtain a given frequency characteristics of device [3]. In present paper for a number of layered piezoelectric structures the influence of dc electric field on the dispersive parameters of Rayleigh and Love (SH) waves which are the functions of h×f product has been examined (f denotes a wave frequency). As a model structures the crystalline layers of strong piezoelectric crystal bismuth germanium oxide ($Bi_{12}GeO_{20}$, BGO) or langasite ($La_3Ga_5SiO_{14}$, LGS) on fused silica have been investigated. Langasite is a most promising crystal in a practical sense because it has a good combination of properties, such as thermal stability, low attenuation of high frequency elastic waves and greater electromechanical coupling coefficients (EMCC) compared with quartz [4].

II. ELASTIC WAVE PROPAGATION IN A LAYERED PIEZOELECTRIC MEDIUM UNDER THE INFLUENCE OF HOMOGENEOUS DC ELECTRIC FIELD)

Let us choose the working orthogonal coordinate system in which the axis X_3 is directed along the outward normal to the surface layer occupying the space of $0 \le X_3 \le h$, and the X_1 axis coincides with the wave propagation direction. For small-amplitude plane waves propagation under the influence of dc electric field on the piezoelectric crystal the equations of motion and electrostatics and the state equations of the piezoelectric medium should have the form:

$$\begin{aligned} &\rho_0 \ddot{\tilde{U}}_I = \tilde{\tau}_{IK,K}, \ \tilde{D}_{M,M} = 0, \\ &\tilde{\tau}_{IK} = C^*_{IKPQ}\tilde{\eta}_{PQ} - e^*_{NIK}\tilde{E}_N, \\ &\tilde{D}_N = e^*_{NIK}\tilde{\eta}_{IK} + \varepsilon^*_{MN}\tilde{E}_M. \end{aligned} \qquad (1)$$

In equation (1) the following notation has been used: ρ_0 is the crystal density in the undeformed (initial) state, and $\tilde{U}_I$ is the vector of dynamic elastic displacements. Here and below summation over twice repeated indices is meant. Effective elastic, piezoelectric and dielectric constants which are the linear functions of dc electric field are defined by:

$$\begin{aligned} &C^*_{ABKL} = C^E_{ABKL} + \left(C^E_{ABKLQR}d_{JQR} - e_{JABKL}\right)M_J E, \\ &e^*_{NAB} = e_{NAB} + \left(e_{NABKL}d_{JKL} + H_{NJAB}\right)M_J E, \\ &\varepsilon^*_{NM} = \varepsilon^\eta_{NM} + \left(H_{NMAB}d_{PAB} + \varepsilon^\eta_{NMP}\right)M_P E. \end{aligned} \qquad (2)$$

Here E is the value of the dc electric field, M_J is the unit electric field vector, and C^E_{ABKLQR}, e_{NABKL} and H_{NMAB} are the nonlinear elastic, piezoelectric and electrostrictive constants (material tensors).

Acoustic wave propagation in a piezoelectric plate under the action of E must satisfy the relevant boundary conditions. Thus, the normal components of stress tensor must be equal

to zero on the free surface. A continuity of the tangential components of electric field to the interface between piezoelectric layer vacuum should be provided by the condition of continuity of electric potential. Also the equality of normal components of stress tensor τ_{IK} and the continuity of the electric potential φ at the boundary "crystalline layer – substrate" at $X_3 = 0$ should be ensured. As a consequence all these conditions can be written as:

$$\begin{aligned}
&\tau_{3A}^{(1)} = 0\big|_{x_3=h}, \qquad D_3^{(1)} = D^{(\text{вак})}\big|_{x_3=h};\\
&\tau_{3A}^{(1)} = \tau_{3A}^{(2)}\big|_{x_3=0}, \qquad D_3^{(1)} = D_3^{(2)}\big|_{x_3=0};\\
&\varphi^{(1)} = \varphi^{(2)}\big|_{x_3=0}, \qquad U_A^{(1)} = U_A^{(2)}\big|_{x_3=0}.
\end{aligned} \tag{3}$$

As a result of substitution the solutions in the form of homogeneous plane waves into the boundary conditions (3) one can obtain a system of equations for calculating the acoustic waves parameters of a layered structure in a generalized form when a layer and substrate are the piezoelectric crystals:

$$\begin{aligned}
&\sum_{m=1}^{4}\Big\{b_m\Big[\Big(C_{I3KL}^{*(1)} + 2d_{AKF}^{(1)}C_{3IFL}^{(1)E}M_A E\Big)k_L^{(m)}\alpha_K^{(m)} + e_{3PI}^{*(1)}k_p^{(m)}\alpha_4^{(m)}\Big] -\\
&-\sum_{n=1}^{8}a_n\Big[\Big(C_{I3KL}^{*(2)} + 2d_{AKF}^{(2)}C_{3IFL}^{(2)E}M_A E\Big)k_L^{(n)}\alpha_K^{(n)} + e_{3PI}^{*(2)}k_p^{(n)}\alpha_4^{(n)}\Big]\Big\} = 0,\\
&\sum_{m=1}^{4}\Big\{b_m\Big[\Big(e_{3KL}^{*(1)} + 2d_{JKP}^{(1)}e_{3PL}^{(1)}M_A E\Big)k_L^{(m)}\alpha_K^{(m)} + \varepsilon_{3K}^{*(1)}k_K^{(m)}\alpha_4^{(m)}\Big] -\\
&-\sum_{n=1}^{8}a_n\Big[\Big(e_{3KL}^{*(2)} + 2d_{JKP}^{(2)}e_{3PL}^{(2)}M_A E\Big)k_L^{(n)}\alpha_K^{(n)} + \varepsilon_{3K}^{*(2)}k_K^{(n)}\alpha_4^{(n)}\Big]\Big\} = 0,\\
&\sum_{m=1}^{4}\Big[U_I^{(1)(m)}b_m\Big] - \sum_{n=1}^{8}\Big[U_I^{(2)(n)}a_n\Big] = 0,\\
&\sum_{n=1}^{8}\Big[-a_n\Big(C_{3KPI}^{*(2)} + 2d_{APF}^{(2)}C_{3KFI}^{(2)E}M_A E\Big)k_I^{(n)}\alpha_p^{(n)} -\\
&-a_4 e_{P3K}^{*(2)}k_p^{(n)}\alpha_4^{(n)}\Big]\exp\big(ik_3^{(n)}h\big) = 0,\\
&\sum_{n=1}^{8}\Big[-a_n\Big(e_{3KL}^{*(2)} + 2d_{JKP}^{(2)}e_{3PL}^{(2)}M_J E\Big)k_L^{(n)}\alpha_K^{(n)} -\\
&-a_4\Big(\varepsilon_{3K}^{*(2)}k_K^{(n)} - i\varepsilon_0\Big)\alpha_4^{(n)}\Big]\exp\big(ik_3^{(n)}h\big) = 0.
\end{aligned} \tag{4}$$

Numerical superscripts (1) and (2) denote the substrate and layer terms, respectively; $\alpha_K^{(m)}$ and b_m are amplitudes and weight coefficients of m-th partial wave (m = 1, ..., 4) in the piezoelectric substrate, respectively; $\alpha_K^{(n)}$ and a_n are the same ones of n-th partial wave (n = 1, ..., 8) in the piezoelectric layer.

Note that the equations (4) for the boundary conditions have been derived at the assumptions about the influence of homogeneous dc electric field on the crystal layer without edge effects. In the obtained equations it has been taken into account all changes in the configuration of an anisotropic continuum, in particular, changes of the sample form (geometric nonlinearity) due to direct piezoelectric effect, and changes of the material constants (2) (physical nonlinearity) under the influence of strong dc electric field.

For the purpose of this paper there was selected a model structure which was consisted of a piezoelectric crystalline layer mounted on an isotropic substrate (fused silica). Thus the equations (4) should be specified as

$$\begin{aligned}
&\sum_{m=1}^{3}b_m C_{I3KL}^{(1)}k_L^{(m)}\alpha_K^{(m)} -\\
&-\sum_{n=1}^{8}a_n\Big[\Big(C_{I3KL}^{*(2)} + 2d_{AKF}^{(2)}C_{3IFL}^{(2)E}M_A E\Big)k_L^{(n)}\alpha_K^{(n)} + e_{3PI}^{*(2)}k_p^{(n)}\alpha_4^{(n)}\Big] = 0,\\
&b_4\varepsilon_{3K}^{(1)}k -\\
&-\sum_{n=1}^{8}a_n\Big[\Big(e_{3KL}^{*(2)} + 2d_{JKP}^{(2)}e_{3PL}^{(2)}M_A E\Big)k_L^{(n)}\alpha_K^{(n)} + \varepsilon_{3K}^{*(2)}k_K^{(n)}\alpha_4^{(n)}\Big] = 0,\\
&\sum_{m=1}^{4}U_I^{(1)(m)}b_m - \sum_{n=1}^{8}U_I^{(2)(n)}a_n = 0,\\
&\sum_{n=1}^{8}\Big\{-a_n\Big[\Big(C_{3KPI}^{*(2)} + 2d_{APF}^{(2)}C_{3KFI}^{(2)E}M_A E\Big)k_I^{(n)}\alpha_p^{(n)} -\\
&-a_4 e_{P3K}^{*(2)}k_p^{(n)}\alpha_4^{(n)}\Big]\Big\}\exp\big(ik_3^{(n)}h\big) = 0,\\
&\sum_{n=1}^{8}\Big[-a_n\Big(e_{3KL}^{*(2)} + 2d_{JKP}^{(2)}e_{3PL}^{(2)}M_J E\Big)k_L^{(n)}\alpha_K^{(n)} -\\
&-a_4\Big(\varepsilon_{3K}^{*(2)}k_K^{(n)} - i\varepsilon_0\Big)\alpha_4^{(n)}\Big]\exp\big(ik_3^{(n)}h\big) = 0.
\end{aligned} \tag{5}$$

III. Dispersive Characteristics of Elastic Waves in Layered Piezoelectric Structures

To define in the linear approximation a measure of dc electric field influence on the phase velocities of Rayleigh and Love waves it is convenient to introduce the controlling coefficients as:

$$\alpha_v = \frac{1}{v(0)}\left(\frac{\Delta v}{\Delta E}\right)_{\Delta E\to 0}. \tag{6}$$

On the basis of equations (1) - (5) in a layered piezoelectric structures for a few modes of Rayleigh and Love waves the calculation of such parameters as the phase velocities, EMCCs and α_v coefficients has been carried out. The material coefficients of linear and nonlinear electromechanical properties of BGO and LGS were taken from [4, 5].

Figure 1 shows the dispersion curves of phase velocities, EMCCs and α_v coefficients of Rayleigh and Love waves depending on the h×f value when waves are propagated along the [100] direction of (001) BGO/fused silica. In this case pure piezoactive Love wave and non-piezoactive Rayleigh wave are propagated. It is clear that the interval of phase velocities of Love waves lies between the values of the shear waves velocities of fused silica and BGO. Rayleigh wave phase velocity at h×f increasing tends to the Rayleigh wave phase velocity of BGO (1625.92 m/s). The maximum value of $K^2 = 2.9$ % at h×f = 1000 m/s takes place for zero Love mode. When dc electric field is applied along the E||[010], i.e. orthogonally to the sagittal plane, the modes of elastic waves remain the pure ones. The α_v coefficient of Love wave at h×f increasing tends to $\alpha_v = -3\cdot10^{-11}$ m/V for the slow shear bulk acoustic wave (BAW) of BGO, and α_v coefficient of all the Rayleigh type waves at h×f increasing tends to $\alpha_v = -6.9\cdot10^{-12}$ m/V value as the same one for the fast shear BAW of BGO.

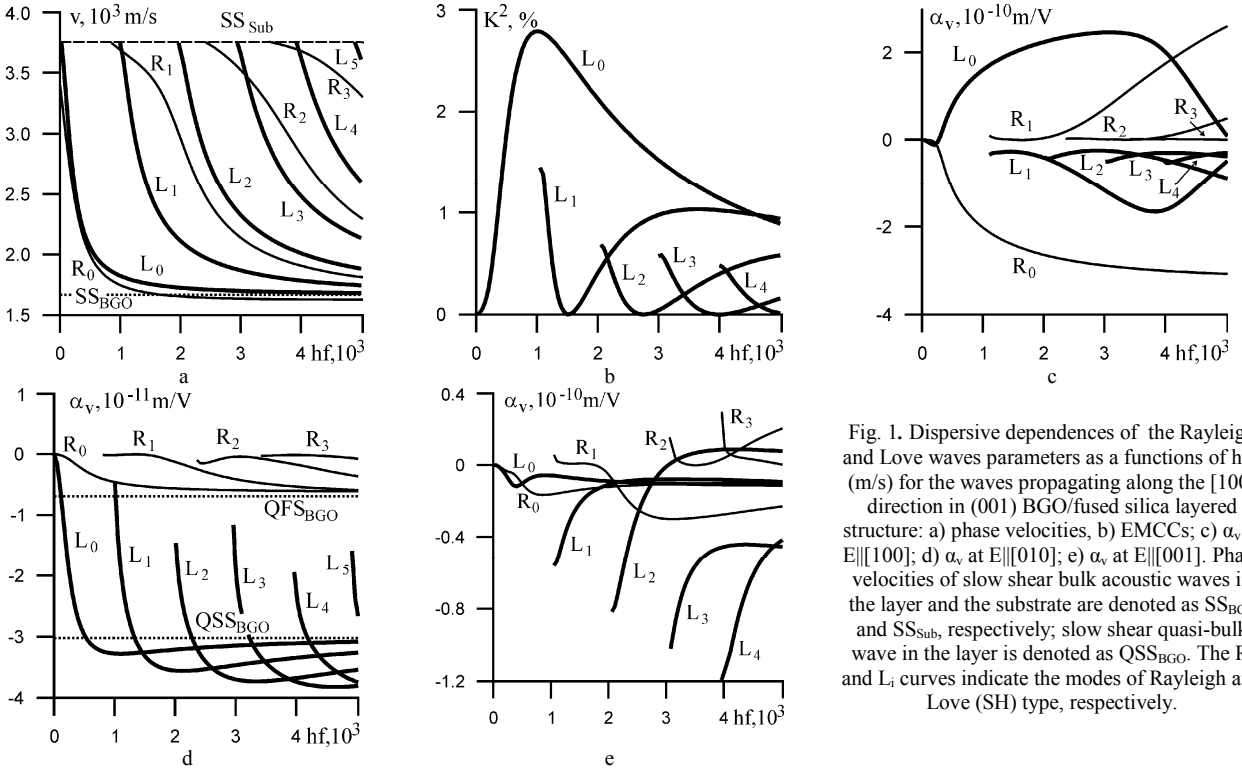

Fig. 1. Dispersive dependences of the Rayleigh and Love waves parameters as a functions of h×f (m/s) for the waves propagating along the [100] direction in (001) BGO/fused silica layered structure: a) phase velocities, b) EMCCs; c) α_v at E||[100]; d) α_v at E||[010]; e) α_v at E||[001]. Phase velocities of slow shear bulk acoustic waves in the layer and the substrate are denoted as SS_{BGO} and SS_{Sub}, respectively; slow shear quasi-bulk wave in the layer is denoted as QSS_{BGO}. The R_i and L_i curves indicate the modes of Rayleigh and Love (SH) type, respectively.

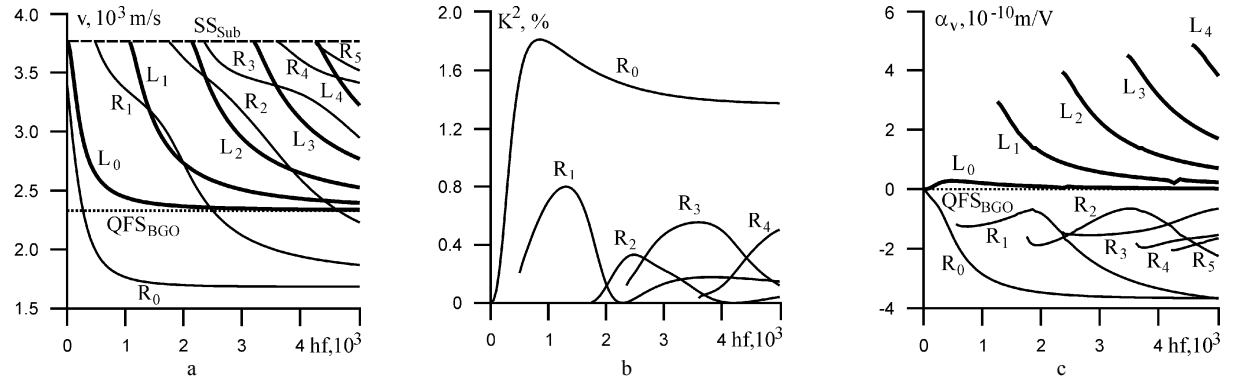

Fig. 2. Dispersive dependences of the Rayleigh and Love waves parameters as a functions of h×f (m/s) for the waves propagating along the [110] direction in (001) BGO/fused silica layered structure: a) phase velocities, b) EMCCs; c) α_v at E||[001].

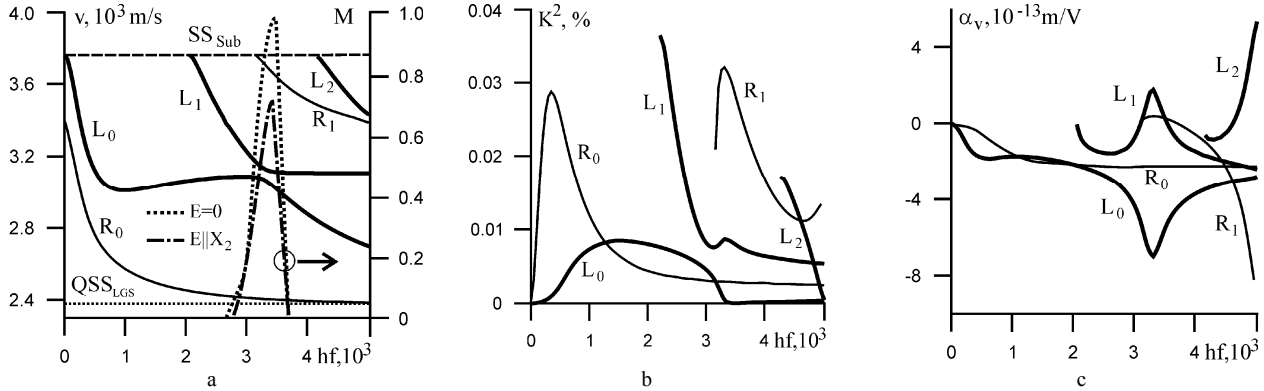

Fig. 3. Dispersive dependences of the Rayleigh and Love waves parameters as a functions of h×f (m/s) for the wave propagating along the [100] direction in (001) LGS/fused silica layered structure: a) phase velocities; b) EMCCs; c) α_v at E||[001].

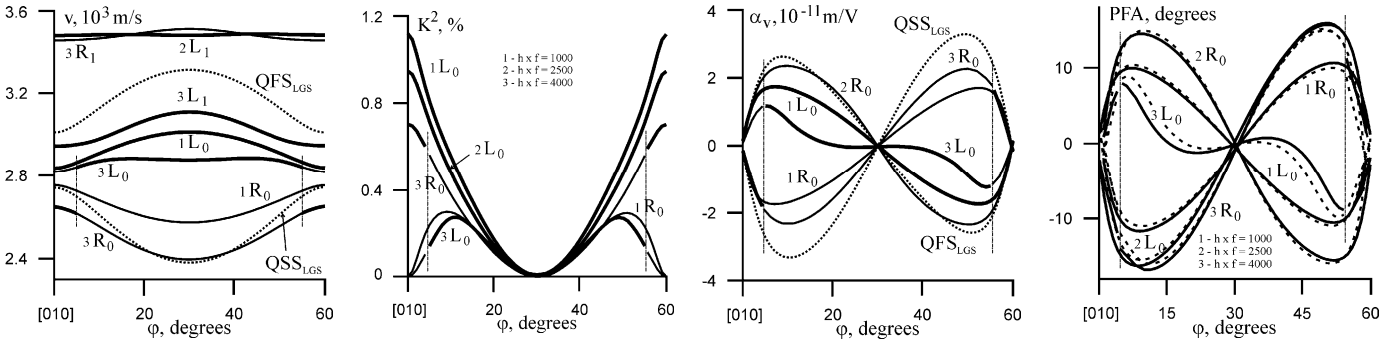

a b c d

Fig. 4. Anisotropy of Rayleigh and Love wave parameters for the wave propagating in the (001) LGS/fused silica layered structure for a few values of h×f (m/s): a) phase velocities; b) EMCCs; c) α_v at E||X_3; d) PFA at E = 0 (solid lines) and E||X_1 (dashed lines). Curves denoted as QSS_{LGS} and QFS_{LGS} are associated with quasi-bulk slow and fast shear waves in a layer, respectively.

When dc electric field is applied along the E||[100] or E||[001] elastic waves modes will turn into a generalized form. Note that if dc electric field coincides with the wave propagation direction there should be observed a maximal E influence on the phase velocities especially for R_0 and L_0 modes (fig. 1c). Thus the maximal α_v value for the zero Love mode of $2.5 \cdot 10^{-10}$ m/V at h×f = 3050 m/s is achieved at E||[100].

Figure 2 shows the dispersion curves of phase velocities, EMCCs and α_v coefficients of Rayleigh and Love waves depending on the h×f value when waves are propagated along the [110] direction of (001) BGO/fused silica. In this case a Rayleigh wave possesses a piezoelectrical activity. The range of variation of the Love waves phase velocities lies between the phase velocities of shear wave in fused quartz and fast quasi-shear wave in bismuth germanium oxide. The maximal value of K^2 = 1.8 % at h×f = 850 m/s exists for R_0 zero mode of Rayleigh wave. In the most practically significant version of dc electric field application E||[001] the hybridization between the modes is negligibly small [6]. The α_v coefficient of Love wave under h×f increasing tends to $\alpha_v = -5.6 \cdot 10^{-13}$ m/V for fast shear acoustic wave in the BGO layer.

In the [100] propagation direction of (001) LGS/fused silica layered structure there are only Rayleigh and Love waves of generalized type (fig. 3). The small EMCCs indicate on the low piezoelecrical activity of these waves (fig. 3b). An unique feature is the effect of hybridization between zero and first modes of SH waves (generalized Love waves). Either way the applied electric field reduces the effect of hybridization leading to a "splitting" of phase velocity values in this area and reducing the hybridization coefficient M [6]. Maximal values of $\alpha_v = -3.9 \cdot 10^{-12}$ m/V and $\alpha_v = 2.4 \cdot 10^{-12}$ m/V occur at the h×f = 3300 m/s close the center of hybridization area for the zero and first SH modes, respectively. The α_v coefficient increasing for the second mode with h×f increasing is also caused by a similar hybridization effect arising between the L_1 and L_2 modes.

Figure 4 shows the anisotropy characteristics of elastic waves propagating in (001) LGS/fused silica structure. Vertical dashed lines mark the points of hybridization that in this case occur between the R_0 and L_0 modes when h×f = 4500 m/s. The counting of φ angle is produced from the initial [010] direction along which the pure modes of Rayleigh and Love waves are propagated. In this direction there is a maximum of K^2 = 1.1 % at h×f = 1000 m/s for the L_0 mode. Power flow angle (PFA) has a maximal value of 16,4° for L_0 mode at h×f = 2500 m/s and of -16,8° for R_0 mode at h×f = 4000 m/s. Application of dc electric field along the X_3 direction which is three-fold axis leads to the symmetry decreasing up to point symmetry group 3 and as a result the value of PFA is increased insignificantly (up to 0,2°), but E application along X_1 axis leads to PFA increasing up to 2°.

IV. Conclusion

Using the obtained theoretical results one can analyze in detail the dispersive behavior and anisotropy of acoustic modes in a piezoelectric layered structure under the influence of homogeneous dc electric field if constants of linear and nonlinear electro-mechanical properties of the crystal are known. It was shown that for different variants of an electric field application interaction can occur between of different elastic modes. BGO layered structure has a better EMCC than that for LGS layered structure. The data obtained may be of interest in terms of study of AE devices geometry controlling by the dc electric field.

***Abstract*— This paper considers the determination of the mode shapes using x-ray topography and the application of this method to resonant piezoelectric devices made of various materials (Quartz, LGS, Lithium tantalate). The basis of the method is recalled briefly and its application to thickness mode resonators or filters is particularly considered. A comparison of the observed mode shapes with those computed using the "essentially thickness mode" theory of H.F.Tiersten indicates that this theory give very good results concerning the modes shapes and the properties of the thickness mode devices even when materials presenting large coupling coefficients are used.**

INTRODUCTION.

X-ray topography is a powerful mean to observe the vibration modes of the piezoelectric devices. Many years ago, Spencer et al. [1] have given an interesting overview of the application of the Lang topography [2] to determine the mode shapes of quartz resonators and monolithic filters. Several authors have proposed approximate expressions of the diffracted intensity in presence of vibration modes that can have some validity in particular conditions. However, the image formation occurring due to x-ray diffraction by deformed crystals is a very complex phenomenon governed by the dynamical theory of x-ray diffraction and the Takagi-Taupin partial derivatives equations. A complete description of this theory can be found in the book of A. Authier [3]. Numerical simulations of diffraction images obtained with vibrating crystals, made in solving these equations, have shown that X-ray topography can provides accurate images of the vibration modes of the piezoelectric devices if favorable diffraction conditions are chosen [4]. In other cases, the relation the between the diffracted intensity and the displacement may be quite complex. In Figure 1 (from [4]), we compare a computed topograph image obtained in solving the Takagi-Taupin equations and the corresponding experimental image (AT-cut quartz 19MHz, fundamental mode thickness 80µm, (-2,1.0) diffraction at λ#0.70Å). These diffraction conditions are particularly favorable to obtain a good observation of the mode shape (near linear increase of the diffracted intensity with the displacement in time integrated conditions). In such conditions, X-ray topography gives more accuracy and more information in a single experiment than the other techniques. The contrasts recorded in the topographs are dependant on the product of the displacement vector by the diffraction vector, on the values of partial derivatives of the displacement and on several parameters characterizing the diffraction process. X-ray topography allows observing the different components of the displacement, often separately.

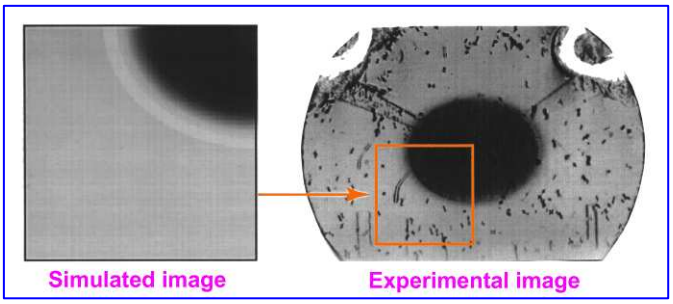

Figure 1. Comparison of computed and experimental image.

They can also be determined simultaneously if white beam topography is used. The X-ray films or the nuclear plates have a large dynamic (up to four decades) and X-ray counting can be used if necessary. The shapes so recorded of the thickness modes of energy trapping devices are most often extremely similar to those predicted by the theory proposed by H.F. Tiersten et al. [5-6]. The topography experiments reported here were made using synchrotron radiation at the LURE (Orsay - France) and at ESRF (Grenoble - France) using beam lines ID19 and BM05.

I. OBSERVED AND COMPUTED MODES IN AT-CUT QUARTZ.

A. Plane resonators with conventional electrodes:

Here after we compare the mode shapes observed for 12 MHz plane AT-cut quartz resonators (12.7mm diameter, about 134.5µm thick) having various electrode geometries, but the same electrode area. The topographs of figure 2 and 3 were obtained using (-2,1.0) reflection with an X-ray wave length of 0.70Å. As already noticed these diffraction conditions are very favorable to obtain a nearly linear relationship between the displacement and the increase of the diffracted intensity (up to the saturation of the film, and to a certain level of excitation). At very large exciting currents the diffraction process change some how (kinematical diffraction) and other diffraction techniques have to be used to determine the mode shapes [7].

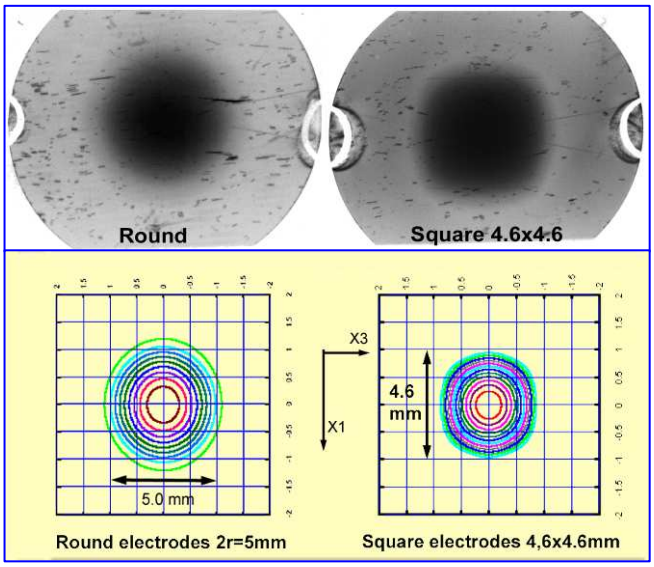

Figure 2. Observed and computed mode shapes of 12.MHz resonators (a)

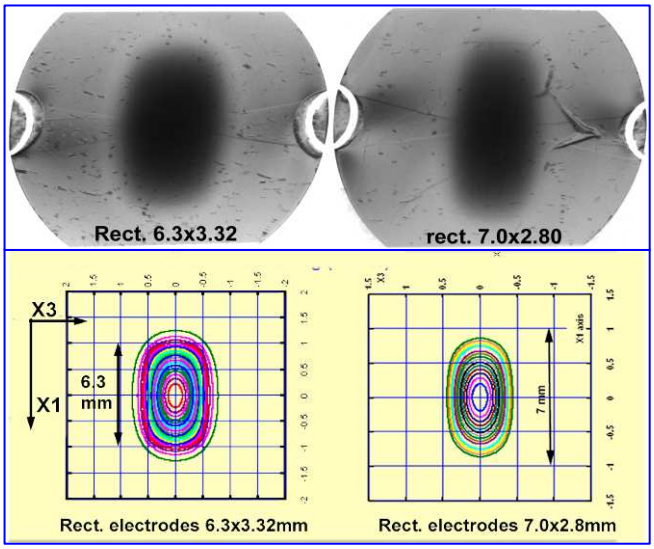

Figure 3. Observed and computed mode shapes of 12.MHz resonators (b)

Energy trapping of the modes in the electrode region occurs due to the electrical effect of the electrodes and to their mass (mass loading 0.96%). We can observe that the trapping effect is efficient for such values of the electrode dimensions and of the mass loading. The computed modes shapes (here normalized to 1 at the center of the electrodes) are very similar to the observed ones. A more detailed observation of the properties of these resonators reveals some difference concerning the resonance frequencies of the anharmonic modes and the values of the elements of the equivalent schemes. The equivalent inductance is some how more favorable (lower) for the round electrodes. This advantage results of a smaller efficiency of the corners of the square or rectangular electrodes.

Anharmonic modes: The dimensions of the electrodes chosen allow the existence of two anharmonic modes (except for the 7x2.8 electrodes that give only one anharmonic).

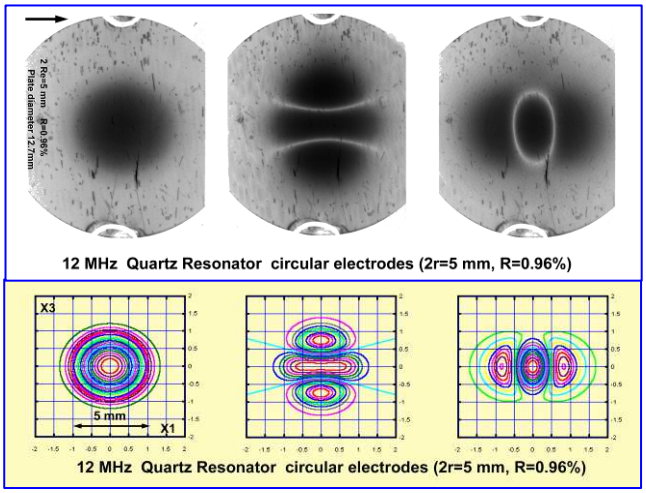

Figure 4. Mode shapes of the anharmonics (round electrodes).

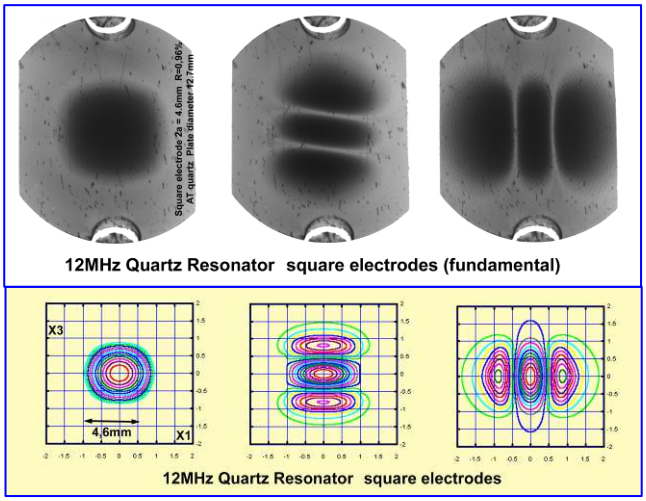

Figure 5. Mode shapes of the anharmonics (Square electrodes).

The modes corresponding to the round and the square electrodes are represented in figure 4 and 5 (same diffraction conditions as for figure 2 and 3). For some of these modes

slight differences appear between the experiment and the calculation, this is mostly the case for the 2nd mode of the resonator with square electrodes. The difference is probably due to a small defect of parallelism in the external region of the plate. These anharmonic modes appear to be more sensitive to imperfections and to the electrodes tabs than the first one, due to their larger extension. The theory elaborated by H.F. Tiersten indicates the existence, in most cases, of an intrinsic lateral anisotropy of the modes [8]. For the fundamental mode of the AT-cut of quartz this anisotropy is noticeable while it is weak for the 3rd and 5th overtone modes. It results of the ratio of the M_1 to the P_1 coefficients of the Tiersten partial derivative equations that governs the lateral dependence of the main displacement u_1 (M_1= 0.1098D+12, P_1=0.686D+11 N/m²). This anisotropy can be observed in the case of the round electrodes where the mode is slightly elongated in the x direction.

B. Electrodes taking into account the lateral anisotropy.

The use of elliptical electrodes with a particular axis ratio derived from the theory $([M_1/P_1]^{1/2}=1.265)$ leads to devices with more interesting properties, particularly for filter applications (less unwanted response and lower inductances at equal electrode surface, etc…). In this case the mode shape has the same eccentricity as the electrodes and all the anharmonic modes with 2p nodal line converge toward the same modes that have either p elliptical nodal lines or 2p radial nodal line (or a mix of that). The modes with radial nodal lines are not electrically excited (centric-symmetry in a particular coordinate system), except when some asymmetry exists (this is the case for the resonator represented in figure 6). This electrode geometry leads also to the maximum frequency separation between the main mode and the anharmonics. It is thus easier to suppress them by choice of the dimensions of the electrodes and/or of the mass loading. These properties make that well designed resonators using this electrode shape are more interesting to build filters

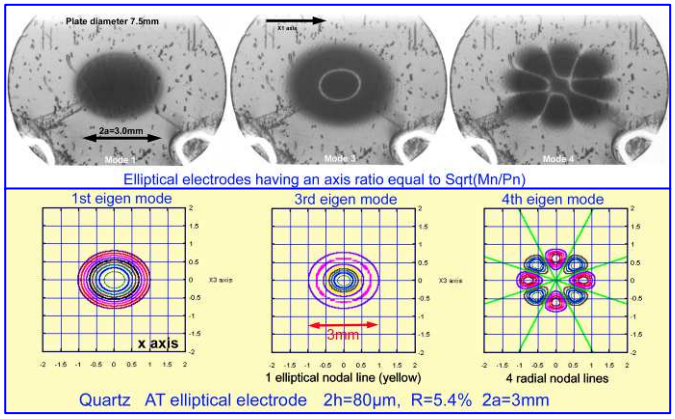

Figure 6. Modes shapes of a resonator using elliptical electrodes.

Figure 6 represents several modes of a resonator using a large elliptical electrode with an important mass loading made on a plate presenting a slight defect of symmetry (the electrode tabs are not directed along one axis of the ellipse); this allows the existence of some theoretically unexcited modes (here the mode with 4 straight nodal lines). However, the other observed modes shapes are very similar to the computed ones (same sample as for figure 1 and same diffraction conditions).

Another way to illustrate the lateral anisotropy of the fundamental modes of AT-cut quartz is given in figure 7 where we compare the mode shape produced by elliptical electrodes with the same axis ratio as considered above, either elongated in the correct direction (x1=x axis) or elongated in the x3=z' direction. It can be observed that in the first case the mode is elliptical with the same eccentricity as the electrodes while in the second case, it is nearly circular (same diffraction conditions as for figures 2 to 4).

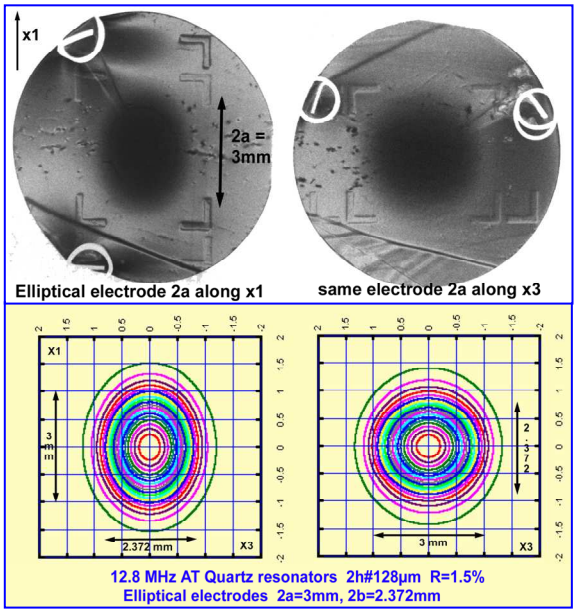

Figure 7. Elliptical electrodes elongated in the x or Z' directions.

II. LANGASITE RESONATORS

The theory proposed by Tiersten et al. makes use of some approximations considering a moderate piezoelectric effect. Most of these approximations concern in fact the cut-off frequencies of the different regions of the device that appear in the partial derivative equations. However these quantities are fundamentally one dimensional ones and they can be computed exactly for any piezoelectric material. Thus it is possible to expect good results of the application of the theory to the materials having medium or even large coupling coefficients. Some times ago [9], we have made calculations of the modes shapes of the overtone modes of plane and plano-convexe Y-cut langasite resonators. For several overtones, the results were not in very good agreement with the observations. At this time, we have noticed, for this material and also for gallium phosphate, that the computed mode shapes, and somehow the computed inductances were sensitive to the constant set used for the calculation. Since that time, these materials have been perfected and several new sets of material constants have been measured. New calculations were made using some of these more recent sets of material constants [10-11-12] for the same resonators using Y-cut LGS (thickness=0.432mm, electrode diameter D=3.5mm, plate

diameter #10mm). As can be observed in figure 8 and 9, a much better agreement is obtained, even for the overtones modes of large ranks using the constants of reference [11] (Experimental conditions (-2,1.0) diffraction, λ#0.70Å, plate thickness 0.432mm (more absorbing crystal)). The sensitivity of several important parameters appearing in the energy trapping theory to the values of the elastic constants noticed for LGS and gallium phosphate results much probably of the fact that these quantities imply many products of differences between constants or products of constants

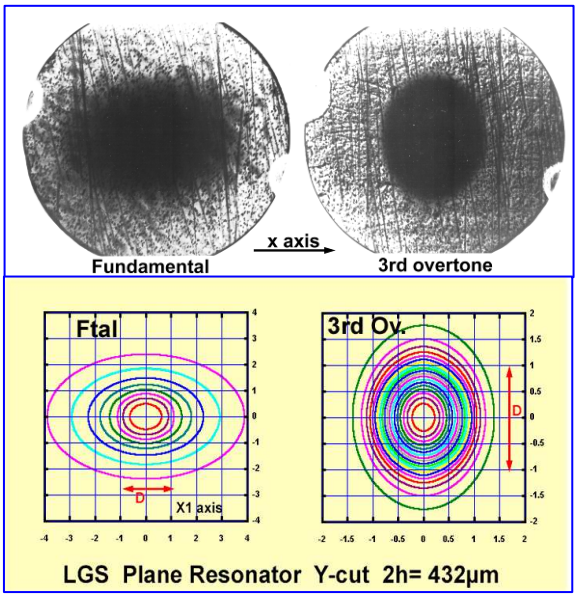

Figure 8. Fundamental and 3rd overtone modes of a LGS plane resonator

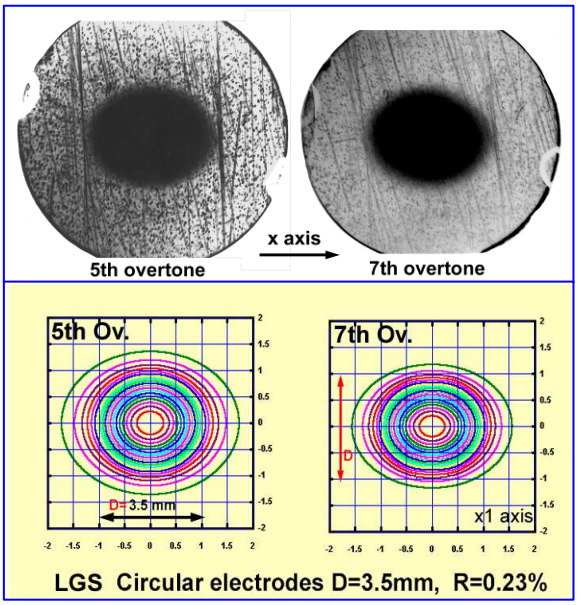

Figure 9. 5th and 7th overtone modes of a Y-cut LGS plane resonator.

. Another observation concerns the quite large anisotropy of the overtone modes of Y-cut LGS resonators.

Similarly, a better agreement between the observed and the computed modes can also be obtained for gallium phosphate resonators using the recently determined constants [13-14].

III. LITHIUM TANTALATE RESONATORS.

We have observed that the theory of essentially thickness modes of H.F. Tiersten leads to realistic results for many orientations of this material (X-cut, Y rotated cuts, doubly rotated cuts, etc…). The mode shapes computed with different sets of constants [115-16-17] have only minor differences. Hereafter, we compare the results given by this theory to the mode shapes observed using x-ray topography for x-cut resonators. Figure 10 represents the electrical response of a 27.7 MHz fundamental X-cut resonator having small electrodes and a small mass loading (aluminum electrodes) that give no trapped anharmonics for the fast shear mode (filter type resonators).

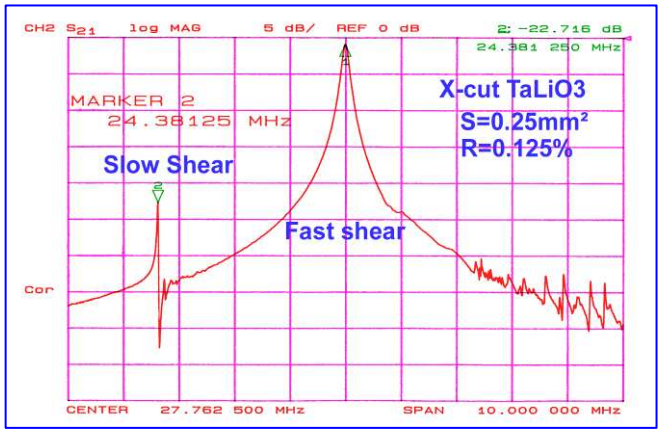

Figure 10. Response of an X-cut resonator (with compensation of Co)

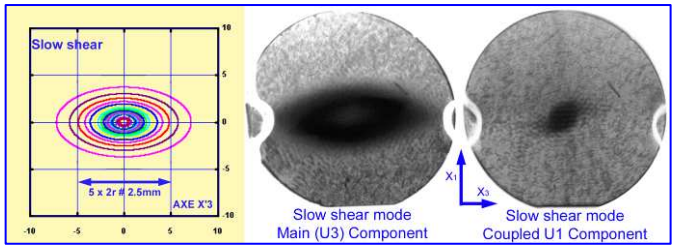

Figure 11. Slow shear mode of an X cut resonator

The slow shear mode is sufficiently close to the fast shear, so that theses mode are coupled and that some excitation of the u1 component (of the fast shear) occurs at the resonance frequency of the slow shear. This can be observed experimentally by X-ray topography (figure 11) or in considering the response curve obtained with compensation of the static capacitance (the slow shear mode is in the "slope" of the response of the fast shear). This is a forced mode effect included in the theory. It results mostly of the very large coupling coefficient of the fast shear mode (very broad response curve). This effect can be taken into account theoretically in considering the forced mode (linear combination of all the Eigen-modes verifying the boundary conditions) at this frequency, or more simply in connecting in parallel the motional arms of the equivalent schemes of both

modes. This coupling appears in the topographs taken at the resonance frequency of the slow shear mode (figure 11). The observed and the computed slow shear modes have a large and very similar anisotropy. It should also be noticed that the slow shear is very weakly trapped by small electrodes presenting a small mass loading and that its experimental mode shape is probably slightly modified, in the most external region, by the mounting clips of the plate and the conducting cement (plate diameter 5.5mm). The coupled fast shear mode excited at the resonance of the slow shear seems correctly confined in these conditions but it is also coupled to a weak plate mode (flexure). The mode shapes of the anharmonics of the fast shear were observed in a similar resonator made with larger square electrodes (S#0.66mm², 2h#70µm, plate diameter 5.5mm). Due to the large coupling coefficient (about 45%) two of them have a resonance frequency lower than the "nominal" anti-resonance frequency. The computed modes shapes are in reasonable agreement with the computed ones if the modest Q factor of mode 2 is considered. It should be noticed that for all the orientations studied (except for the Z-cut), an important lateral anisotropy of the trapped mode modes was observed in lithium tantalate. In some cases, concerning for example the doubly rotated cuts giving a zero temperature coefficient for the overtone modes, no trapping may exist in one direction for a particular overtone rank.

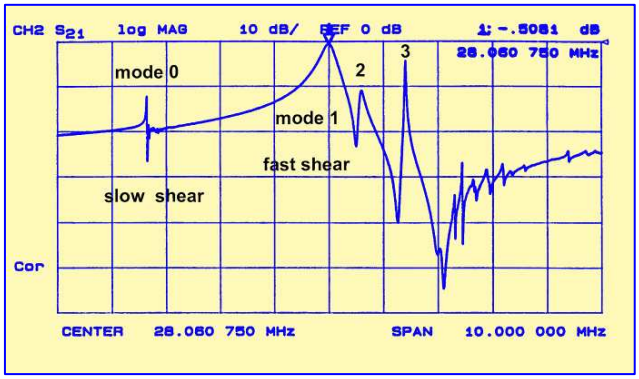

Figure 12. Response curve of an X-cut resonator made with large electrodes

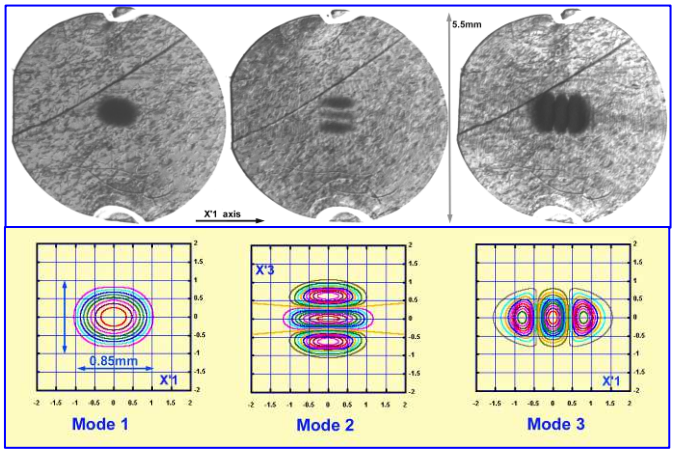

Figure 13. Mode shape of the fundamental and of its two first anharmonics.

IV. UNWANTED STATIONARY AND PROGRESSIVE PLATE MODES

The theory of the essentially thickness modes takes into account the possibility of (small) components other than the main displacement but neither that of strong resonant plate modes nor that of progressives modes. The resonant plate modes are most often very weakly coupled to the thickness modes existing in plates having a large ratio of the lateral dimensions to the thickness. They are more frequent in devices using rectangular plates and/or rectangular electrodes and in beveled resonators with a moderate ratio of the lateral dimensions to the thickness. They are very difficult to avoid in miniaturized devices where this ratio is small, at least, for one lateral dimension. Several approximate or exact theories are able to consider the coupling of the plate modes with the thickness modes. However there is a difficulty to describe theoretically the fixation conditions of the plate in a manner which represent accurately those used in real devices. Most often the actual plate modes (resonant or progressive) are extremely dependant to the fixation conditions. Nevertheless, these theories are extensively used for the design of miniaturized resonators.

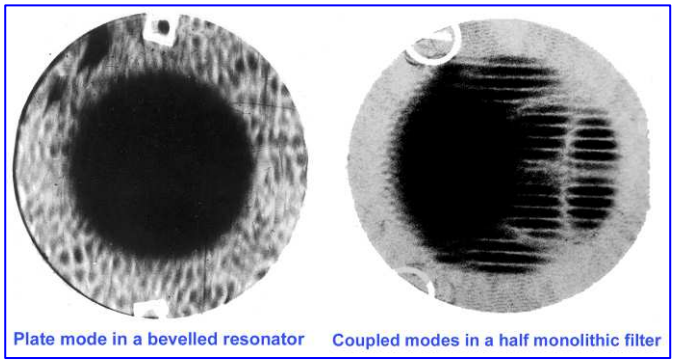

Figure 14. Plate modes coupled to the fundamental thickness shear.

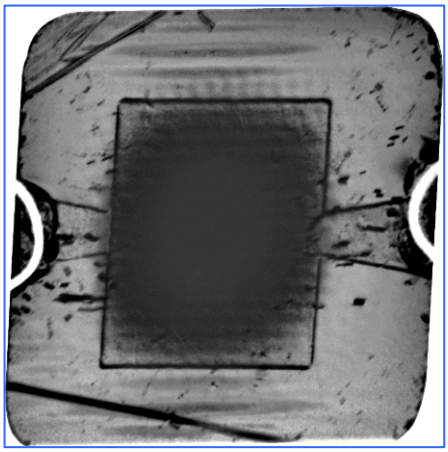

Figure 15. Flexure coupled to thickness shear in a plane rectangular AT-cut quartz resonator

Some examples of coupled plate modes are given in figure 14. One was observed in a beveled resonator. The other was observed in a monolithic filter (only one pair of electrodes is excited here). Our observations have shown that the coupled

modes are more frequent in plates having a rectangular shape and/or using rectangular electrodes (figure 15). In quartz resonators with one small lateral dimension, it is usual to choose the plate mode coupled to the thickness mode so to keep an acceptable Q factor and a good temperature coefficient.

A. *Progressive coupled modes*

We have observed progressive modes coupled to the thickness shear in all the fundamental mode plane resonators studied by time resolved (synchronous) topography. They carry a noticeable energy in devices made with high coupling materials and, in all cases, including quartz; they explain the modest Q.F products observed for fundamental mode devices. We consider that they can be detected in resonators having a Q factor lower than a few hundred thousands. The observation of these progressive plate modes by stroboscopic X-ray topograph indicates clearly that they carry energy towards the fixations of the device. The energy loss per period and the stored energy can be estimated roughly using x-ray topographs (or more adequately using video recordings of the diffraction images obtained in stroboscopic conditions). They seem to correspond approximately to the measured Q factor. For the different kinds of fundamental mode resonators this quantity is typically of the order of a very few thousands for X-cut lithium tantalate, of several ten thousands for medium coupling materials such as LGS and GaPO4, and up to a very few hundred thousands for large fundamental mode quartz resonators. Most often, the progressive modes have at least two components (u1 and u3) and present a quite large standing wave ratio which facilitates their detection. *It is extremely probable, that in fact, the progressive modes are the real responsible of the activity dips (by a modification of the progressive wave due to a thermal effect) and of several other annoying phenomena existing in resonators.* These modes are very complex and presently no satisfactory theory (or numerical solution) seems to exist. An example of the progressive modes observed in an X-cut TaLiO3 resonator by time resolved topography is presented in figure 16. It should be noticed that in these images a non-linear relation exist between the diffracted intensity and the strains (giving rise to the phenomena of partial contrast inversion).

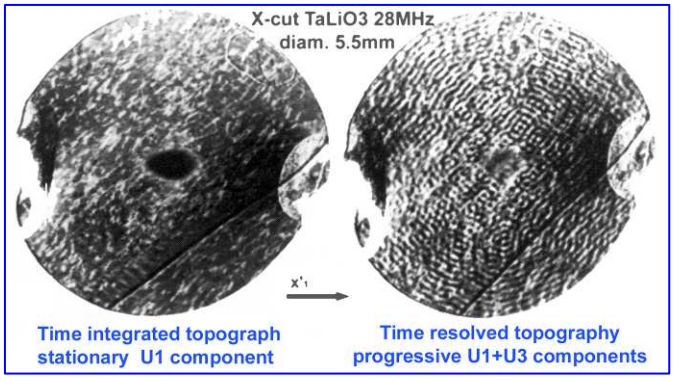

Figure 16. Progressive mode coupled to the fast shear in X-cut TaLiO3.

V. CONCLUSION

X-Ray topography constitutes an accurate method to determine the mode shapes of piezoelectric devices. The theory of the essentially thickness mode established by H.F. Tiersten predicts most often very accurately the mode shape of the resonators that have sufficiently large ratios of the lateral dimensions to the thickness. Several effects resulting of the finite dimensions of the plate are taken into account by this theory, but other ones are not relevant of its hypothesis. This is the case of the coupling of the thickness mode with resonant or progressive plate modes of significant amplitudes which are difficult to avoid in miniaturized devices. The progressive plate modes are clearly responsible of the limited Q.F product, at least, of the fundamental mode of plane thickness mode resonators. They are much probably implied in many other annoying phenomena such as the activity dips.

Compact Parametric Model of Capacitive BAW Resonators

Giorgio Casinovi, Ashwin K. Samarao and Farrokh Ayazi

Atlanta, GA 30332, USA

***Abstract*—This paper presents a new equivalent-circuit model of SiBARs, derived in a mathematically rigorous way from the physics equations governing the behavior of the device. The model is parametric, that is, the model component values can be computed directly from the dimensions of the resonator and the properties of the material. The model also accounts fully, accurately and automatically for aspects of the device behavior that arise from the interaction of multiple physics domain: the shift in the resonance frequency with the polarization voltage ("spring softening"), the effect of the polarization voltage and gap size on the insertion loss, and the reduction in the resonator loaded *Q* as the polarization voltage is increased. In contrast, those effects are not automatically accounted for by other models, such as mass-spring combinations. Finally, the model described is load- and source-independent, and thus it reproduces accurately the behavior of the device itself, regardless of the type and characteristics of the surrounding circuitry.**

I. INTRODUCTION

Much research activity in recent years has been directed at the development of bulk acoustic resonators that are compatible with standard integrated circuit technologies. In this respect, capacitive silicon resonators offer a particularly attractive option, since they can be made entirely of materials that are used routinely in IC fabrication processes, resulting in significant advantages in terms of ease of integration and cost savings. For this reason, their use is becoming increasingly common in a wide variety of RF circuits, such as reference oscillators and filters [1].

Disk resonators were among the first examples of micromechanical bulk resonators, but more recently width-extensional-mode resonators based on an alternative, rectangular-bar geometry were demonstrated [2]. In this paper this particular type of capacitive resonators will be referred to as silicon bulk acoustic resonators, or SiBARs. The basic structure of a SiBAR is schematically shown in Fig. 1: the resonating bar element is placed between two electrodes, supported by two thin tethers. A DC polarization voltage applied between the resonator and the electrodes generates an electrostatic field in the capacitive gaps. When an AC voltage is applied to the drive electrode, the electrostatic force applied to the corresponding face of the resonator creates an elastic

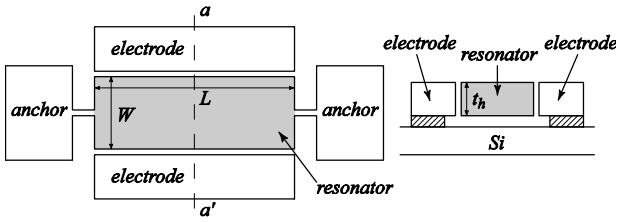

Figure 1. Schematic structure of a SiBAR: top view (left) and cross-sectional view (right)

wave that propagates through the bar. Small changes in the size of the capacitive gap on the other side of the device induce a voltage on the sense electrode, the amplitude of which peaks near the mechanical resonant frequencies of the bar.

While the behavior of bulk resonators is well understood in broad, qualitative terms, sufficiently accurate analytical models of those devices that can be used in place of full-blown finite-element simulation are still lacking. This is a significant drawback in the design of mixed-technology systems that rely on micromechanical resonators. In the simulation of such systems it is common practice to use simple RLC models for the resonators [3][4]. However these models are usually derived using empirical or semi-empirical techniques, often relying on qualitative analogies with similarly behaving systems, such as mass-spring combinations. Consequently, the accuracy of such models cannot be demonstrated or even estimated theoretically: at best, it can only be verified numerically or empirically, and on a case by case basis. In fact, an empirical *RLC* model could not track changes in *Q* and the insertion loss of a silicon bulk acoustic resonator (SiBAR) with the polarization voltage without the introduction of an artificial parasitic resistance [5].

This paper presents an equivalent circuit model of a SiBAR that is derived in a mathematically rigorous way from the governing equations of the device. The model is parametric, in that the model component values can be computed directly from the dimensions of the resonator and the properties of the material. The only exceptions are the resistances in the model, whose values depend on the energy

This work was supported in part by a NSF EAGER grant.

losses in the resonator, which are difficult to model analytically.

The model also accounts fully, accurately and automatically for aspects of the device behavior that arise from the interaction of multiple physics domain: the shift in the resonance frequency with the polarization voltage ("spring softening"), the effect of the polarization voltage and gap size on the insertion loss, and the reduction in the resonator loaded Q as the polarization voltage is increased. In contrast, those effects are not automatically accounted for by other models, such as mass-spring combinations. Finally, the model described in this paper is load- and source-independent, and thus it reproduces accurately the behavior of the device itself, regardless of the type and characteristics of the surrounding circuitry. The model has been validated numerically against finite-element simulations and experimentally against measurements taken on a SiBAR fabricated using the HARPSS process [2].

II. Resonator Model

As in all capacitive MEMS resonators, the operation of a SiBAR is based on the principle of electromechanical transduction. Let W, L and t_h denote respectively the width, length and thickness of the resonator, as shown in Fig. 1. If a DC polarization voltage V_p is applied across the drive and sense capacitive gaps, the resulting electric fields create pressure on the faces of the resonator and a consequent elastic deformation of the structure. If a small-signal voltage v_d is superimposed to the DC voltage at the drive electrode, the change in the electric field in the capacitive gap and the corresponding change in the pressure applied to the resonator face generate an elastic wave that propagates across the width of the resonator.

Therefore a compact SiBAR model can be derived from the equations of elastic wave propagation, under the approximate assumption that the resonant modes of interest are created by the propagation of plane waves in the direction of the width of the resonator. Under this assumption, an analytical solution of the elasticity equations can be obtained. By means of appropriate circuit synthesis methods, this solution is used to derive an equivalent circuit, that is, a circuit the behavior of which is described by the same equations that characterize the operation of the SiBAR.

The resulting equivalent circuit model of the SiBAR is shown in Fig. 2. The values of the circuit elements are given by the following expressions

$$\begin{aligned} C_1 &= C_g/8 & L_1 &= 8/(\omega_0^2 C_g) \\ C_2 &= 2C_g/\pi^2 & L_2 &= \pi^2/(2\omega_0^2 C_g) \\ C_0 &= \varepsilon^2 A^3 c_{33}/WQ_p^2 & R_1 R_2 &= (2\pi/\omega_0 C_g)^2 \end{aligned} \tag{1}$$

In the expressions above, Q_p is the value of the DC charge that is present on the drive and sense gap capacitances. Specifically $Q_p = C_g V_p = (\varepsilon A/g)V_p$, where g is the size of the capacitive gap, ε the dielectric permittivity, $A = Lt_h$ and C_g the value of the gap capacitance. Furthermore $\omega_0 = 2\pi f_0$, where f_0 is the mechanical resonance frequency of the resonator, and c_{33} is the stiffness coefficient of the resonator material in the direction of propagation of the elastic waves.

The values of R_1 and R_2 depend on the energy losses in the resonator, that is, on its mechanical Q. Note that (1) imposes a constraint on the product $R_1 R_2$. Consequently the value of only one of those resistors can be chosen independently. For example, the measured ratio between the input voltage and the short-circuit output current of the SiBAR at resonance can be used for this purpose. An approximate but sufficiently accurate expression for this ratio can be obtained by observing that near the resonant frequency the current through the series $R_2 L_2 C_2$ circuit will dominate the current through the parallel $R_1 L_1 C_1$ circuit: it is therefore reasonable to assume that $i_3 \cong i_4$. After some algebraic manipulations, the following expression is obtained

$$i_s = \frac{j\omega C_g/L_2 C_0}{-\omega^2 + j\omega(R_2/L_2) + (1 - 2C_2/C_0)/(L_2 C_2)} v_d \tag{2}$$

The expression above shows that the electrical resonant frequency ω_1 — i.e. the frequency at which i_s achieves its maximum value — is lower than the mechanical resonant frequency ω_0 and is given by

$$\omega_1 = \omega_0 \sqrt{1 - 2C_2/C_0} \tag{3}$$

In particular, since the value of C_0 depends on the DC bias voltage V_p, so does the value of ω_1. This is a well-known effect, which has been consistently observed in experimental setups [3][5]. Setting $\omega = \omega_1$ in (2) yields the desired

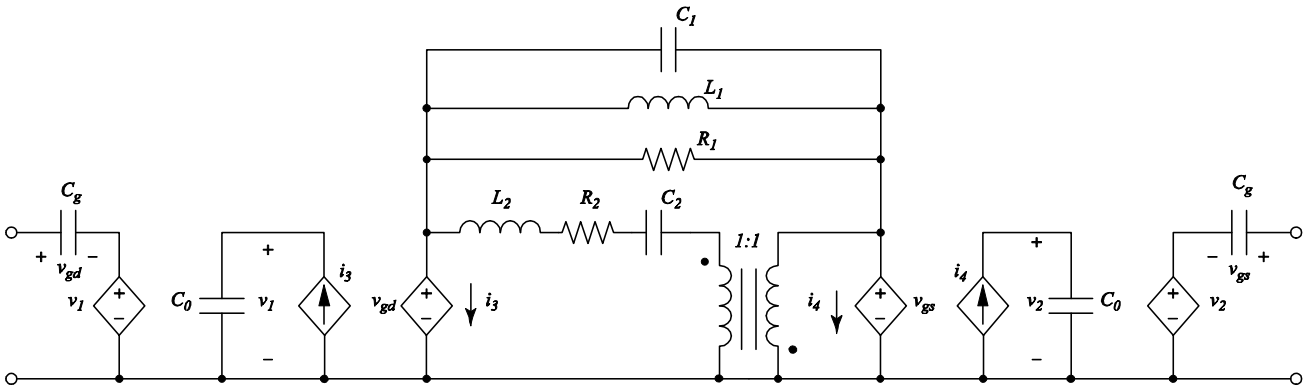

Figure 2. SibAR equivalent circuit model

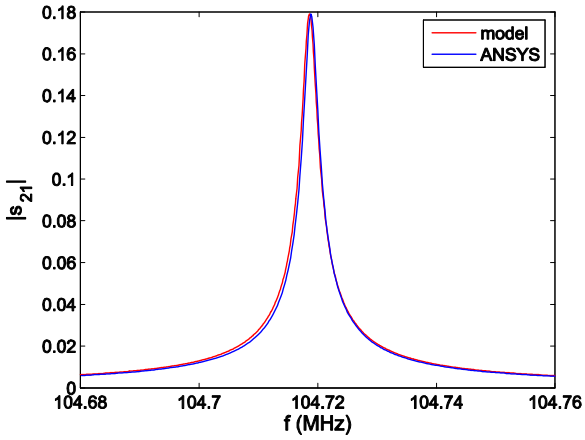

Figure 3. SiBAR s_{21} parameter extracted from simulations

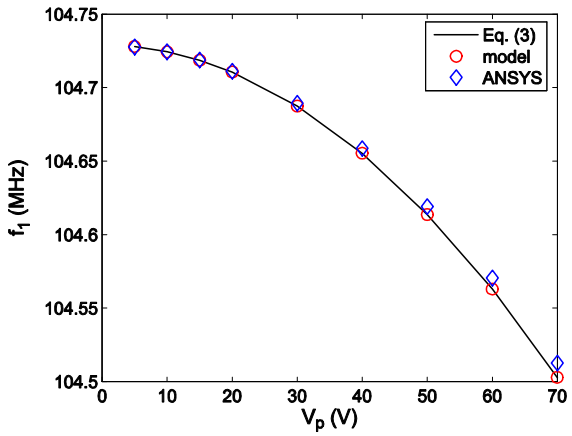

Figure 4. SiBAR electrical resonance frequency vs. polarization voltage

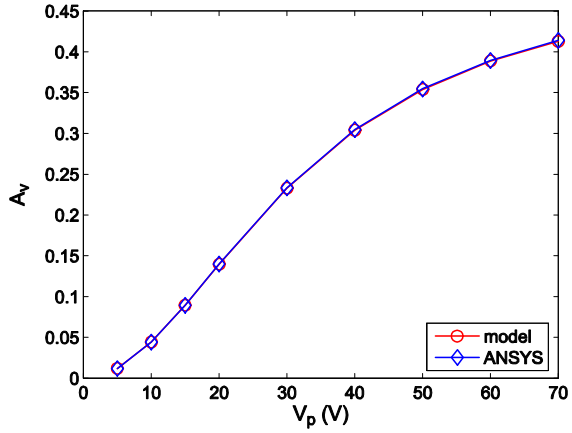

Figure 5. SiBAR voltage gain at resonance vs. polarization voltage

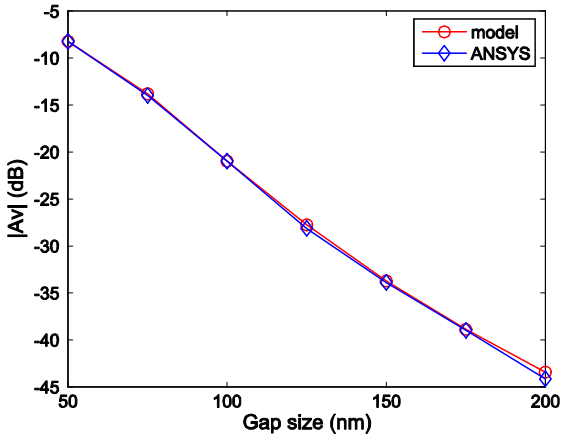

Figure 6. SiBAR voltage gain at resonance vs. capacitive gap size

relationship between the value of R_2 and the v_d/i_s ratio at resonance, namely

$$R_2 = \frac{C_g}{C_0}\left(\frac{v_d}{i_s}\right)_{\omega=\omega_1} \tag{4}$$

Note that once the value of R_2 has been computed for a particular geometry, it can be extrapolated to other geometries if the rate of energy loss in the resonator does not change.

Further improvements to the model can be made by solving the elasticity equations more accurately, taking the finite thickness of the resonator into account [6]. Because of space limitations the calculations are omitted here, but the end result is a modified expression for C_0, while the rest of the equivalent circuit model remains unchanged.

III. Numerical Simulations

The equivalent circuit model described in the previous section was compared to finite-element simulations of a SiBAR performed in ANSYS. A detailed description of the ANSYS model is given in [6]. The device used in the comparisons was a resonator of dimensions L = 400 µm, W = 40 µm, t_h = 20 µm, with a DC bias voltage V_p = 15 V. Fig. 3 compares the s_{21} parameter obtained from an ANSYS simulation of the device with 50 Ω source and load resistances with the s_{21} parameter of the model under the same conditions.

A second set of simulations was then performed on the same device with various DC polarization voltages, ranging from 5 V to 70 V, while keeping the values of the source and load resistances fixed at 50 Ω. Fig. 4 shows the electrical resonant frequency $f_1 = \omega_1/2\pi$ of the device at each value of V_p, obtained both from ANSYS and model simulations. The same figure shows also the graph of the relationship between f_1 and V_p given by (3). It can be seen that the simulation results track very closely the relationship in (3), which in turn matches actual measurements taken on SiBARs, as will be shown in Sec. IV. Fig. 5 shows the value of the voltage gain $A_v = v_{out}/v_{in}$ at resonance as a function of V_p, obtained both from ANSYS and model simulations.

A final set of simulations was performed to evaluate the effect of the size of the capacitive gaps on the voltage gain of the device. It should be noted that for these simulations the values of R_1 and R_2 were changed assuming an inversely proportional relationship to C_g. This assumption stems from the fact that R_1 and R_2 are determined by the mechanical Q of the resonator, which is independent of the gap size. Based on the expressions in (1), keeping the Q of resonant circuits

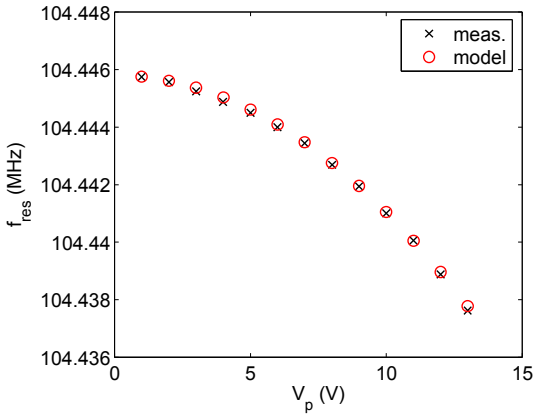

Figure 7. SiBAR resonance frequency predicted by the model compared to measured values

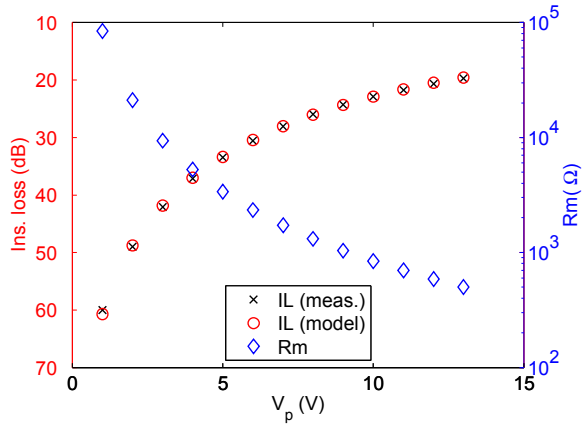

Figure 8. Left axis: SiBAR insertion loss predicted by the model compared to measured values. Right axis: SiBAR motional resistance

$R_1L_1C_1$ and $R_2L_2C_2$ constant with the gap size requires the resistance values to be inversely proportional to C_g. The results of this last set of simulations obtained from the model and from ANSYS are shown in Fig. 6. It can be seen that in all cases the graphs in the figures show excellent agreement between the two sets of data, a result that clearly supports the validity of the model.

IV. Experimental Model Validation

In addition to finite-element simulations, the SiBAR model was validated experimentally against measurements taken on a device fabricated using the HARPSS process [2]. The nominal dimensions of the device were L = 400 µm, W = 40 µm, t_h = 20 µm. The extracted values of the width and gap size were W = 40.028 µm and g = 99 nm, respectively. Fig. 7 compares the measured resonance frequency of the device with that predicted by the model, as a function of the polarization voltage V_p. Fig. 8 shows a similar comparison for the insertion loss of the device, also as a function of V_p. For reference purposes, the corresponding values of the motional resistance R_m are also plotted. Finally, the values of the quality factor Q of the device, both measured and predicted by the model, are plotted versus V_p in Fig. 9. Although the agreement is not as good as in the two previous figures, it can be seen that the

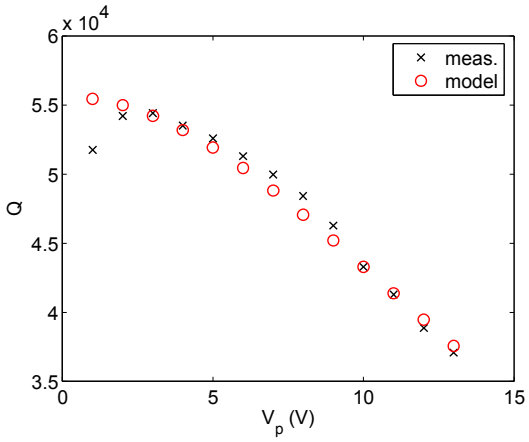

Figure 9. SiBAR quality factor Q predicted by the model compared to measured values

model tracks with good accuracy the drop in Q with the increase in V_p without introducing an artificial additional resistance, which is instead needed in simpler, empirically derived resonator models [5].

V. Conclusion

This paper has introduced a parametric equivalent circuit model for SiBARs that is derived directly from the equations governing the electromechanical behavior of the device. Consequently the values of most of the components in the model can be computed analytically, based on the dimensions of the resonator and the properties of the material. The only model parameters that cannot be determined in this way are the resistance values, which are tied to energy losses in the device. Simulation results show that the performance parameters extracted from the model are in excellent agreement with those obtained both from finite-element analysis of the device and from actual measurements. Thus the model can be profitably used in the design of complex mixed-technology circuits that include SiBARs among their components, such as VHF oscillators.

***Abstract*—As the systematic study of nonlinear vibrations of quartz crystal resonators, we have established the nonlinear Mindlin plate equations which include the strongly coupled thickness-shear and flexural modes. Based on the simplification of these complicated nonlinear equations, equations of thickness-shear vibrations of quartz crystal plates have been solved by the combination of the Galerkin method and homotopy analysis method (HAM). The amplitude-frequency relation we have obtained shows that the nonlinear frequency of thickness-shear vibrations depends on the vibration amplitude and thickness and length of plate, which is quite different from the linear cases. All these efforts will result in applicable solution techniques for further studies of nonlinear effects of quartz plates under bias fields for the precise analysis and design of quartz crystal resonators.**

I. INTRODUCTION

Common types of piezoelectric resonators such as the quartz crystal resonators always operate at a desired resonant frequency with broad applications for frequency control and detection in electronic and mechanical products and systems [1-2]. The linear piezoelectric plate theories for these applications have been successfully studied by Mindlin, Tiersten, and Lee et al and yielded many satisfactory results [3-5]. However, with demand for higher frequency and miniaturization of piezoelectric structures, many nonlinear phenomena such as the derive level dependency (DLD) and activity dip have emerged and required analysis [6]. These intrinsic nonlinearities are responsible for the coupling between the vibration modes and external or internal bias field effects which ultimately cause frequency instability and affect the operation precision of piezoelectric devices. Therefore, there is a strong need to study nonlinear properties and behaviors of vibrations of quartz crystal resonators for many different purposes. Actually, some preliminary and challenging work has been done by many researchers. Yang has established equations for the extensional and flexural vibrations of electroelastic plates under strong electric field [7]. Yang and his collaborators also studied many nonlinear couplings between thickness-shear and other vibration modes [8-9]. In his doctoral dissertation, Patel has employed the finite element method based on equations of nonlinear three-dimensional piezoelectricity to analyze well-known DLD phenomenon in quartz crystal resonators [10].

In our earlier studies, we have already established the nonlinear Mindlin plate equations which include the thickness-shear and flexural vibration modes that are strongly coupled [11-12]. We found the nonlinear Mindlin plate equations are indeed complicated, and cannot be directly solved by known methods we are familiar with from linear equations. On the other hand, even with powerful computers, both linear and nonlinear Mindlin plate equations are still difficult to solve with numerical methods due to difficulties in solving extremely large scale linear systems at high frequency. The finite difference method also has been tried without any valuable results [13]. For this reason, we focused on solving the nonlinear equations of flexural and thickness-shear vibrations of quartz crystal plate by the Galerkin method and homotopy analysis method (HAM). Both the analytical and numerical results have shown some inherent characteristics of nonlinear vibration and given some valuable directions for further research.

II. THE NONLINEAR MINDLIN PLATE EQUATIONS

Through the consideration of kinematic and material nonlinearities, nonlinear Mindlin plate equations have been established by following the procedure of Mindlin with the signature expansion of displacements in the thickness coordinate [11-12]. The nonlinear equations of flexural and thickness-shear vibrations are [12]

&-2bc_{1212}\left(u_{2,1}^{(0)}+u_1^{(1)}\right)-bc_{121112}u_{2,1}^{(0)}u_{2,1}^{(0)}\left(u_{2,1}^{(0)}+u_1^{(1)}\right)\\
&-bc_{122212}u_1^{(1)}u_1^{(1)}\left(u_{2,1}^{(0)}+u_1^{(1)}\right)-bc_{2211}u_{2,1}^{(0)}u_{2,1}^{(0)}u_1^{(1)}\\
&-bc_{2222}u_1^{(1)}u_1^{(1)}u_1^{(1)}-\frac{b}{4}c_{221111}\left(u_{2,1}^{(0)}u_{2,1}^{(0)}\right)^2u_1^{(1)}\\
&-\frac{b}{2}c_{221122}u_{2,1}^{(0)}u_{2,1}^{(0)}u_1^{(1)}u_1^{(1)}u_1^{(1)}-\frac{b}{4}c_{222222}\left(u_1^{(1)}u_1^{(1)}\right)u_1^{(1)}\\
&-bc_{221212}u_1^{(1)}\left(u_1^{(1)}u_{1,1}^{(1)}\right)^2=\frac{2b^3}{3}\rho\ddot{u}_1^{(1)}\ ,
\end{aligned}
\tag{1}
$$

where $u_2^{(0)}$ and $u_1^{(1)}$ are the displacements of flexural and thickness-shear vibrations modes, c_{ijkl} and c_{ijklmn} are the second and third elastic constants of material, b and ρ are the half thickness of plate and density of material, respectively. Not surprisingly, we found that the nonlinear Mindlin plate equations with the consideration of kinematic and material nonlinearities are indeed complicated. Therefore, we first carry out the analysis of linear Mindlin plate equations for comparison purpose. When the nonlinear terms in (1) are neglected, we have

$$
\begin{aligned}
&2bc_{66}\left[u_{2,11}^{(0)}+u_{1,1}^{(1)}\right]=2b\rho\ddot{u}_2^{(0)},\\
&\frac{2b^3}{3}c_{11}u_{1,11}^{(1)}-2bc_{66}\left[u_{2,1}^{(0)}+u_1^{(1)}\right]=\frac{2b^3}{3}\rho\ddot{u}_1^{(1)}.
\end{aligned}
\tag{2}
$$

By assuming a long thickness-shear wave mode, we have corresponding displacements as [3-4]

$$
u_2^{(0)}=A\sin(\xi x_1)\cos(\omega t),\quad u_1^{(1)}=B\cos(\eta x_1)\cos(\omega t),
\tag{3}
$$

where $A, B, \xi, \eta,$ and ω are amplitudes, wavenumbers, and angular frequency, respectively.

For the case when the two ends of the plate are free, the corresponding boundary conditions we have are [3, 14]

$$
u_{2,1}^{(0)}(x_1=\pm a)=0,\quad u_1^{(1)}(x_1=\pm a)=0.
\tag{4}
$$

Substituting (3) into (4), we have

$$
\xi=\frac{n\pi}{2a}, n=1,3,5,7\cdots,\quad \eta=\frac{m\pi}{2a}, m=1,3,5,7\cdots.
\tag{5}
$$

By inserting (5) back into (3) and (2), and consider thickness-shear approximation [3-4], we have

$$
\omega^2\cong\frac{3c_{66}}{b^2\rho}+\frac{c_{11}}{\rho}\left(\frac{m\pi}{2a}\right)^2.
\tag{6}
$$

This is the known long thickness-shear vibration frequency of a finite quartz crystal plate [1]. Particularly, if $m=1$, it is the fundamental long thickness-shear frequency.

III. Galerkin Approximation

We are mostly interested in the effect of the flexural mode and nonlinear terms on thickness-shear vibration frequency and mode shapes. The Galerkin method is frequently employed to solve nonlinear wave propagation problems in finite regions [15-16]. By assuming the spatial variation of displacements in the form of linear mode shape, we can use the orthogonal properties of the linear mode shapes to obtain equation to determine temporal behavior.

Based on (3) and (5), for the lowest-order effect of the flexural mode on the fundamental thickness-shear mode $m=1, n=1$, we have

$$
u_2^{(0)}=\overline{A}u(t)\sin\left(\frac{\pi x_1}{2a}\right),\quad u_1^{(1)}=\overline{B}u(t)\cos\left(\frac{\pi x_1}{2a}\right),
\tag{7}
$$

where $\overline{A}$ and $\overline{B}$ are new nonlinear amplitudes. We move the inertia term from right side of the second equation of (1) to left side and define this expression as the weighting error. We also require this weight error to vanish in one period, or over the length, as

$$
\int_{-a}^{a}\varepsilon\cdot\cos\left(\frac{\pi x_1}{2a}\right)dx_1=0.
\tag{8}
$$

Substituting (7) into (8) and integrating through the length of the plate, we have the equation

$$
\ddot{u}+\widetilde{C}_1u+\widetilde{C}_2u^3+\widetilde{C}_3u^5=0,
\tag{9}
$$

where

$$
\begin{aligned}
\widetilde{C}_1&=\omega_F^2\cong\frac{3c_{66}}{b^2\rho}+\frac{c_{11}\pi^2}{4a^2\rho},\\
\widetilde{C}_2&=\frac{\overline{B}^2c_{22}}{b^2\rho}+\frac{\overline{B}^2c_{222}}{4b^2\rho}+\frac{\overline{B}^2c_{266}}{b^2\rho}+\frac{\overline{A}\overline{B}c_{266}\pi}{2ab^2\rho}+\frac{\overline{B}^2c_{166}\pi^2}{12a^2\rho}\\
&\quad+\frac{\overline{A}^2c_{12}\pi^2}{4a^2b^2\rho}+\frac{\overline{A}^2c_{166}\pi^2}{4a^2b^2\rho}+\frac{\overline{A}\overline{B}c_{166}\pi^3}{24a^3\rho}+\frac{\overline{A}^3c_{166}\pi^3}{8\overline{B}a^3b^2\rho},\\
\widetilde{C}_3&=\frac{\overline{A}^2\overline{B}^2c_{122}\pi^2}{10a^2b^2\rho}+\frac{\overline{B}^4c_{266}\pi^2}{20a^2b^2\rho}+\frac{\overline{B}^4c_{266}\pi^2}{60a^2\rho}+\frac{\overline{A}^2\overline{B}^2c_{166}\pi^4}{240a^4\rho}+\frac{\overline{A}^4c_{112}\pi^2}{80a^4b^2\rho},
\end{aligned}
\tag{10}
$$

where ω_F is fundamental and referential frequency of long thickness-shear vibration of quartz crystal plate.

IV. Nonlinear Solutions

The standard homotopy analysis method proposed by Liao has been successfully applied to solve many types of nonlinear equations in science and engineering [17-19]. We want to

employ this method to solve nonlinear equation of thickness-shear vibrations of quartz crystal plate as shown in (9). First, we introduce two new variables, $\tau = \omega t$ and $y = u$, to (9) and assume corresponding initial condition as

$$\begin{aligned} &\omega^2 y'' + \widetilde{C}_1 y + \widetilde{C}_2 y^3 + \widetilde{C}_3 y^5 = 0, \\ &y(0) = \widetilde{B}, y'(0) = 0, \end{aligned} \tag{11}$$

where ω is the nonlinear frequency which will be determined later, and $\widetilde{B}$ is the initial condition. It should also be pointed out that primes denote derivatives with respect to the new variable τ in (11).

Now we want to solve (11) by homotopy analysis method. Based on the boundary conditions (11), it is reasonable to assume the solution expression as [17]

$$y = \sum_{m=0}^{+\infty} c_m \cos[(2m+1)\tau], \tag{12}$$

where c_m is a constant coefficient. Under the rule of solution expression in (12), we choose

$$y_0 = \widetilde{B}\cos(\tau), \tag{13}$$

as the initial guess of $y(\tau)$. First of all, we define two Taylor series as

$$\begin{aligned} &\phi(\tau,q) = y_0(\tau) + \sum_{m=1}^{+\infty} y_m q^m, \ \omega(q) = \omega_0 + \sum_{m=1}^{+\infty} \omega_m q^m, \\ &y_m(\tau) = \frac{1}{m!}\frac{\partial^m \phi(\tau,q)}{\partial q^m}\bigg|_{q=0}, \ \omega_m(q) = \frac{1}{m!}\frac{\partial^m \omega(q)}{\partial q^m}\bigg|_{q=0}, \end{aligned} \tag{14}$$

where $q \in [0,1]$ denotes an embedding parameter. Furthermore, we define auxiliary linear and nonlinear operators as

$$\begin{aligned} &L[\phi(\tau,q)] = \omega_0^2\left[\frac{\partial^2 \phi(\tau,q)}{\partial \tau^2} + \phi(\tau,q)\right], \\ &N[\phi(\tau,q),\omega(q)] = \omega^2 \frac{\partial^2 \phi(\tau,q)}{\partial \tau^2} + \widetilde{C}_1 \phi(\tau,q) + \widetilde{C}_2 \phi^3(\tau,q) + \widetilde{C}_3 \phi^5(\tau,q), \end{aligned} \tag{15}$$

where ω_0 is the initial guess of nonlinear frequency.

We construct the zeroth-order deformation equation

$$(1-q)L[\phi(\tau,q) - y_0(\tau)] = qhH(\tau)N[\phi(\tau,q),\omega(q)], \tag{16}$$

where $h \neq 0$ is an auxiliary parameter, and $H(\tau) \neq 0$ is an auxiliary function of τ. From (16) we know that if q increases from 0 to 1, $\phi(\tau,0)$ and ω_0 varies form initial guess to the exact solutions. If auxiliary function $H(\tau)$ and auxiliary parameter h are so properly chosen that $\phi(\tau,q)$ and $\omega(q)$ are convergent at $q = 1$.

Differentiating the zeroth-order deformation equation (16) m times with respect to q, then setting $q = 0$, and finally dividing them by $m!$, we obtain the higher-order deformation equation

$$\begin{aligned} &L[y_m(\tau) - \chi_m y_{m-1}(\tau)] = hqH(\tau)R_m(y_{m-1},\omega_{m-1}), \\ &\chi_m = \begin{cases} 0, & m \le 1, \\ 1, & m > 1. \end{cases} \end{aligned} \tag{17}$$

with the boundary conditions as

$$y_m(0) = 0, y_m'(0) = 0, \tag{18}$$

where

$$\begin{aligned} R_m(y_{m-1},\omega_{m-1}) &= \frac{1}{(m-1)!}\frac{\mathrm{d}^{m-1} N[\phi(\tau,q),\omega(q)]}{\mathrm{d}q^{m-1}}\bigg|_{q=0} \\ &= \sum_{j=0}^{m-1} y_j''(\tau) \sum_{r=0}^{m-1-j} \omega_r \omega_{m-1-j-r} + \widetilde{C}_1 y_{m-1}(\tau) \\ &\quad + \widetilde{C}_2 \sum_{j=0}^{m-1} y_j(\tau) \sum_{r=0}^{m-1-j} y_r(\tau) y_{m-1-j-r}(\tau) \\ &\quad + \widetilde{C}_3 \sum_{j=0}^{m-1} y_j(\tau) \sum_{i=0}^{m-1-j} y_i(\tau) \sum_{k=0}^{m-1-i-j} y_k(\tau) \sum_{r=0}^{m-1-i-k-j} y_r(\tau) y_{m-1-i-k-j-r}(\tau). \end{aligned} \tag{19}$$

Based on solution expression (12) and inherent properties of nonlinear equation (12), (17) can be expressed as

$$hqH(\tau)R_m(y_{m-1},\omega_{m-1}) = \sum_{n=0}^{\mu_m} b_{m,n}(\omega_{m-1})\cos[(2n+1)\tau], \tag{20}$$

where $b_{m,n}$ is a constant, μ_m is a positive integer determined by m and $H(\tau)$. In order to avoid appearance of secular terms such as $\tau\cos(\tau)$ in solution of (17), we must force coefficient of $\cos(\tau)$ to vanish as

$$b_{m,0}(\omega_{m-1}) = 0, \tag{21}$$

which provides us with another algebraic equation for ω_{m-1}.

For simplicity, we assume $H(\tau) = 1$, hence the solution of (17) can be expressed in the form

$$\begin{aligned} y_m(\tau) &= \chi_m y_{m-1}(\tau) \\ &\quad - \frac{1}{\omega_0^2}\sum_{n=0}^{\mu_m} \frac{b_{m,n}}{4n(n+1)}\cos[(2n+1)\tau] + D_1\sin(\tau) + D_2\cos(\tau), \end{aligned} \tag{22}$$

where D_1 must be forced to zero for satisfying the rule of solution expression [17], and D_2 is determined by the initial conditions. By Mathematica programs, we can obtain the higher order expression for y_m and ω_{m-1}. For example, the zeroth- to first-order solutions of nonlinear frequency are gave as

$$\begin{aligned} \omega_0 &= \frac{\sqrt{8\widetilde{C}_1 + 6\widetilde{B}^2\widetilde{C}_2 + 5\widetilde{B}^4\widetilde{C}_3}}{2\sqrt{2}}, \\ \omega_1 &= \frac{36\widetilde{B}^4 h\widetilde{C}_2^2 + 96\widetilde{B}^6 h\widetilde{C}_2\widetilde{C}_3 + 65\widetilde{B}^8 h\widetilde{C}_3^2}{96\sqrt{2}\left(8\widetilde{C}_1 + 6\widetilde{B}^2\widetilde{C}_2 + 5\widetilde{B}^4\widetilde{C}_3\right)^{3/2}}. \end{aligned} \tag{23}$$

For a practical quartz crystal resonator, we are mostly interested in nonlinear terms on frequency which cause frequency shift. Therefore, we defined frequency shift as

$$\Omega = (\omega - \omega_F)/\omega_F , \tag{24}$$

where ω_F in the fundamental frequency of long wave thickness-shear vibration of quartz crystal plate which has been defined in (10). In this study, we consider an 8.6845 MHz resonator [1].

In the previous derivation we have the assumption that h is to be properly chosen so that the solution series (14) are convergent. The admissible values of this auxiliary parameter can be found by plotting the so-called h-curves [17]. The h-curves for Ω is shown in Fig. 1. It is clear that the series for Ω is convergent with large scope of h for practical vibration amplitude. The nonlinear material properties needed for the calculation are given by Patel [10].

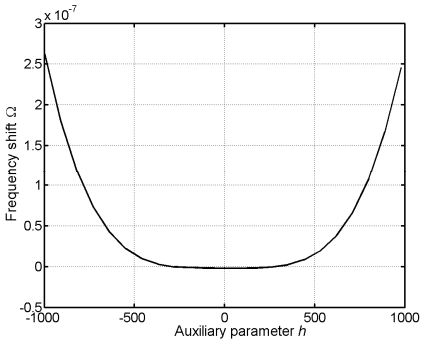

Figure 1. The h-curve for Ω with $\overline{B} = 4\times10^{-7}$.

Table 1 shows the comparison of our analytical solutions of Ω with results of perturbation method with different vibration amplitude. Numerical results show frequency shift caused by vibration amplitude is very small which indicates neither kinematic nor material nonlinearities are the main factor of frequency shifts and performance fluctuation of quartz crystal resonators.

Table 1. The frequency shift Ω with different amplitudes

V. CONCLUSIONS

The nonlinear equations of thickness-shear vibrations of quartz crystal plates have been studied by the Galerkin method and homotopy analysis method, and we obtained amplitude-frequency relation which depends on many factors such as vibration amplitude, thickness, and length of a plate. The amplitude-frequency relation also reveals that with the change of amplitude, the frequency will become unstable which is not known in the linear theory. Numerical results show neither kinematic nor material nonlinearities is the main factor of frequency shifts and performance fluctuation of quartz crystal resonators. This promotes us to study of nonlinear behaviors of quartz crystal resonators with the consideration of many complicating factors.

Motional Impedance Analysis: Bridging the 'Gap' in Dielectric Transduction

Siddharth Tallur, Tiffany J. Cheng, Suresh Sridaran, Sunil A. Bhave
OxideMEMS Laboratory, Cornell University
Ithaca, NY USA

Abstract — **This paper presents an analytical model to estimate the motional resistance for partial air gap capacitively-transduced MEMS resonators. This model serves as a link between the well formulated analytical models for conventional air gap and internal dielectric transduction schemes, thereby helping decide which scheme is optimal for a given design frequency. Using this model, we simulate and experimentally verify the motional resistance for a 303MHz polysilicon disk resonator within a 5% range of accuracy.**

I. Introduction

Semiconductor electromechanical resonators, with quality factors (Q) often >10000, provide a low-power small-footprint CMOS-compatible alternative to various electrical components in wireless communication and signal processing. On-chip fabrication of high Q micromechanical resonators can enable low-cost, miniature, low-power filter banks for radio front ends. Moreover, such resonators have promising applications in high performance microprocessors for synchronized clocking arrays with low power, jitter and skew.

Conventional air gap capacitively-transduced RF MEMS resonators typically have high motional impedances on the order of a few kΩ [1, 2]. Sub-GHz partial gap resonators with 10 nanometer air gaps achieving impedances <1kΩ have been shown [3, 4]. Extending the frequency of these resonators entails scaling of resonator dimensions, leading to increased motional impedance at higher frequencies. Dielectric electrostatic transduction has several benefits over conventional capacitive air gap transduction schemes for higher frequencies and smaller dimensions [5]. However, there is no clear understanding on which of these transduction schemes is better for a given design frequency and desired mode shape of the resonator. This work presents an analytical treatment of this problem, and insights derived from the equations presented here enable the designer to optimize resonator designs for low motional impedances.

II. Prior Modeling efforts

Motional impedance models for air gap transducers [6] and internal dielectric transduced resonators [5] are available in literature. However, partial air gap transduction lacks a good analytical Butterworth Van-Dyke (BVD) model in literature that can accurately predict resonator performance for varied applications. Designers often feel the need for a complete model for dielectric transduction that can help them determine the motional impedance for various schemes for their design of choice, thereby enabling them to pick a scheme that works best. An earlier attempt to model partial gap beam resonators [3] was limited by distortions of the beam geometry at the resonator-electrode interface, resulting in significant deviation from measured results. The next section presents a model that is built on the methodology presented in [6]. However, there are many additional factors to be considered for the case of partial air gap transduced resonators, such as motion of the dielectric, acoustic mismatch between the dielectric and resonator body, stress in the resonator etc. For this simple zero-order model we have made several assumptions that are listed in the following section.

III. Assumptions and methodology

A. Assumptions

The model presented here makes several assumptions to simplify the derivation. Consider a schematic of a beam resonator shown in fig. 1 for illustration. The resonator body comprises of a resonator body of length L and dielectric of length d_2 at both ends. The air gap is d_1 and the dielectric on the electrode has length d_e. The dielectric constant of the dielectric is ε_2 and that of air is ε_1. The various assumptions made are:

1. No acoustic mismatch between dielectric and resonator body.
2. Dielectric on the electrode is rigid.
3. Expressions for electrostatic forces are independent of the mode shape
4. Sense current calculation requires:
   - 4.1. Accounting for both displacement in x (motion at the free end) and displacement in y (motion at the interface between resonator and dielectric).
   - 4.2. Expressing x displacement in terms of y displacement.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

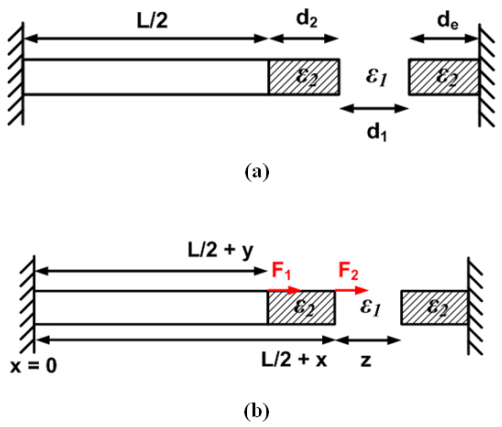

Fig 1. Schematic highlighting half the resonator geometry for a beam resonator for illustrating model assumptions and methodology

B. Methodology

The model essentially follows the derivation for motional impedance presented in [6]. As listed in step 4-5 below, we need to account for motion at the resonator-dielectric interface and air-dielectric interface also.

1. Write down the equation for mode shape in the resonator assuming no acoustic mismatch.
2. Express total capacitance between electrode and resonator body (dielectric and air gap combination) in terms of displacements.
3. Express forces in the form $F_i = \frac{V^2}{2}\frac{\partial C_{tot}}{\partial x_i}$ where V is the total applied voltage, C_{tot} is the total capacitance and x_i is the corresponding displacement.
4. Write down displacement amplitude, and hence the velocity amplitude at the free end of the resonator in terms of effective force (sum of individual forces shaped by the mode shape), stiffness and the quality factor.
5. Use these expressions to write down sense current as $i_{sense} = V_{dc}\frac{dC_{tot}}{dgap} = V_{dc}\frac{\partial C_{tot}}{\partial gap}\frac{\partial gap}{\partial t}$, where V_{dc} is the DC bias applied across the resonator.
6. Express the motional resistance R_x in terms of the applied RF voltage v_{ac} as $R_x = \frac{v_{ac}}{i_{sense}}$
7. Comparing the expression for effective force from step 4 with $F_{net} = \eta v_{ac}$, find the effective electromechanical transduction factor η.
8. Expressions for the inductance and capacitance are given by $L_x = \frac{M}{\eta^2}, C_x = \frac{\eta^2}{K}$, where M is the effective mass and K is the stiffness.

C. Equations for a beam resonator

The equations for a beam resonator can be obtained by following the methodology presented in sub-section B. For the schematic presented in fig. 1, the mode shape can be written as in equation (1), where U_0 is the amplitude of displacement, $k_n = \frac{(2n+1)\pi}{(L+2d_2)}$ is the wave number and ω is the frequency.

$$u(x) = U_0 \sin(k_n x) e^{j\omega t} \tag{1}$$

The total capacitance, C_{tot} can be written as

$$C_{tot} = \frac{\varepsilon_2\varepsilon_1 A}{\varepsilon_1 d_e + \varepsilon_2(d_1+d_2) + x(\varepsilon_1-\varepsilon_2) - \varepsilon_1 y} \tag{2}$$

The forces at resonator-dielectric and air-dielectric interfaces can be written as follows, where V is the voltage applied at the electrode. For our purposes we use expressions obtained by substituting x = d_2 and y = 0. Moreover, we have $\frac{V^2}{2} = V_{dc} v_{ac}$

$$F_1 = \frac{V^2}{2}\frac{\partial C_{tot}}{\partial y} = \frac{V^2}{2}\frac{\varepsilon_2\varepsilon_1^2 A}{[\varepsilon_1 d_e + \varepsilon_2(d_1+d_2) + x(\varepsilon_1-\varepsilon_2) - \varepsilon_1 y]^2} \tag{3}$$

$$F_2 = \frac{V^2}{2}\frac{\partial C_{tot}}{\partial x} = -\frac{V^2}{2}\frac{\varepsilon_2\varepsilon_1 A(\varepsilon_1-\varepsilon_2)}{[\varepsilon_1 d_e + \varepsilon_2(d_1+d_2) + x(\varepsilon_1-\varepsilon_2) - \varepsilon_1 y]^2} \tag{4}$$

$$F_{net} = F_1 \sin\left(\frac{k_n L}{2}\right) + F_2 \tag{5}$$

The expression for displacement can be written down as in equations (6)-(7) using expression for stiffness from [5].

$$U_0 = \frac{F}{|b\omega_0|} = \frac{F}{\left|\frac{m\omega_0^2}{Q}\right|} = \frac{FQ}{K} \tag{6}$$

$$\therefore U_0 = \frac{2Q(L+2d_2)}{Y(2n+1)^2\pi^2}\frac{\varepsilon_2\varepsilon_1 V_{dc} v_{ac}\left\{\varepsilon_1 \sin\left(\frac{k_n L}{2}\right) - (\varepsilon_1-\varepsilon_2)\right\}}{[\varepsilon_2 d_1 + \varepsilon_1 d_2 + \varepsilon_1 d_e]^2} \tag{7}$$

Then the sense current can be written as

$$i_{sense} = V_{dc}\frac{dC_{tot}}{dgap} = V_{dc}\frac{\partial C_{tot}}{\partial gap}\frac{\partial gap}{\partial t} = V_{dc}\frac{\partial C_{tot}}{\partial y}\frac{\partial y}{\partial t} \tag{8}$$

While carrying out this derivation, we express x in terms of y. The reason for this is that motion at the free end also contributes to the sense current which wouldn't be captured if we only carry out a partial differentiation of C_{tot} with y.

$$x = d_2 + \frac{y}{\sin\left(\frac{k_n L}{2}\right)}, \frac{\partial y}{\partial t} = 2\pi f_n U_0 \sin\left(\frac{k_n L}{2}\right) \tag{9}$$

Thus, we can get an expression for R_x as follows:

$$R_x = \frac{v_{ac}}{i_{sense}} = \frac{(2n+1)\pi\sqrt{Y\rho}}{2QV_{dc}^2\varepsilon_1^2\varepsilon_2^2 A}\frac{[\varepsilon_2 d_1+\varepsilon_1 d_2+\varepsilon_1 d_e]^4}{\left\{\varepsilon_1 \sin\left(\frac{k_n L}{2}\right)-(\varepsilon_1-\varepsilon_2)\right\}^2} \quad (10)$$

We obtain η from (5), and thus can express L_x and C_x as follows:

$$L_x = \frac{\rho(L+2d_2)[\varepsilon_2 d_1+\varepsilon_1 d_2+\varepsilon_1 d_e]^4}{\varepsilon_1^2\varepsilon_2^2 V_{dc}^2 A\left\{\varepsilon_1 \sin\left(\frac{k_n L}{2}\right)-(\varepsilon_1-\varepsilon_2)\right\}^2} \quad (11)$$

$$C_x = \frac{2\varepsilon_1^2\varepsilon_2^2 V_{dc}^2 A(L+2d_2)\left\{\varepsilon_1 \sin\left(\frac{k_n L}{2}\right)-(\varepsilon_1-\varepsilon_2)\right\}^2}{Y\pi^2(2n+1)^2[\varepsilon_2 d_1+\varepsilon_1 d_2+\varepsilon_1 d_e]^4} \quad (12)$$

D. Equations for a disk resonator

Beam resonators have significant mode distortion at the resonator-electrode interface [3] that are not accounted for in this model. However, we can establish the validity of this model by deriving a similar set of equations for disk resonators which do not have mode distortion.

Consider the disk resonator geometry in fig. 2. The mode shape for disk resonators can be written as [8] in (13) where $k_0 = \omega_0(R+d_2)\sqrt{\frac{\rho(1-\nu^2)}{E}}$

$$u(r) = A\frac{k_0}{R}J_1\left(\frac{k_0 r}{R}\right)e^{j\omega t} \quad (13)$$

The total capacitance can be written as follows:

$$C_{tot} = \frac{t}{\frac{1}{\theta\varepsilon_2}\ln\left(\frac{R+d_2+d_1+d_e}{R+d_2+d_1}\right)+\frac{1}{\theta\varepsilon_1}\ln\left(\frac{R+d_2+d_1}{R+d_2+x}\right)+\frac{1}{2\pi\varepsilon_2}\ln\left(\frac{R+d_2+x}{R+y}\right)} \quad (14)$$

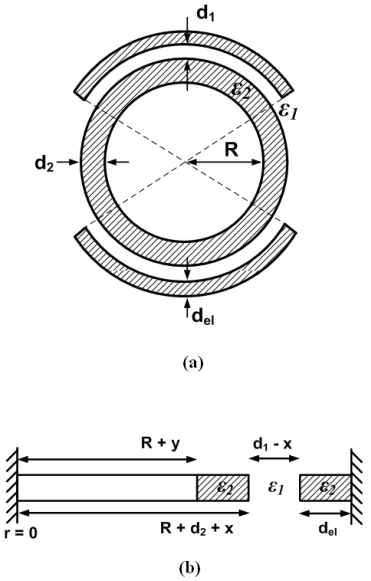

Fig 2. Schematic for a partial gap disk resonator highlighting (a) the geometry, (b) displacements at various interfaces

One can derive the stiffness (and hence effective mass) from the modeling presented in [8]

$$K = \pi\rho t(R+d_2)^2\omega_0^2\frac{J_2^2(k_0)}{J_1(k_0)} \quad (15)$$

Also, the forces and hence the effective force can be written down as in equations (16)-(18)

$$F_1|_{y=0,x=0} = \frac{V^2}{2}\frac{\partial C_{tot}}{\partial y} = V_{dc}v_{ac}\frac{\partial C_{tot}}{\partial y} \quad (16)$$

$$F_2|_{y=0,x=0} = \frac{V^2}{2}\frac{\partial C_{tot}}{\partial x} = V_{dc}v_{ac}\frac{\partial C_{tot}}{\partial x} \quad (17)$$

$$F_{net} = \frac{F_1 J_1\left(\frac{k_0 R}{R+d_2}\right)}{J_1(k_0)} + F_2 \quad (18)$$

The displacement amplitude can then be written down as follows:

$$U_0 = \frac{FQ}{K} = \frac{QV_{dc}v_{ac}\left[\frac{J_1\left(\frac{k_0 R}{R+d_2}\right)}{J_1(k_0)}\frac{\partial C_{tot}}{\partial y}+\frac{\partial C_{tot}}{\partial x}\right]_{x=0,y=0}}{\pi\rho t(R+d_2)^2\omega_0^2\frac{J_2^2(k_0)}{J_1(k_0)}} \quad (19)$$

Similar to (8)-(9), we obtain

$$i_{sense} = V_{dc}\frac{\partial C_{tot}}{\partial y}\frac{\partial y}{\partial t} \quad (20)$$

$$x = \frac{yJ_1(k_0)}{J_1\left(\frac{k_0 R}{R+d_2}\right)},\ \frac{dy}{dt} = \omega_0 U_0\frac{J_1\left(\frac{k_0 R}{R+d_2}\right)}{J_1(k_0)} \quad (21)$$

Thus we can obtain following expressions for R_x, L_x and C_x

$$R_x = \frac{\pi\rho t(R+d_2)^2\omega_0 J_2^2(k_0)}{QV_{dc}^2\left[\frac{J_1\left(\frac{k_0 R}{R+d_2}\right)}{J_1(k_0)}\frac{\partial C_{tot}}{\partial y}+\frac{\partial C_{tot}}{\partial x}\right]_{x=0,y=0}\left[\frac{dC_{tot}}{dy}\right]_{x=\frac{yJ_1(k_0)}{J_1\left(\frac{k_0 R}{R+d_2}\right)},y=0}J_1\left(\frac{k_0 R}{R+d_2}\right)} \quad (22)$$

$$L_x = \frac{\pi\rho t(R+d_2)^2 J_2^2(k_0)}{J_1(k_0)\left\{V_{dc}\left[\frac{J_1\left(\frac{k_0 R}{R+d_2}\right)}{J_1(k_0)}\frac{\partial C_{tot}}{\partial y}+\frac{\partial C_{tot}}{\partial x}\right]_{x=0,y=0}\right\}^2} \quad (23)$$

$$C_x = \frac{J_1(k_0)\left\{V_{dc}\left[\frac{J_1\left(\frac{k_0 R}{R+d_2}\right)}{J_1(k_0)}\frac{\partial C_{tot}}{\partial y}+\frac{\partial C_{tot}}{\partial x}\right]_{x=0,y=0}\right\}^2}{\omega_0^2\pi\rho t(R+d_2)^2 J_2^2(k_0)} \quad (24)$$

IV. DISCUSSIONS

We compare the model for a beam resonator in the limiting cases of air gap transduction and internal dielectric transduction. The equation for air gap transduction is

presented in (25) [6], and the equation derived from our model is presented in (26).

$$R_x = \frac{\sqrt{KM}}{Q\eta^2} = \frac{(2n+1)\pi d^4\sqrt{Y\rho}}{2QV_{dc}^2\varepsilon_0^2 A} \quad (25)$$

$$R_x = \frac{v_{ac}}{i_{sense}} = \frac{(2n+1)\pi d_1^4\sqrt{Y\rho}}{2QV_{dc}^2\varepsilon_1^2 A} \quad (26)$$

Similarly, equations (27) and (28) present equations for the fundamental mode for internal dielectric transduced resonators in literature [5] and from our model respectively.

$$R_x = \frac{\pi g^4\sqrt{Y\rho}}{2QV_{dc}^2\varepsilon_2^2 A\left\{\sin\left(\frac{k_0 L}{2}\right)\right\}^2} \quad (27)$$

$$R_x = \frac{\pi(d_2+d_e)^4\sqrt{Y\rho}}{2QV_{dc}^2\varepsilon_2^2 A\left\{\sin\left(\frac{k_0 L}{2}\right)\right\}^2} \quad (28)$$

The model converges to the well established models for both cases, thereby serving as a 'bridge' between them.

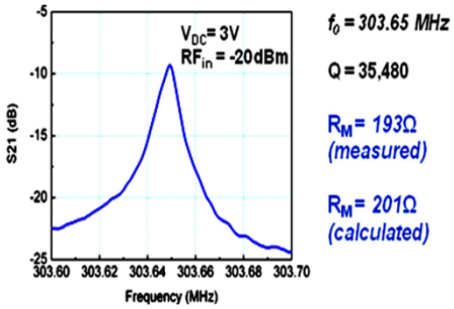

Fig 4. Transmission response of the resonator shown in fig. 3 highlighting measured resistance value

V. COMPARISON OF MODEL TO MEASURED RESULTS

We compared predictions made from our model to measured motional resistance for a radial breathing mode disk resonator designed at OxideMEMS laboratory. The resonator comprises of a poly silicon disk resonator with a radius of 8.83µm actuated through a 10nm air + 90nm hafnia gap. Fig. 3 shows a scanning electron micrograph of this resonator. As shown in the transmission response of the resonator in fig. 4, the predicted motional resistance from the model matches the measured resistance value to within 5% accuracy. To further corroborate the validity of the model, we compared predictions from the model to a wine-glass mode disk resonator reported earlier [7] in table 1.

The model thus compares quite well for measured resistance for these disk resonator geometries. For higher accuracy, the model must include the effects of strain in the dielectric and acoustic mismatch [9] to make it useful for varied applications [10] of partial air gap transduced resonators.

ACKNOWLEDGMENT

The authors extend their thanks to Prof. Ehsan Afshari at Cornell University for interesting discussions on modeling electrostatic forces and NSF career award for support.

***Abstract*—This paper reports the fabrication of Lateral Field Excitation resonators on a free-standing Aluminum Nitride membrane. We present a very simple fabrication process, and discuss the electrical measurements. In particular, the influence of the electrode width on the generation of parasitic longitudinal waves is demonstrated. We also provide measurements of the temperature dependence of the resonance frequency of the thickness-shear mode, which is of -14 ppm/°C, being much lower than the temperature dependence of the thickness-extensional mode in the same material stack.**

I. INTRODUCTION

Bulk Acoustic Wave resonators have now come to maturity for telecommunication applications, especially in RF front-ends. They have also demonstrated a large potential for sensor application, for their large frequency sensitivity versus added mass. They come mainly in two configurations, differing on how the acoustic waves are trapped within the piezoelectric film and prevented from radiating within the substrate. This is either achieved by leaving an air/solid interface in membrane-based Film Bulk Acoustic Wave Resonators or by forming an acoustic Bragg mirror underneath Solidly Mounted Resonators. Both configurations exploit the resonance of bulk acoustic waves generated by a vertical electric field applied by the means of electrodes positioned at the top and bottom of the piezoelectric field. Alternatively, Lateral Field Excitation (LFE) [1] resonators exploit vertically propagating bulk acoustic waves generated by an electric field parallel to the piezoelectric layer, generated by pairs of coplanar electrodes located on top of the piezoelectric material. Such structures, which should not be mistaken with the same denomination introduced recently for Lamb wave resonators [2], were initially proposed for quartz resonators [1], [3], but have recently been proposed in the thin film form. In particular, Corso *et al.* [4] used Zinc Oxide (ZnO) films and ensured an acoustic isolation by using an acoustic Bragg mirror.

LFE offer some advantages over bulk acoustic wave resonators. First, in piezoelectric materials of hexagonal class, like ZnO or Aluminum Nitride (AlN), they enable the excitation of shear waves which are otherwise not excited by a vertical electric field. These kind of waves are said theoretically to suffer from lower acoustic losses, both because they exhibit less viscoelastic damping, as they do not induce volume changes in the material and because they do not normally couple to pressure waves in the atmosphere surrounding the resonator. Moreover, no metal, which usually exhibit relatively large acoustic losses, lie in the acoustic path. Therefore, LFE resonators are usually expected to exhibit improved quality factors compared to conventional bulk wave resonators. More practically, they are technologically simpler to fabricate, requiring only one metallization level. The fact that they do not require a bottom electrode can be utterly interesting as the growth of piezoelectric film atop electrodes requires using materials with compatible crystalline lattices, for example, when depositing Aluminum Nitride (AlN) films, using Platinum or Molybdenum bottom electrodes, which suffer from poor electrical conductivity. Without the need for a bottom electrode, piezoelectric films can directly be deposited atop the substrate and take for example benefit of its crystalline properties, thus enabling the use of epitaxially grown films which are otherwise tedious to use [5].

In this paper, we focus on AlN based resonators acoustically isolated by forming free standing membranes. Such a structure offers the advantage of being very easy to fabricate, as it does not require the deposition of multiple materials. In section II, we detail the fabrication process used to fabricate such LFE resonators. We then present electrical characterizations in section III and discuss them in section IV. Finally, in section V, we present the influence of temperature on the electrical response of these resonators and use it to determine the effect of temperature on shear bulk waves in AlN.

II. RESONATOR FABRICATION

The devices presented here consist of two square electrodes deposited side-by-side on top of a piezoelectric free-standing membrane. The electrodes are 230x212 µm² rectangles separated by 2, 4 or 8 µm. Images of a device are presented in figure 1.

The fabrication of resonators, summarized in Figure 2, starts with the thermal oxidation of a high resistivity silicon wafer to get a 500 nm-thick SiO_2. A 2 µm thick AlN film is then deposited by reactive pulsed DC sputtering. 200 nm-thick aluminum is then deposited and patterned using dry etching. An additional silicon dioxide layer is deposited and patterned

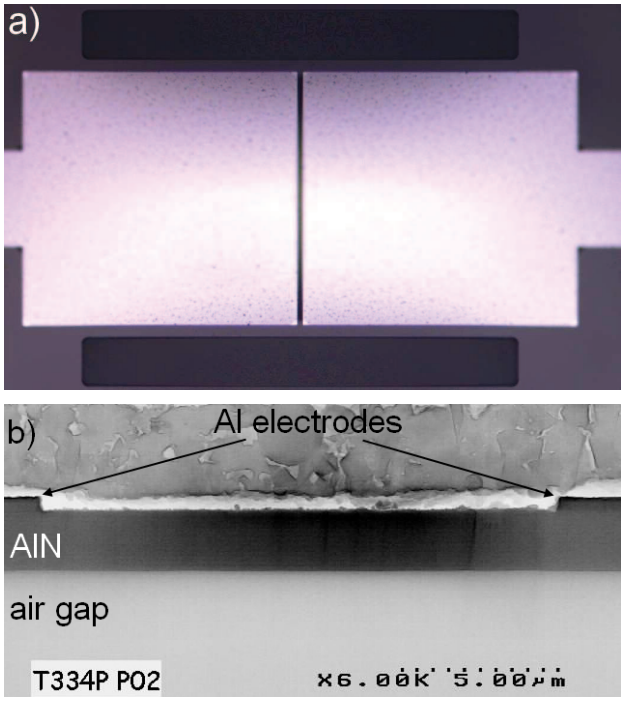

Figure 1: a) Optical image of the LFE device and b) scanning electron micrograph of the cross section of a LFE device

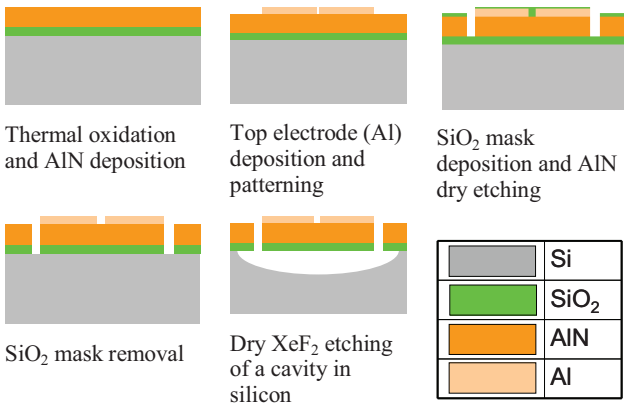

Figure 2: Process flow for the fabrication of the LFE devices

by dry etching to form a mineral mask for the etching of release holes in the aluminum nitride layer.

This oxide mask, as well as the thermal oxide located at the bottom of the release holes through the AlN film is then dry etched.

Finally, a cavity is formed below resonators by an isotropic chemical etching of the silicon substrate using XeF_2. During this step, part of the SiO_2 is removed, especially on the edges of the device. The SEM image of Figure 1.b) is taken on the edge of the device, explaining the lack of SiO_2.

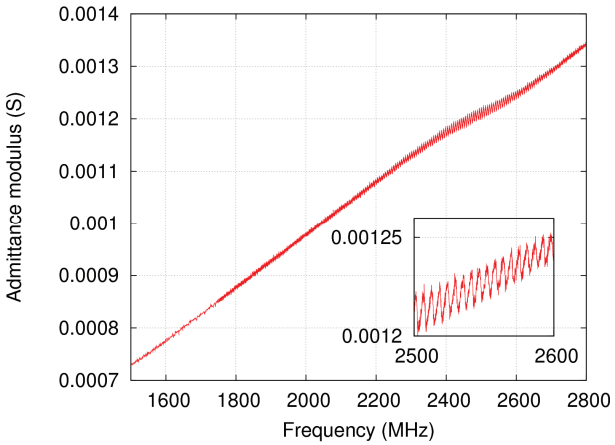

Figure 3: RF measurements of an unreleased LFE device with a 2 µm spacing

III. RF CHARACTERIZATION

Devices are characterized using a vector network analyzer and coplanar RF probes. RF measurements were performed between 10 MHz and 20 GHz, with more accurate frequency steps of 100 kHz between 1.5 GHz and 3.1 GHz to optimize the measurement accuracy in this band. A full 2-port Short-Open-Load-Thru (SOLT) calibration was done. A semi-automatic RF prober was used to ensure repeatable contact resistance between the different devices. Measurements are performed using two-port probes, the second port being shorted, hence corresponding to a signal applied on one of the electrodes when the other one is grounded. For each device presented in the following, we removed the contribution from pads and ground lines by measuring a reference device similar to the measured one but without the resonator electrodes (so as to feature an open circuit) and substracting this measurement from the one of the resonator. The admittance is presented using its modulus.

The first measurement we present here is a High-overtone Bulk Acoustic Resonator (HBAR), obtained before the final fabrication step consisting in releasing the structure. At this stage, the resonator is comprised of the piezoelectric and SiO_2 layers directly located on top of the substrate; the top electrode is the same as in the released structure. Figure 3 presents the electrical measurements of these unreleased devices. First, we observe periodic peaks separated by 5.7 MHz. This frequency spacing between resonances corresponds to the spacing between overtones of the thickness-extensional mode of an AlN layer deposited on top of a 725 µm Si substrate, hence demonstrating the HBAR behavior of the device. The envelope of resonance peaks having its maximum around 2.53 GHz is characteristic of the generation of longitudinal waves by the AlN film. At this stage, no electrical response related to shear waves could be determined.

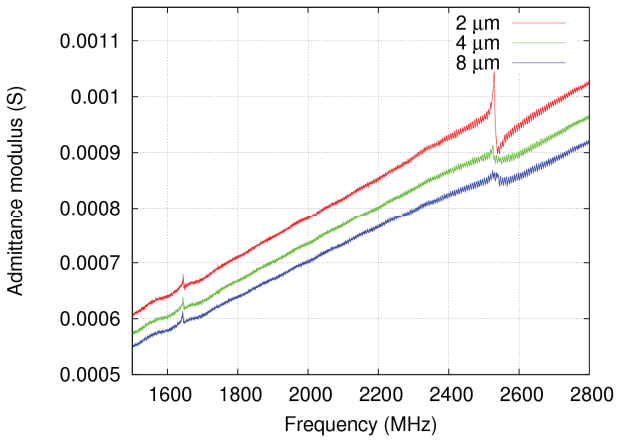

Figure 4: RF measurements of LFE devices with varying spacing

The structures are then released, leaving an AlN/SiO_2 membrane, with their top electrodes. Figure 4 shows the electrical response of the resonators inter-electrodes spacings of 2 to 8 µm. On these curves we can see three different contributions. The first is the resonance located around 1.65 GHz, which corresponds to the first thickness-shear resonance in the AlN film, and hence is the actual LFE resonance. The second one around 2.52 GHz is characterisistic of the thickness-extensional mode in the membrane, being the proof of the generation of also longitudinal waves in the piezoelectric film. The last contribution, represented by small periodic peaks, corresponds to the HBAR resonance we presented above. The LFE and HBAR resonances seem not to depend upon the distance between the electrodes, while the thickness-extensional resonance is attenuated when the inter-electrodes gap increases.

IV. Discussion

To confirm the assumptions related to the nature of the waves excited in the membrane, we calculated the electrical response of our stack using a Mason model. We used a device with an inter-electrode spacing of 2 µm for the fit to get the better resonances. Figure 5 a) shows the fit of the low amplitude multiple resonances using parameters for longitudinal waves. Frequencies fit very well with measurements, revealing a periodicity of about 5.7 MHz, hence corresponding to overtones of the thickness-extensional mode observed on the HBAR structure, confirming our hypothesis.

Using a similar Mason model, also with parameters for the longitudinal wave, we will now focus on the resonance located at 2.52 GHz. Here we model only the membrane made of SiO_2, AlN and Al. To fit correctly this resonance, we needed to dramatically reduce the piezoelectric properties of the piezoelectric material. This was performed by adding an additional capacitance in series with the piezoelectric layer in the electrical model. The result is presented in figure 5b). The position of the thickness-extensional resonance is fitted by

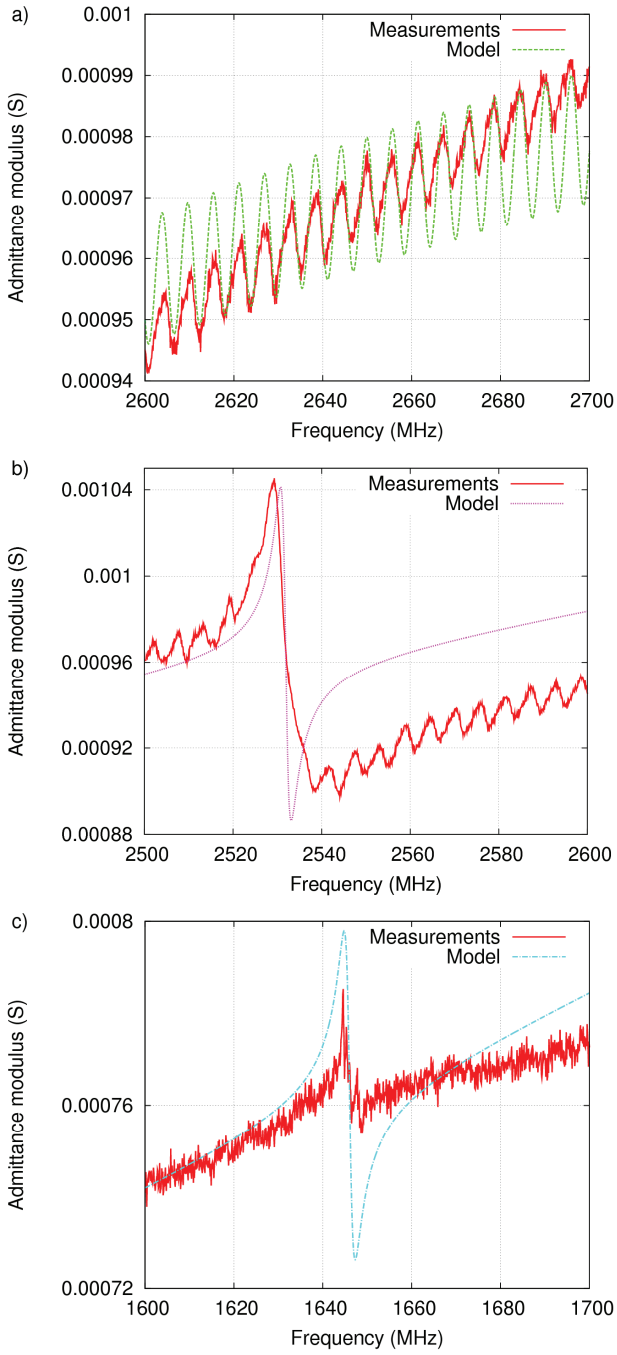

Figure 5: Mason fits a) of the HBAR resonance, b) of the FBAR resonance and c) of the LFE resonance.

varying the thickness of the SiO_2 layer. We deposited 500 nm of SiO_2, but the chemical product of the reaction between Si and XeF_2 is reacting slowly with SiO_2, leaving a thinner layer [6]. This fit gave about 290 nm of remaining SiO_2, but it is over-evaluated (probably around 240 nm).

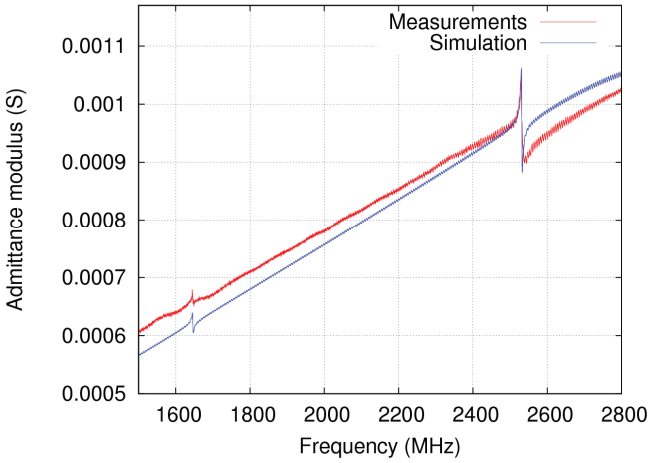

Figure 6: Complete simulation of the device

Finally, we look at the thickness-shear resonance. We used the acoustic velocity of shear waves in AlN and an estimation of the capacitance formed by the two top electrodes. The frequency is closely related to the thickness of the AlN layer. By fitting the frequency, we conclude that the AlN thickness is about 1.78 µm, which is close to what was observed experimentally on SEM pictures and through reflectometric measurements, which is around 1.87 nm.

We combined all these contributions together, assuming that each of them is related to parts of the device, and connecting each model in parallel. Each contribution was ponderated by its respective static capacitance value, which contributed to the overall electric response. The result is presented in Figure 6. The simulation is qualitatively very close to the measurements, presenting the same kind of resonances. Because of its high electromechanical factor, the relative contribution of the thickness-extensional mode needed to remain very low (close to 0.5 % of the total static capacitance), even when using a series capacitor to decrease it. The major contribution was attributed to the thickness-shear mode, and the remaining to the high-overtone resonator response. The resulting electrical schematic is shown in Figure 7.

To provide a physical meaning to each contribution, we performed Finite Element (FEM) simulations. Figure 8 shows that, as expected, most of the electric field strength is located in the gap between the two electrodes, corresponding to the thickness-shear resonance. However, although it may be considered horizontal in most of the inter-electrode gap, simulations reveal that it is vertically aligned under the electrodes, where it is normal to the equipotential surfaces. Therefore, under the electrodes, the piezoelectric material is excited by a vertical electric field, from which the longitudinal waves originate. Although the electric potential drop across the thickness of the AlN film remains low, the surface over which this happens is relatively large, explaining the relatively large

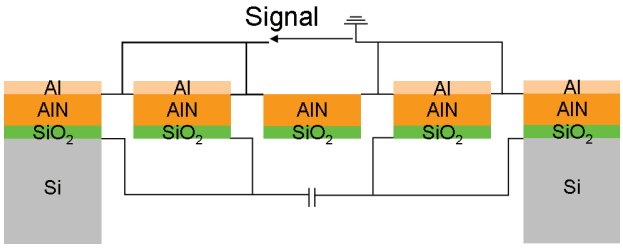

Figure 7: Equivalent circuit for the LFE resonator

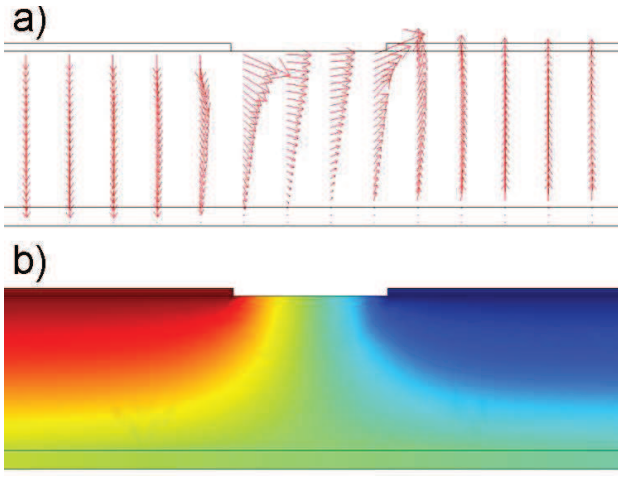

Figure 8: Electric field (a) and electric potential (b) distribution obtained from FEM simulations

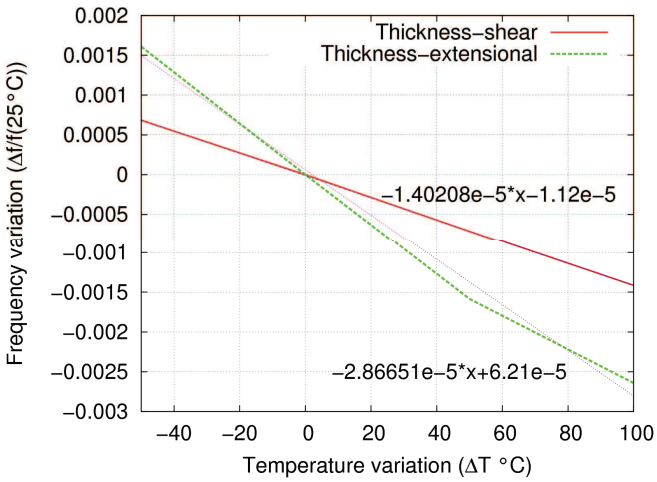

Figure 9: Relative frequency shifts of the thickness-shear and thickness extensional resonances with temperatures

contribution of the thickness-extensional resonance. When the spacing between the two top electrodes is reduced, the electric field distribution in the inter-electrodes gap is only weakly affected, while the strength of the electric field under the electrodes is much more affected. This is the reason why the thickness-extensional mode seems more sensitive to the spacing between electrodes.

The generation of longitudinal waves due to a vertical electric field occurs also at the edges of the resonator, where electrodes are no more located on top of the air-gap: longitudinal waves propagate then both in the piezoelectric film and in the substrate, generating overtone resonances.

V. TEMPERATURE BEHAVIOUR

After having identified each contribution, we measured the frequency shifts of the thickness-extensional and thickness-shear resonances with temperature using a 4 kHz step around each resonance. Their evolution is shown in Figure 9. The temperature coefficient of variation of the thickness extensional resonance is measured to be of –29 ppm/°C, being in agreement with the values usually considered for FBAR [7] resonators. For the thickness-shear mode, the coefficient of temperature is measured to be of –14 ppm/°C, being significantly smaller than the thermal sensitivity of the thickness-extensional mode. This result is consistent with data available in the literature [8].

VI. CONCLUSION

This paper reports the first example so far of Lateral Field Excitation (LFE) resonator fabricated on a free-standing AlN membrane. The electrode shape were not fully optimized, and in particular were very large, leading to the generation of parasitic longitudinal waves due to vertically oriented electric field out of the inter-electrode gap. These parasitic contributions are noticed on the electric response and tend to decrease the performances of the thickness-shear mode. Future work will look at reducing them by reducing the width of the electrodes. Nevertheless, we also reported the characterization of the thermal dependence of frequency of the thickness-shear mode, which was found to be of –14 ppm/°C, being much lower than that of the thickness-extensional mode usually exploited in AlN.

Ningbo Zhejiang, China 315800
E-mail: obi-wan@txc.com.tw

Abstract—**This paper studied the evaluation of activation energy(Ea) based on the experimental data from quartz resonators' biased aging and high temperature storage. 5.0 mm × 3.2 mm metal seam sealed quartz resonators were used in this study. To assure the results are trustable, two approach methods were used for Ea evaluation. The first method is data fit by Arrhenius model for biased aging data. The second method is MTBF evaluation based on high temperature storage data. Both methods conclude the close Ea value, about 0.578eV, and which means 85℃ for 7days accelerated aging is equivalent as 0.83 year at 25℃.**

I. INTRODUCTION

For cost and efficiency consideration, electronic device manufacturers usually cannot take a long time room temperature testing for product life evaluation. Instead, most of the electronic devices are through the reliability acceleration tests [1, 2, 3] to estimate the device life. The predominant method to estimate the equivalent life of passive devices is based on Arrhenius's law. Arrhenius proposed the model to describe how temperature affects the materials inter diffusion as following equation.

$$AFT = e^{\left[\frac{Ea}{K_B}\cdot\left(\frac{1}{Tu}-\frac{1}{Ta}\right)\right]} \quad (1)$$

Where AFT is the temperature acceleration factor, which means equivalent life ratio, K_B = 8.616 × 10^{-5}(eV/°K) — Boltzmann's constant, Ta(°K) is the temperature of acceleration environment, Tu(°K) is the device operated temperature, and Ea is the activation energy. The common reliability accelerating temperatures of quartz resonator are 125℃, 105℃ and 85℃. The AFT (or the life estimation) will be affected by Ea value a lot, as shown in Table I. For the quartz resonator's Ea studies, some researches were already done more than 20 years ago [4, 5, 7]. However, the device size and structure changed a lot during past decades. It is necessary to re-evaluate the Ea value for today's quartz crystal resonators. To assure the results are trustable, two approach methods were used for Ea evaluation. The first method is data fit by Arrhenius model for biased aging data. The second method is MTBF evaluation based on high temperature storage data.

TABLE I. PRODUCT ACTIVATION ENERGY(EA) VERSUS TEMPERATURE ACCLEARTION FACTOR (AFT) AT 125℃

T_L(℃)	T_H(℃)	Ea(eV)	K(eV/ °K)	Tu(°K)	Ta(°K)	AFT
25	125	0.7000	$8.617*10^{-5}$	298	398	943.17
25	125	0.6000	$8.617*10^{-5}$	298	398	354.53
25	125	0.5000	$8.617*10^{-5}$	298	398	133.26
25	125	0.4000	$8.617*10^{-5}$	298	398	50.09
25	125	0.3000	$8.617*10^{-5}$	298	398	18.83

Like common microelectronic devices, the function of aging frequency change can be expressed as Equation (2) which relates with current, temperature, and time [6]

$$\frac{\Delta f}{f}(i,T,t) = R(i)\cdot R(T)\cdot R(t) \quad (2)$$

For the sake of simplicity, this study we focused on Ea for thermal effect only. Which means we need to minimize the R(i) effect in experiments and neglect it in calculations. 3 elevated temperatures, 85℃, 105℃, 125℃ were selected to make thermal effects stronger, and no room temperature condition in this study. After neglect electrical current effect (or drive level effect), Equation (2) can be re-state as following

$$\frac{\Delta f}{f}(T,t) = R(T)\cdot \ln(1+bt) \quad (3)$$

Where $R(T) = C\cdot e^{\left(\frac{-Ea}{K_B\cdot T}\right)}$, b is constant, and for a specified time, Equation (3) can be expressed as the relationship of frequency change versus to temperature in Equation (4).

$$\ln\frac{\Delta f}{f} = \ln C - \frac{Ea}{K_B}\cdot\frac{1}{T} \quad (4)$$

II. Approach A: Activation Energy for Aging Testing

A. Aging Experiment

We took 60 pieces samples for each elevated temperature, 85℃, 105℃, 125℃. 5.0mm × 3.2mm metal seam sealed, 40MHz fundamental quartz crystal resonators were used. Each sample was working in separated oscillation circuit simultaneously. Frequency were measured daily for 1000hrs (about 42days). The results are shown as Fig. 1.

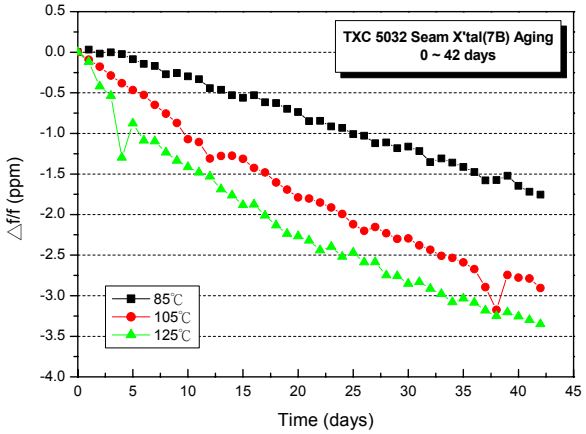

Figure 1. The aging frequency change of 5.0mm × 3.2mm metal sealed quartz resonator for 1000 hrs

TABLE II. EA FIT FROM FIGURE 1 FOR SELECTED DAYS

Days	7	14	21	31	42
Ea	0.578	0.372	0.311	0.270	0.200

B. Activation Energy Estimation through Arrhenius Prediction Modle

In Equation (3), if bt >> 1 it can be simplified as Equation (5) and Equation (6).

$$\frac{\Delta f}{f} = R(T)\ln b + R(T)\ln t \quad (5)$$

$$\frac{\Delta f}{f} = C\cdot e^{-\frac{Ea}{K_B\cdot T}}\cdot \ln t \quad (6)$$

For a lower temperature and time, T_L and t_L, we can get the frequency change from Equation (6). Similarly, we can have another frequency change for a higher temperature and time, T_H and t_H.

$$if\ \delta f_L = \frac{\Delta f}{f}(T_L, t_L), \text{and } \delta f_H = \frac{\Delta f}{f}(T_H, t_H)$$

$$\Delta = \frac{\delta f_H}{\delta f_L} = \frac{\ln t_H}{\ln t_L}\cdot e^{\frac{Ea}{K_B}\left(\frac{1}{T_L}-\frac{1}{T_H}\right)} = \frac{\ln t_H}{\ln t_L}\mathrm{A} \quad (7)$$

$$\Delta = \frac{\delta f_H}{\delta f_L} = \frac{\ln t_H}{\ln t_L}\cdot \exp\frac{1}{KB}\left(\frac{1}{TL}-\frac{1}{TH}\right)Ea \quad (8)$$

For now, we can calculate the Δ ratio from Equation (8) by specified Ea, and we can also calculate the Δ ratio from experiment data, and compare these two results to verify the Ea is suitable or not. For T_H=105 ℃, t_H=7 days, and T_L=85℃, t_L = 7, 14, 21, 31, 42 days, we can get the comparison results as Table III, and the ratio is close when Ea = 0.578 eV.

TABLE III. THE ARRHENIUS VERIFICATION MODEL OF 105℃ VERSUS TO 85℃

105 vs 85 Verification						
Formula Prediction by Real Ea						Real Ratio
	7	14	21	31	42	NA
Ea	0.578013	0.372427	0.310908	0.269896	0.200391	NA
△7/7	3.212913	2.070151	1.728199	1.500231	1.113883	3.84529
△7/14	2.369043	1.526427	1.274289	1.106196	0.821322	2.411959
△7/21	2.053537	1.32314	1.104581	0.958875	0.71194	2.123997
△7/31	1.820636	1.173076	0.979305	0.850124	0.631195	1.954337
△7/42	1.672711	1.077765	0.899737	0.781052	0.579911	1.655865

We compared different temperature and time conditions (125℃, 7days vs. 105℃, 42days and 105℃, 7days vs. 85℃, 42days) and found the ratio will closest when Ea = 0.578eV as shown in Fig. 2.

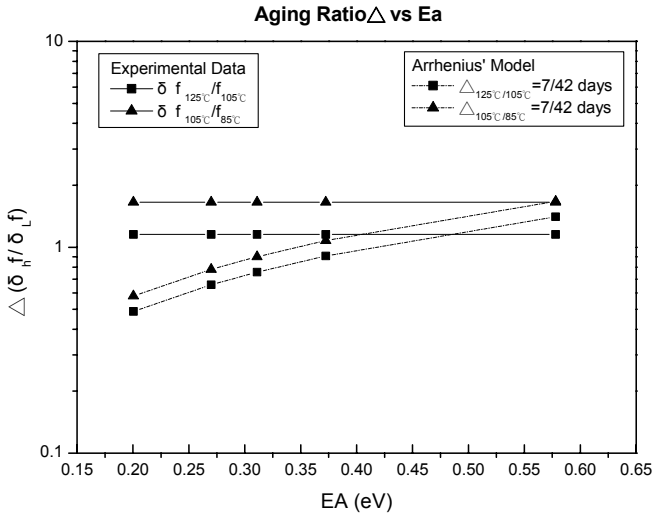

Figure 2. The verification model of 7days at higher tempearure compare to 42days at lower temperature

III. Approach B: Activition Engery Based on MTBF Estimation with High Temperature Storage Data

The classical Arrhenius equation show as Equation (9), where t is the time, T is the temperature, replace t as the definition of MTBF in reliability, Equation (9) could further express as Equation (10).

$$\ln t = a + b \cdot \frac{1}{T} \tag{9}$$

$$\ln(MTBF) = \ln\left(\frac{n \times t}{r}\right) = \frac{Ea}{K_B} \cdot \frac{1}{T} \tag{10}$$

Where n is the sample number, t is the experimental time, r is the number of failure device. TABLE IV is the experimental results of high temperature storage [8]. The failure number could be calculated by various device specification, but the meaningful MTBF must satisfied the normal electronics device's failure principle, which means the failure number should between 1 and total samples. Based on it, we selected the blue area as meaningful MTBF area and used as Ea estimation. The results were showed as Table V, the average Ea is 0.569, which is close to 0.578 as estimated by approach A. Because high temperature storage had only thermal effect, no drive level effect inside, and the Ea is close to elevated temperature biased aging test, it can also show thermal effect is dominate in elevated high temperature biased aging.

TABLE IV. The Failure Nomber of Different Device Specification for High Tempeerature Storage

Temp (℃)	Device Houre (hr)			Failure Number						
	Samples	Time(H)	Total Time	±4ppm ±4ohm	±4.5ppm ±4.5ohm	±4.8ppm ±4.8ohm	±5ppm ±5ohm	±5.5ppm ±5.5ohm	±5.8ppm ±5.8ohm	±6ppm ±6ohm

IV. Conclusion

We studied the evaluation of activation energy (Ea) based on the experimental data from quartz resonators' biased aging and high temperature storage. 5.0 mm × 3.2 mm metal seam sealed quartz resonators with fundamental frequency 40MHz were used in this study. To avoid the interference between thermal and drive level effect, we selected 3 elevated temperatures in aging test. To assure the results are trustable, two approach methods were used for Ea evaluation. The first method is data fit by Arrhenius model for biased aging data. The second method is MTBF evaluation based on high temperature storage data. Both methods conclude the close Ea value, about 0.578eV (for thermal effect), and which means 85℃ for 7days accelerated aging is equivalent as 0.83 year at 25℃. The aging mechanism and the effects by drive level or other factors still need more studies in the future.

***Abstract*—Strong high-order Rayleigh or Sezawa modes, in addition to the fundamental Rayleigh mode, have been observed in ZnO/GaAs(001) systems along the [110] propagation direction of GaAs. The dispersion of the different acoustic waves has been calculated and compared to the experimental data. The bandwidth and impedance matching characteristics of the multimode SAW delay lines operating at high frequencies (2.5-3.5 GHz regime) have been investigated.**

I. Introduction

ZnO films are known to enhance the piezoelectric coupling of GaAs substrates, facilitating the integration of surface acoustic wave (SAW) devices with the GaAs electronics. In spite of the small sound velocity mismatch between the two materials, this slow-on-fast structure supports several guided waves in the overlayer. However, only the fundamental Rayleigh wave has been studied so far [1,2].

The dynamic modulation of the band diagram induced by the piezoelectric field of a SAW in GaAs-based systems has allowed the development of single-electron transistors using the split-gate technique [3]. More recently, these constrictions have been combined with lateral *n-p* junctions pursuing a high frequency single-photon source [4]. Other approaches to SAW-assisted anti-bunched photon emitters rely on the controlled injection of excitons into quantum dots [5] or the modulation of their emission by means of the SAW strain fields [6]. All these applications would benefit strongly not only from the enhanced piezoelectric coupling provided by the ZnO but also from the capacity of modulating the optoelectronic systems using waves with different piezoelectric and strain field depth profiles to those of the fundamental Rayleigh mode.

In this paper we report on the characteristics and dispersion of the different acoustic waves supported by the ZnO/GaAs heterostructure and on the performance of the SAW delay lines used to generate them.

II. ZnO Films And Device Design

ZnO films of different thickness *H*, ranging from 1 to 2.5 μm, were deposited on semi-insulating GaAs(001) substrates by high target utilization sputtering (HiTUS) [7] at room temperature. In this technique, an argon plasma is generated in a side chamber and steered onto the target, avoiding the direct contact of the plasma with the substrate. This prevents the ion bombardment of the substrate, providing high quality films with very low stress and defect density even at high deposition rates and at room temperature [7].

The sputtering parameters were optimized in order to obtain highly resistive films oriented along the (001) crystal axis, conditions that ensure a strong piezoelectricity. A Zn target (99.999 %) was exposed to the Ar plasma with a constant target power of 800 W. The flows of Ar and O_2 were 65 and 41 sccm, respectively, providing a deposition rate of ~50 nm/min. The crystal quality of the sputtered ZnO films was assessed by X-ray diffractometry, confirming the unique orientation of the films along the (001) axis. The resistivity of all the films was very high (10^{10} Ω m).

SAW delay lines, formed by split-finger interdigital transducers (IDTs), were patterned by e-beam lithography on

the ZnO films along the [110] direction of the underlying GaAs(001) substrates. The IDTs were formed by Ti/Au (10/10 nm) contacts and had a period λ of 1 μm and a metallization ratio of 0.5, i.e. finger width and pitch of 125 nm. The IDTs had an aperture W of 60 μm, whereas the number of finger pairs N_p was varied in order to modify the bandwidth of the passband. The delay lengths were 1 and 2 mm. The S parameters of the devices were measured with a coplanar probe station connected to a network analyzer, and in some cases (when specifically stated) the devices were also characterized once mounted on a sample holder with SMA connectors.

III. RESULTS

A. *High-order Rayleigh or Sezawa modes*

Fig. 1 shows the insertion loss of identical SAW delay lines fabricated on a series of ZnO films of different thickness on GaAs(001) substrates. The spectra of the devices on films with thickness H ranging from 1 to 1.4 μm present two clear resonances, whereas the device on the thickest film (H=2.5 μm) supports three. The lowest-frequency resonance, at 2.53 GHz for all the devices, corresponds to the fundamental Rayleigh mode (labeled as R). The resonances at higher frequencies are associated with high-order Rayleigh modes, also called Sezawa modes (labeled as S_i, i≥1). These are guided waves in the overlayer that arise since the ZnO/GaAs structure forms a slow-on-fast system, i.e. the bulk transverse velocity in the substrate is larger than in the overlayer. The frequency of the first Sezawa mode (S_1) decreases from 3.20 to 2.86 GHz as the film thickness increases from 1 to 2.5 μm (as indicated by the arrow in Fig.1), whereas the second Sezawa mode (S_2) appears only for the thickest film, at a frequency of 3.08 GHz.

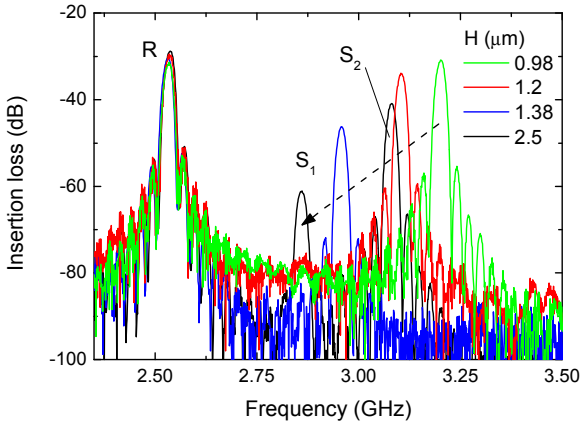

Figure 1. Insertion loss of identical SAW delay lines on ZnO films of different thickness H on GaAs. R, S_1, and S_2 denote the Rayleigh and the first and second Sezawa modes, respectively.

B. *Dispersion of the ZnO/GaAs structure*

The identification of the acoustic modes shown in Fig. 1 is based on the comparison of the experimental data with the numerical calculation of the dispersion of the ZnO/GaAs structure. The calculation is based on a Green's function formalism which was developed to calculate Brillouin spectra [8]. The material parameters of ZnO and GaAs used for the calculation have been taken from Refs. [9] and [10], respectively.

The results of the simulations for the ZnO/GaAs(001) heterostructure with propagation along the GaAs [110] direction are summarized in Fig. 2. ZnO has a wurzite structure (crystal class 6mm) with isotropic elastic properties in the (00.1) plane, so that the propagation direction is referred to that of the underlying cubic structure of GaAs (crystal class -43m) that presents a four-fold symmetry in the elastic properties in the (001) plane. The gray scale in Fig. 2 depicts the magnitude of the shear vertical component of a wave having the given velocity and $kH=2\pi H/\lambda$ value. The experimental data (circles) have been determined from the resonance frequency of the IDTs (Fig. 1). The velocity of the R mode decreases from its value in GaAs for kH=0, to that in ZnO for approximately kH>7. Additionally, S_i modes emerge nearly periodically beyond their threshold values of kH. The velocity of the S_i modes decreases monotonically with increasing kH. The numerical results are in good agreement with the experimental data. The small discrepancy on the S_i modes in the thickest ZnO film could originate from a slight misalignment of the delay line pattern from the [110] direction. The broadening of the R mode is an artifact of the calculation when resolving simultaneously the intense R mode and the less intense S_i modes.

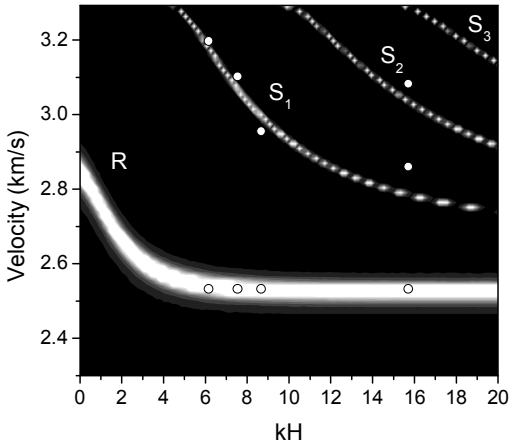

Figure 2. Dispersion of the Rayleigh (R) and Sezawa (S_i) modes in the ZnO/GaAs(001) structure for propagation along the [110] direction of GaAs. The brighter the scale is, the larger the calculated intensity of the mode. The experimental data are shown by the circles.

C. *Device bandwidth*

Figs. 3(a) and 3(b) depict, respectively, the insertion and return loss of a series of SAW delay lines with varying number of finger pairs (N_p) fabricated on a 2.5 μm-thick ZnO film on GaAs(001). The resonances of the R, S_1, and S_2 modes are clearly observed in both the transmission and the reflection spectra for all the cases except for the S_1 mode in the reflection spectra for the lower N_p cases, where it is hardly distinguished from the background.

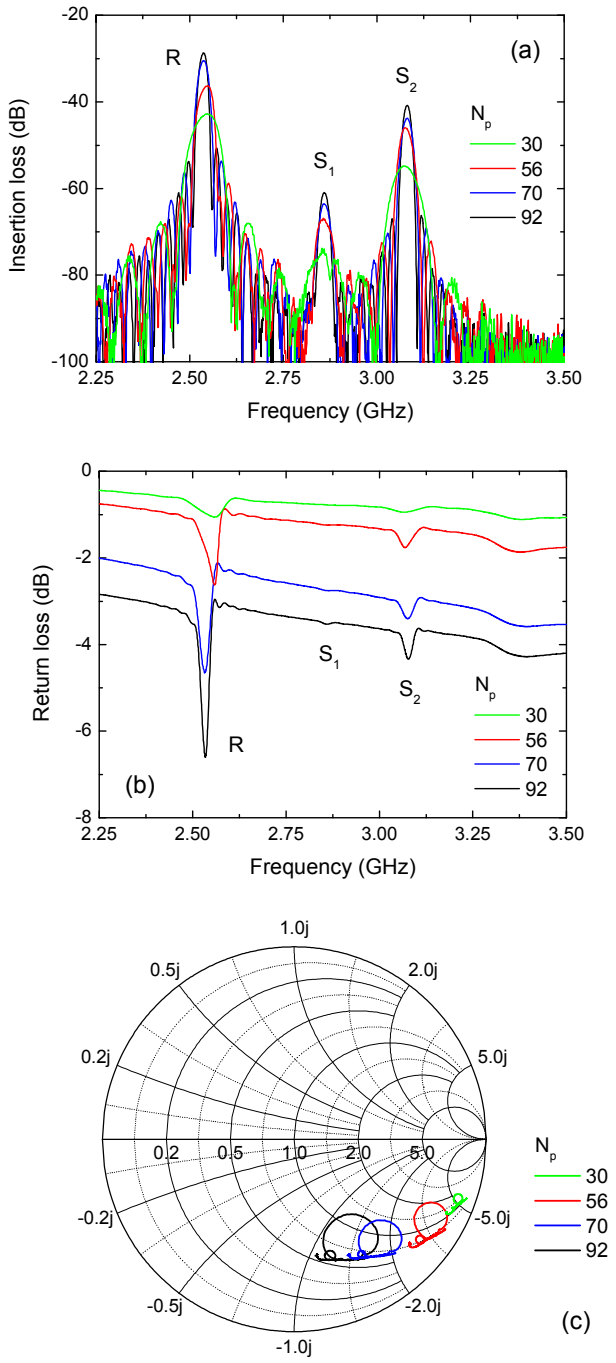

Figure 3. (a) Insertion loss, (b) return loss, and (c) Smith chart (normalized to 50Ω) of SAW delay lines with varying number of finger pairs N_p on a 2.5-μm thick ZnO film on GaAs. R, S_1, and S_2 denote the Rayleigh and the first and second Sezawa modes, respectively.

The variation of N_p modifies the losses of the devices by means of two different mechanisms. On the one hand, the passband of the devices narrows as N_p increases and this translates into a reduction of the losses. This correlation is clearly observed in Figs. 3(a) and 3(b). On the other hand, the increase in N_p produces an increase in the capacitance of the IDT, decreasing its reactance and thus enhancing the impedance matching condition of the device. Fig. 3(c) shows the Smith chart of the impedance of the devices. The traces, in the capacitive half of the chart, move approximately along curves of constant resistance, except at the mode resonances, where a loop is formed. As N_p increases, the traces present larger loops, i.e. stronger resonances, and they shift towards smaller values of capacitive reactance.

The evolution of the bandwith with N_p for the different mode resonances shown in Fig. 3(a) is summarized in Fig. 4. Both, the bandwidth between first nulls on either side of the resonance frequency (BW_{nn}) and between points 3 dB below the main lobe maximum (BW_3) have been extracted from the experimental data in Fig. 3(a). The experimental bandwidths in Fig 4 (labeled as $BW_{nn\ exp}$ and $BW_{3\ exp}$) are compared to their theoretically expected values (labeled as $BW_{nn\ th}$ and $BW_{3\ th}$). The theoretical bandwidth between first nulls is given by the expression $BW_{nn} = 2f_0/N_p$, where f_0 is the resonance frequency of the mode. The theoretical value of the bandwidth at 3 dB is $BW_3 \approx 0.31BW_{nn}$, the characteristic value of a square sinc function at that level. The comparison of the experimental and theoretical values of BW_3 shows an overall good agreement, whereas the experimental values of BW_{nn} are systematically lower than the theoretically predicted ones. This discrepancy is likely to be related to the error in determining the position of the nulls. This error is especially large in the case of the S_1 mode where first nulls appear at a very high insertion loss, as can be noticed in Fig. 3(a).

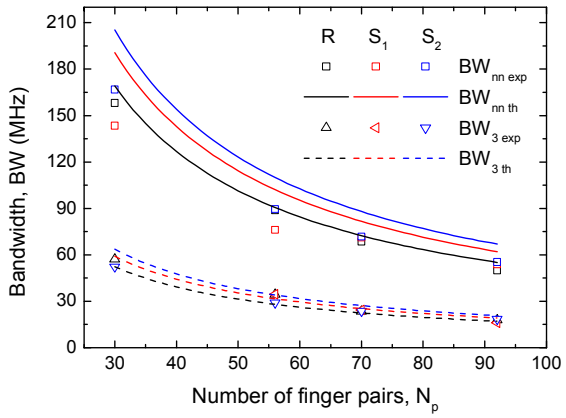

Figure 4. Evolution of the bandwidth of the Rayleigh (R), first Sezawa (S_1), and second Sezawa (S_2) mode resonances with the number of finger pairs in SAW delay lines on a 2.5-μm thick ZnO film on GaAs. See text for details.

D. *Impedance matching*

A stub tuner has been used to impedance match one of the IDTs forming the SAW delay lines under study in order to determine the maximum potential of the devices. The selected device was patterned on a 2.5 μm-thick ZnO film on GaAs(001) formed by IDTs with W=60 μm, λ =1 μm, and N_p=70. The device was mounted on a sample holder with SMA connectors. The contribution of the measurement set-up, including an SMA cable and the stub tuner in its initial contracted position, has been eliminated by means of the calibration.

Fig. 5 shows the return loss spectra of an IDT before and after using the stub tuner to impedance match it, whereas the inset presents the data in the format of a Smith chart, where the variation of the impedance with frequency is depicted. The comparison of the spectra in Fig. 5 and its inset for the untunned IDT with those of a similar IDT (N_p=70) in Figs. 3(b) and 3(c) indicates the contribution of the sample holder. The traces, which are in the capacitive half of the chart when measured on wafer with probes [see Fig. 3(c)], cross over from inductive to capacitive when measured on housing, as shown in the inset of Fig. 5. In particular, the resonance of the R mode lies in the inductive half of the chart. The inductance measured is likely to originate from the wire bondings used to connect the device to the sample holder.

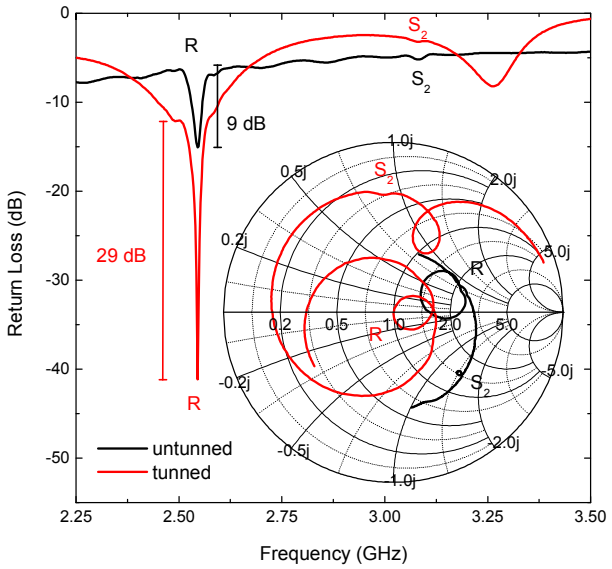

Figure 5. Return loss of an IDT with N_p =70 on a 2.5-μm thick ZnO film on GaAs (device mounted on a sample holder). The inset shows the Smith chart (normalized to 50Ω) of the return loss. R and S_2 denote the Rayleigh and second Sezawa modes, respectively.

When the stub tuner is used to impedance match the R mode, as indicated by its resonance centered at 1 on the real axis (i.e. 50 Ω) of the Smith chart (inset of Fig. 5), the deep associated to that mode in the return loss spectrum (Fig. 5) is enhanced by more than 25 dB. Nonetheless, the stub tuner introduces an additional modulation of the background of approximately 8-10 dB in amplitude and a period of 715 MHz. One of the minima of this modulation coincides with the resonance of the R mode, broadening its base. If that contribution is subtracted, the net enhancement of the magnitude of the R mode amounts to 20 dB, as indicated in Fig. 5.

IV. Conclusions

Strongly oriented and highly resistive ZnO films on GaAs substrates have been obtained by sputtering at room temperature. The different acoustic waves propagating along the [110] direction of GaAs in ZnO/GaAs(001) systems have been experimentally and theoretically investigated. In addition to the fundamental Rayleigh mode, strong high-order Rayleigh or Sezawa modes propagate confined in the overlayer. In particular, the insertion loss of the S_1 mode can be as low as that of the R mode for certain thickness-to-wavelength ratios. The bandwidth and impedance matching characteristics of the different resonances in SAW delay lines operating at high frequency (2.5-3.5 GHz regime) have been investigated.

***Abstract*—This paper presents a UHF CMOS MEMS resonator working at 384MHz at its bulky mechanical mode. The novel topology proposed allows us to design the resonator taking into account the coupling area of the movable resonator as an important parameter in the design. The structure is fabricated using a commercial CMOS technology. This fact allows to integrate directly the microelectromechanical structure with the electronic. This work presents the measurement of both, the stand alone resonator and the resonator with an amplification circuitry.**

I. INTRODUCTION

Microelectromechanical resonators are widely used in RF applications, both at HF, VHF and UHF ranges. In particular, CMOS MEMS are a promising solution for the implementation of RF front-ends due the facility of MEMS integration, reduced area and low power consumption. Very competitive devices have been reported using these fully integrated structures not only for RF applications but also for sensing. A CMOS metal cantilever, electrostatically excited, with an exceptional 1 ag/Hz mass sensitivity is used as frequency-determining element of an oscillato [1-2]. A CMOS polysilicon Clampled Clamped shaped beam with a Q of 4400 [3] is an example of CMOS MEMS resonators used for RF filters in the range of HF. In this work, two resonators are electrically coupled in order to obtain a IF filter. In [4] a squared frame resonator based on four FF-Beams anchored by their nodal points was fabricated by an stack of metal and intermetal oxide in a collaborative way to increased the coupling area and achieve a quality factor Q of around 1400. Other interesting solutions can be found in [5] where flexural modes and a stack of CMOS metals are used to obtain a resonator working at HF range. Higher frequency CMOS MEMS flexural resonators have been demonstrated in [6] to reach 200 MHz with a 40 nm gaps. However, the use of the flexural approach has the intrinsic problem of the scaling. An increase of frequency implies a length reduction of the beam and therefore the reduction of the coupling area. Bulk modes offer the solution to the scaling problems and reach very good results at VHF and UHF ranges as it has been proven in [6-9].

In this paper a Bulk Acoustic Resonator working at 380 MHz is presented. The LBAR resonator structure presented in [12] suffers for a limitation in the coupling area. An increase of this area, in order to achieve a better coupling, changes the resonance frequency due to variations in the resonator width.

This paper shows a novel geometry that allows at the same time to preserve the coupling area and increase the resonance frequency.

II. DESIGN

An LBAR resonator working in its longitudinal vibration mode has been selected to implement the novel structure. Figure 1 shows the diagram of the resonator, whose topology is similar to the suspensions founded in [13]. A maximum displacement occurs at the end of the structure while the center of the resonator presents zero movement. This center point is selected as anchorage point.

The design technique is based on the merge of two imaginary ellipses, with major and minor axis of *a* and *b* microns respectively, over a rectangle presenting and area of WxL. The LBAR is defined by the area that separates the two ellipses. As it will be seen, the novel structure allows to predefine the length (W) of the coupling area, and fix the rest of the dimensions to achieve the desired resonant frequency.

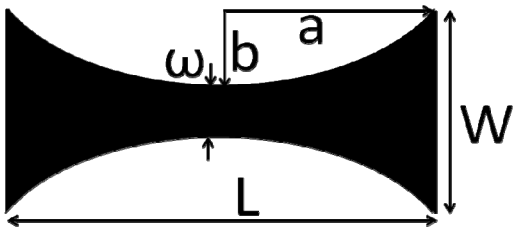

Figure 1. Diagram of the resonator, *b,* corresponds on the minor axis and *a to* the major axes. WxL defines the rectangle over the ellipses.

Equation 1 allows to obtain the frequency as a function of the stiffness of the structure for the desired mode, K_x and the mass, *M.* The mass is obtained by subtracting the mass of the imaginary ellipse ($M=a\cdot b\cdot\pi\cdot t\cdot\rho$) to the mass of the rectangle ($L\cdot W\cdot t\cdot\rho$) in equation (2), being t and ρ the thickness and density of the resonator. The stiffness is obtained using

978-1-61284-110-6/11/$26.00 ©2011 IEEE

expression (3) presented in [13], where E is the young modulus.

The design process starts fixing the length of the coupling surface (*W*) and therefore, the coupling area in each arm of the resonator. Design rules of the technology impose the minimum width of the device near the anchors (*w)*. Therefore, the minor axis of the ellipse is determined by the subtraction of *W* and ω. Finally, the major axis (*a*) length of each arm is determined by the resonant frequency, following expression 1.

The new resonator has been fabricated using the polysilicon capacitance module present in the commercial CMOS technology of the Austria Microsystems (AMS) of 350 nm. The resonator has been dimensioned to operate in the free band of 434 MHz. The previous described design process has been followed to implement the structure. In particular, a coupling length of W=3µm with a minimum width ω=850nm has been fixed. Figure 2 represents the dependence of the major axis with the resonant frequency. Final dimensions are detailed in Table 1

TABLEI TABLE OF DIMENSION OF THE RESONATOR

A	Area of the rectangle (LxW)	21 pm^2
Ae	Area of the ellipse	12.9 pm^2
ρ	PolySi density	2230 kg/cm^3
L	Length of the resonator	7 µm
W	Coupling lenght	3 µm
a	Ellipse major axis	3.5 µm
b	Ellipse minor axis	1.075 µm
K_x	Resonator stiffness	46.764 N/m
E	Young modulus	160 Gpa
ω	Minimum width of the resonator	850 nm
t	PolySi thickness	280 nm
M	Mass of the resonator	6.21 pg

$$f = \frac{1}{2\pi}\sqrt{\frac{K_x}{M}} \tag{1}$$

$$M = (A - A_e)t\rho = \left[2a(2b+\omega) - \pi ab\right]t\rho \tag{2}$$

$$K_x = \frac{4Ebt}{\frac{4a(2b+w)}{\sqrt{w(4b+w)}}\arctan\sqrt{1+\frac{4b}{w}} - a\pi} \tag{3}$$

III. FABRICATION

The new resonator has been fabricated using the polysilicon capacitance module where the movable structure is fabricated using the 280 nm thickness polysilicon 1 layer

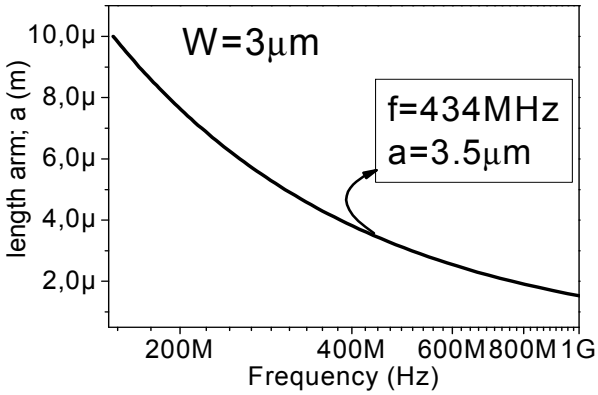

Figure 2.Length of semi resonator vs Frequency (*a*) for a fixed length of the coupling area, *W*

while the two drivers are fabricated using the polysilicon 2 layer. The layout is drawn with a 0 gap between drivers and resonator in order to take advantage of the fabrication process, using the interpoly oxide as spacer [9]. Therefore, it is expected to achieve a gap of 40 nm, corresponding to the oxide between the two polysilicon layers.

To enable the release of the resonator a pad window is opened over the structure, in order to remove the pasivation layer. Vias 3 and 2 are added to eliminate the different inter

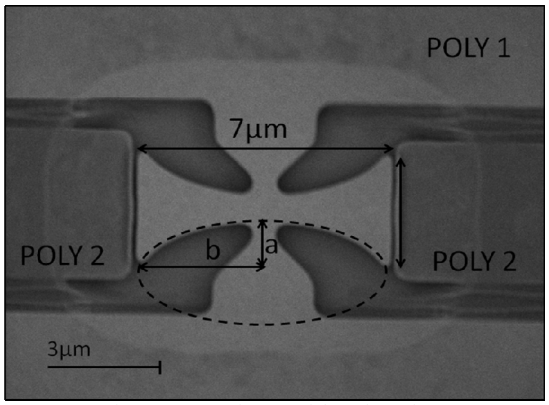

Figure 3. SEM image of the released resonator

metal oxides that would cover the MEMS. A mask less wet etching is performed using an HF based solution to release the resonator. Figure 3 shows a SEM image of the released resonator.

IV. ELECTRICAL CHARACTERIZATION

Two versions of the resonator have been implemented. The first one corresponds to the stand alone resonator while the second implementation adds a transimpedance amplifier in charge of amplifying the signal provided by the MEMS. This second implementation will allows discussing the effect of the presence of an amplifier on the characterization of the MEMS. Fig.7 shows an optical image of the MEM resonator, the circuitry and pads.

In both cases the measurement set up is shown in fig. 4. A biasing voltage, which allows to read the current provided by the movement, is applied over the resonator as well as the excitation ac signal. A Bias-tee has been included. To enlarge the output signal, the two electrodes are joined together to read the motional current. The output is applied directly to the Network analyzer or to the transimpedance amplifier. Scattering parameter S21 is used to characterize the LBAR.

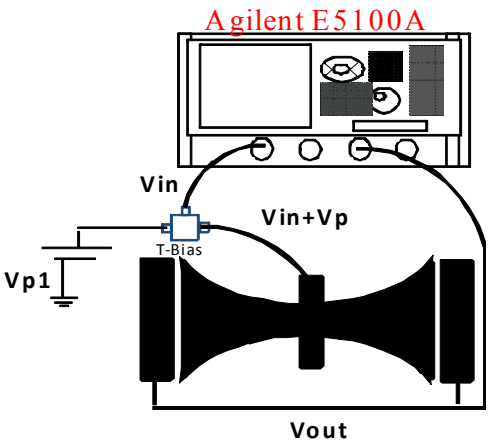

Figure 4. Electrical characterization set up, for stand alone resonator.

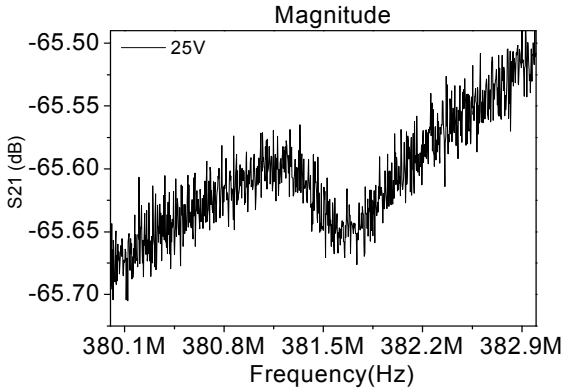

Figure 5. Transmission coefficient S21 for the stand alone resonator in air conditions.

Figure 5 shows the test results corresponding to the stand alone resonator. The resonance frequency is shown at 384 MHz with a level of around 65.6 dB. The small value of the peak is attributed to the presence of the parasitic capacitance between the movable structure and the drivers that mask the motional current.

The measurements of the fully integrated (see fig.6) prototype are shown in the figure 7. As it is expected, the coupling level is increased up to 39.2, due the 30 dB gain provided by the amplifier. In this case the resonance frequency is located at 387 Mhz due to the tolerances in the fabrication process. Contrary to other cases, it can be observed that there is not benefit of using the amplifier in the reduction of the parasitic current. This fact is attributed to the one port set-up measurement. Although the amplifier allows to eliminate the capacitance between the excitation and read-out pads, that exist in the stand-alone resonator, the dominant capacitance, corresponding to the physical capacitance between the movable polysilicon 1 layer and the electrodes polysilicon 2, is still present.

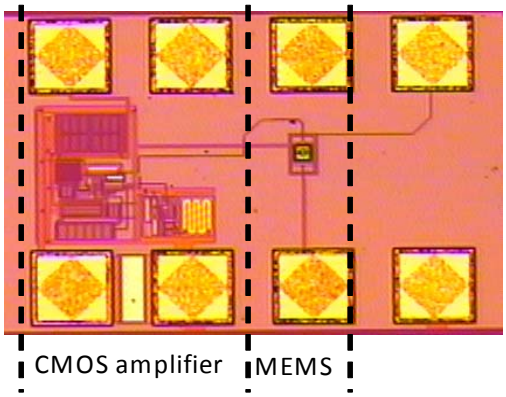

Figure 6. Optical image of the fully integrated prototype. The output of the mechanical device is connected to the input of the transimepedance amplifier

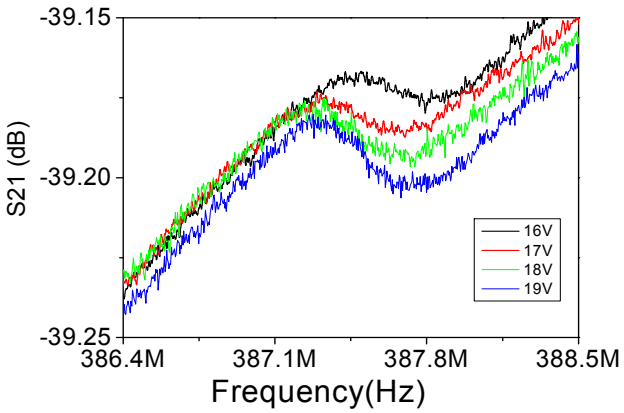

Figure 7. Transmission coefficient S21 for fully integrated resonator and CMOS amplifier.

V. Conclusions

We have presented a novel LBAR resonator that allows in a very simple manner to design a high frequency resonator, making independent the coupling area and resonance frequency.

To demonstrate the viability of the structure, a resonant micro-electromechanical LBAR working at 380 MHz with, and without CMOS on-chip readout circuitry has been implemented and tested.

The test results confirm the functionality of the LBAR, although a reduction of the parasitic capacitance is desired to enhance the resonance peak. The differential integrated fabrication with a dummy LBAR could solve the problem of the parasitic currents as were demonstrated in [3].

The Properties of M^{th} Order Differences and Their Relationship to M^{th} Order Random Stability

Victor S. Reinhardt, Raytheon Space and Airborne Systems, El Segundo, California, USA

Abstract—Allan and Hadamard variances are well-known examples of M^{th} order difference (Δ) variances. These are mean square (MS) averages over data of the M^{th} order Δ-measure $\Delta(\tau)^M v(t)$, where $\Delta(\tau)v(t) = v(t+\tau) - v(t)$. Many of the important properties of Allan and Hadamard variances are specific examples of the more general properties of M^{th} order Δ-measures. This paper first provides a useful compendium of these properties along with proofs. Allan and Hadamard variances are also known as MS measures of M^{th} order random stability (or instability). But what is M^{th} order random stability? The second part of this paper offers a definition of such stability as the prediction error *solely due to the random error or noise in the data* at an $(M+1)^{th}$ point from an M-parameter calibration function that is passed through M previously measured data points. Using this definition and the properties of Δ-measures, it is shown that M^{th} order Δ-variances are natural measures of M^{th} order MS random stability when the deterministic drift in the data has $(M-1)^{th}$ or lower order polynomial behavior, the calibration function is an $(M-1)^{th}$ polynomial, and the measured data and predicted value are all spaced by τ. When the drift (aging plus environmental variation) does not have this behavior, it is further shown that Δ-variances are biased measures of such polynomial random stability, even when one uses fitting techniques to remove the drift from the data. This drift removal process is shown to alter the spectral kernel $K_{stat}(f)$ that relates the Δ-variance in question to the power spectral density (PSD) of the random noise in the data, even if the fit perfectly removes the direct drift effects. Methods are presented for computing such altered $K_{stat}(f)$ and are illustrated by computing the changes in $K_{stat}(f)$ that occur due to various drift-removal techniques in the unmodified Allan variance. These results are then used to explain why biases in drift-removed Δ-variances can change so drastically as a function of power law PSD type and fit methodology. Finally, it is shown that M^{th} order Δ-measures that are natural measures of random stability in the presence of intrinsic aging can become highly biased as a result of environmental drift removal.

I. INTRODUCTION

Allan [1] and Hadamard [2] variances are well-known examples of M^{th} order difference variances or Δ-variances. These variances are proportional to the mean square (MS) of the M^{th} order forward difference or Δ-measure $\Delta(\tau)^M v(t)$ [3]. Here, v(t) is some data variable such as x(t) the time error or y(t) the fractional frequency error [1], and the operator $\Delta(\tau)^M$ is the M^{th} application of the 1^{st} order forward difference operator $\Delta(\tau)$ defined by $\Delta(\tau)v(t) = v(t+\tau) - v(t)$ [3]. Many of the important properties of Allan and Hadamard variances are specific examples of the more general properties of Δ-measures and their variances. Some of these properties have been well-known since the time of Newton [3][4], but others are less well-known [5]. This paper provides a useful compendium of these properties as they relate to error measures such as Allan and Hadamard variances along with their proofs.

Allan and Hadamard variances are also known as MS measures of M^{th} order random stability (or instability) [1][2]. But exactly what does one mean by such stability? The second part of this paper offers a definition of M^{th} order random stability as the prediction error *solely due to the random error or noise in the data* at an $(M+1)^{th}$ point from an M-parameter calibration function that is passed through M previously measured data points. Using this definition and the properties of Δ-measures, the paper investigates nature of biases in M^{th} order Δ-variances used as measures of polynomial M^{th} order random stability (defined as M^{th} order random stability when the calibration function is an $(M-1)^{th}$ order polynomial and all points are equally spaced by τ). Here, bias is used in the sense of the mean difference between the Δ-variance value and that of the above definition of random stability.

It is shown that M^{th} order Δ-variances are natural bias-free measures of such M^{th} order polynomial stability when the deterministic drift in the data (intrinsic aging in v(t) over time plus environmentally induced changes in v(t) over time) is an $(M-1)^{th}$ or lower or polynomial. When this is not the case, it is also shown that attempting to remove the drift using data fitting techniques will leave a residual bias that alters the spectral kernel $K_{stat}(f)$ that relates the Δ-variance in question to the power spectral density (PSD) of the random noise in the data, even if the fit perfectly removes the direct drift effects. Methods are presented for computing such altered $K_{stat}(f)$ and are illustrated by computing the changes in $K_{stat}(f)$ that occur due to various drift-removal techniques in the unmodified Allan variance. These results are then used to explain why biases in drift-removed Δ-variances can change so drastically as a function of power law PSD type [1][6] and fit methodology. Finally, it is shown that M^{th} order Δ-measures that are natural measures of random stability in the presence of intrinsic aging can become highly biased as a result of environmental drift removal.

A. Basic Terminology

Figure 1 and Table I describe the basic terminology and truth model to be used in this paper. v(t) in (1) is any

continuous data variable, such as x(t) the time error or y(t) the fractional frequency error [1]. Here, t is the ideal error free continuous observation time, and $v(t_n)$ is a set of data samples at the error free sampling times t_n over the data interval T as described in (2) and (3). In our truth model, v(t) is additively partitioned into random error or noise $v_r(t)$ (4) and drift $v_c(t)$ (5), which is the deterministic component of v(t). Here, changes in $v_c(t)$ over time are due both to intrinsic aging, which is a pure function of time, and independent environmental parameters $\upsilon(t)$ (6), which mediate the change in $v_c(t)$ over time. Note in (5) that $\upsilon(t)$ is subsumed into the t-variable in $v_c(t)$. This simply assumes that $\upsilon(t)$ does not change with ensemble averaging over a specific data interval T; that is, $\upsilon(t)$ is deterministic. In the paper, we will also assume that $v_r(t)$ is both zero mean (ZM) and wide-sense stationary (WSS), but the paper's results can be straightforwardly generalized to include noise that is neither ZM nor WSS [7]. Finally, we note that drift is in general neither ZM nor WSS.

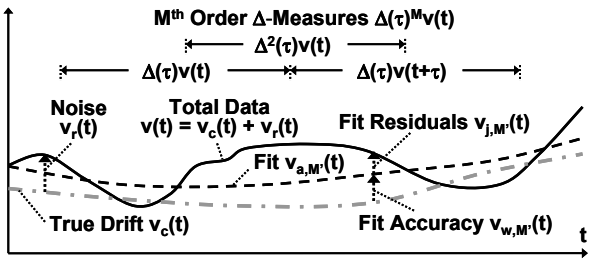

Figure 1. Basic Terminology

TABLE I. BASIC TERMINOLOGY

Total continuous data variable: $v(t) = v_c(t) + v_r(t)$	(1)
Sampled data: $t = t_n$ [Unless otherwise specified sampling is uniform]	(2)
Uniform sampling: $t_n = t_0 + nt_s$ [n= 0 to N-1 and $t_s = T/N$]	(3)
Random error or noise: $v_r(t)$	(4)
True deterministic drift: $v_c(t) = v_c(t,\upsilon(t))$	(5)
Environmental variables included in $v_c(t)$: $\upsilon(t)$	(6)
Fitted estimate of $v_c(t)$ from the data set $v(t_n)$: $v_{a,M'}(t,v(t_n))$	(7)
M'-parameter model function (before fit) [1]: $v_{a,M'}(t,\mathbf{a})$ [$\mathbf{a} = (a_0 \dots a_{M'-1})^\dagger$]	(8)
True fit accuracy: $v_{w,M'}(t_{n'},v(t_n)) = v_{a,M'}(t_{n'},v(t_n)) - v_c(t_{n'})$	(9)
Fit residuals or data precision: $v_{j,M'}(t_{n'},v(t_n)) = v(t_{n'}) - v_{a,M'}(t_{n'},v(t_n))$	(10)
Theoretical mean square (MS) errors [2]: $\sigma_{\varsigma,M'}(v(t_n))^2 = \mathcal{E}\Sigma_{n=0}^{N-1} v_{\varsigma,M'}(t_n)^2$	(11)
M^{th} order Δ-measure of $v(t_n)$: $\Delta(\tau)^M v(t_n)$ where $\Delta(\tau)v(t_n) = v(t_n+\tau) - v(t_n)$	(12)
$\tau = m_\tau t_s$ is assumed, where m_τ is an integer.	(13)
Theoretical M^{th} order Δ-variance: $\sigma_{\Delta,M}(\tau,v(t_n))^2 = \lambda_M^{-1}\mathcal{E}(\Delta(\tau)^M v(t_n))^2$	(14)
$\lambda_M = \Sigma_{m=0}^{M} c(M,m)^2 = c(2M,M)$ where $c(m,n) = m!/(n!(m-n)!)$	(15)

[1] $(\dots)^\dagger$ = hermitian transpose (transpose for real matrices).

[2] ς = c or r and $\mathcal{E}$ = ensemble averaging operator.

In our truth model, some as yet unspecified fitting technique has generated a data fit $v_{a,M'}(t,v(t_n))$ (7) based on the data set $v(t_n)$ and an adjustable M' **a**-parameter model function $v_{a,M'}(t,\mathbf{a})$ (8). Note that the explicit reference to $v(t_n)$ in $v_{a,M'}(t,v(t_n))$ is important to distinguish it from $v_{a,M'}(t,v_r(t_n))$ and $v_{a,M'}(t,v_c(t_n))$, which are fits based on $v_r(t_n)$ or $v_c(t_n)$ alone as the data set. Two basic error measures associated with the fitting process are the true fit accuracy $v_{w,M'}(t_{n'},v(t_n))$ defined in (9) and the fit error residuals or data precision $v_{j,M'}(t_{n'},v(t_n))$ defined in (10). $\sigma_{\varsigma,M'}(v(t_n))^2$ (ς = w or r) defined in (11) is the ensemble ($\mathcal{E}$) averaged (theoretical) mean square (MS) of $v_{\varsigma,M'}(t_{n'},v(t_n))$ at the point $t_{n'}$. For further detail on this model, see [7].

(12) and (14) are the definitions of $\Delta(\tau)^M v(t_n)$ the M^{th} order Δ-measure of $v(t_n)$ and $\sigma_{\Delta,M}(\tau,v(t_n))^2$ its $\mathcal{E}$-averaged variance to be called the theoretical Δ-variance. Here, the normalization factor λ_M in (15) is chosen so that $\sigma_{\Delta,M}(\tau,v_r(t_n))^2$ equals $\mathcal{E}v_r(t_n)^2$ for $v_r(t_n)$ samples that are uncorrelated with each other [5]. Note that $t_n + M\tau$ must be within the data set for the definition to apply. Further note that $\Delta(\tau)^M v(t)$ is not in general ZM or WSS, since $\Delta(\tau)^M v_c(t)$ is not in general ZM or WSS. Thus, $\sigma_{\Delta,M}(\tau,v(t))^2$ is not in general a true variance in the sense that the ensemble mean has been removed, but we will call it so for simplicity. On the other hand, $\Delta(\tau)^M v_r(t)$ is assumed to be ZM and WSS, and thus $\sigma_{\Delta,M}(\tau,v_r(t))^2$ is a true variance. Finally, we note that $\sigma_{\Delta,2}(\tau,y(t))^2 = \sigma_y(\tau)^2$ the theoretical unmodified Allan variance of y(t) [1], $\sigma_{\Delta,3}(\tau,x(t))^2 = \sigma_x(\tau)^2 = (\tau^2/3)\sigma_y(\tau)^2$ the theoretical unmodified Allan variance of x(t) [1], and $\sigma_{\Delta,2}(\tau,y(t))^2 = {}_H\sigma_y(\tau)^2$ the theoretical unmodified Hadamard variance of y(t) [2].

II. A COMPENDIUM OF M^{TH} ORDER Δ-MEASURE PROPERTIES

This section contains a compendium of the properties of M^{th} order Δ-measures or M^{th} order forward finite differences $\Delta^M(\tau)v(t)$ and their Δ-variances as they relate to stability and fitting error measures. Explicit proofs are provided for properties that do not follow directly from previous ones to make the compendium more complete. Finally, note there are also backward, mean, and divided differences not discussed here [3,8].

The theory of finite differences, which is also called the calculus of finite differences, has a very long history [3,4]. References begin about the time of Newton [4], continuing with an exhaustive 1860 treatise by Boole [3], and on through the 20th century [8]. Finite differences were also utilized in the earliest computing engines, such as the Babbage engine [9], to turn multiplications into additions in the generation of polynomials. The historical material emphasizes such functional generation and the numerical solution of difference equations. Thus, despite the long history of the field, there is still material relating to stability and fitting error that seems to be only recently added [5].

Table II lists basic terminology and properties of M^{th} order Δ-measures [3][5][8]. In the table, secondary properties straightforwardly follow from definitions, so explicit proofs will not be provided. Note that the Fourier properties in the table are important for deriving the spectral properties of Δ-variances. These Fourier properties are generated here by equating time-domain operators (i.e., $\Delta(\tau)^M$) to time-domain impulse response functions (i.e., $h_{\Delta,M}(t)$) and then Fourier transforming these impulse response functions. Finally, two properties of note not in the table are that both $\Theta(\tau)$ and $\Delta(\tau)$ can be represented in terms of the differentiation operator $\mathcal{D}_t = d/dt$ as $\Theta(\tau) = \exp(\tau\mathcal{D}_t)$ and $\Delta(\tau) = \exp(\tau\mathcal{D}_t) - 1$ when τ is not function of t [2]. Fourier transforming $\mathcal{D}_t$ is an alternative method for generating the table's Fourier properties.

TABLE II. BASIC PROPERTIES OF M^TH ORDER Δ-MEASURES

(Forward) τ-displacement operator [1]:

$\Theta(\tau)v(t) = v(t+\tau) = \int dt' h_\Theta(t-t')v(t') = h_\Theta(t-t') \otimes v(t')$ (16)

Equivalent t-domain impulse response: $h_\Theta(t) = \delta(t+\tau)$ (17)

f-domain response function [2]: $H_\Theta(f) = \mathcal{F}_{f,t} h_\Theta(t) = \exp(j\omega\tau)$ (18)

$V_\Theta(f) = \mathcal{F}_{f,t} v_\Theta(t) = \mathcal{F}_{f,t} \Theta(\tau)v(t) = H_\Theta(f)V(f)$ where $V(f) = \mathcal{F}_{f,t} v(t)$ (19)

M^th order displacement: $\Theta(\tau)^m = \Theta(m\tau)$ (20)

Equivalent t-domain impulse response: $h_{\Theta,m}(t) = \delta(t+m\tau)$ (21)

f-domain response function: $H_{\Theta,m}(f) = \mathcal{F}_{f,t} h_{\Theta,m}(t) = \exp(jm\omega\tau)$ (22)

M^th order (forward) difference operator: $\Delta(\tau)^M = (\Theta(\tau)-\Theta(0))^M$ (23)

1st order Δ-measure: $\Delta(\tau)v(t) = v(t+\tau) - v(t) = (\Theta(\tau)-\Theta(0))v(t)$ (24)

Binomial expansion: $\Delta(\tau)^M = \Sigma_{m=0}^M (-1)^{M-m} c(M,m) \Theta(\tau)^m$ (25)

Falling Factorial: $z^{(m)} = z(z-1)\ldots(z-m+1)$ [Note $m^{(m)} = m!$] (26)

$\Delta(\tau)^M t^{M'} = M'^{(M)} t^{(M'-M)}$ if $M \le M'$ otherwise $\Delta(\tau)^M t^{M'} = 0$ (27)

Equivalent t-domain impulse response:

$h_{\Delta,M}(t) = \Sigma_{m=0}^M (-1)^m c(M,m) \delta(t+m\tau)$ (28)

f-domain response function: $H_{\Delta,M}(f) = \Sigma_{m=0}^M (-1)^{M-m} c(M,m) \exp(j\omega\tau)^m$

$H_{\Delta,M}(f) = (\exp(j\omega\tau) -1)^M = (2j)^M \exp(j\pi f\tau)\sin(\pi f\tau)^M$ (29)

[1] Integration limits are $-\infty$ to $+\infty$ unless otherwise stated. Finite limiting factors are assumed to be included in the integrand. $\otimes$ = convolution.

[2] Fourier Tansform: $\mathcal{F}_{f,t} v(t) = \int df \exp(-j\omega t) v(t)$ where $\omega = 2\pi f$.

TABLE III. FURTHER PROPERTIES OF M^TH ORDER Δ-MEASURES

M^th order drift insensitivity: $\Delta(\tau)^M v_{ply,M'}(t,\mathbf{a}) = 0$ if $M' \le M$ (30)

$(M-1)^{th}$ order polynomial: $v_{ply,M}(t,\mathbf{a}) = \Sigma_{m=0}^{M-1} a_m (t-t_0)^m$ (31)

Prediction error [1] at $t_{m'}$ (M+1 total data points)

$v_{e,M,M'}(t_{m'},v(t_m)) = v(t_{m'}) - v_{cal,M'}(t_{m'},v(t_m))$ (32)

where $v_{cal,M'}(t_{m'},v(t_m))$ is fit to M measured points $v(t_m)$ $m \ne m'$ ($t_{m'}$ not in fit)

$\sigma_{e,M,M'}(t_{m'},v(t_m))^2 = \mathcal{E} v_{e,M,M'}(t_{m'},v(t_m))^2$ (33)

Theorem: $v_{e,M,M}(t_{m'},v(t_m)) = \Delta(\tau)^M v(t_0) (-1)^{M-m'}/c(M,m')$ (34)

when $v_{cal,M}(t_{m'},v(t_m)) = v_{poly,M}(t_{m'},v(t_m))$ that passes through M measured $v(t_m)$, all points are spaced by τ, and $t_{m'}$ is not included in the measured t_m.

$\sigma_{e,M,M}(v(t_{m'}))^2 = \lambda_M \sigma_{\Delta,M}(\tau,v(t))^2/c(M,m')^2$ (35)

Theorem: $v_{j,M}(t_m) = \Delta(T/M)^M v(t_0)(-1)^{M-m} c(M,m)/\lambda_M$ (36)

when $v_{a,M}(t_{m'},v(t_m)) = v_{poly,M}(t_{m'},v(t_m))$ is generated with a USLF over M+1 measured points spaced by τ and $t_{m'}$ is included in the measured t_m.

$\sigma_{j,M}(v)^2 = \sigma_{\Delta,M}(\tau,v(t_0))^2$ (37)

WSS spectral representation² of σ_{stat}^2: $\sigma_{stat}^2 = \int df K_{stat}(f)|H_s(f)|^2 L_v(f)$ (38)

$K_{stat}(f) = |H_{\Delta,M}(f)|^2$ for $\sigma_{stat}^2 = \sigma_{\Delta,M}(\tau,v_r(t_0))^2$ (39)

[1] $v_{e,M,M'}(t_{m'},v(t_m))$ and $v_{j,M'}(t_{m'},v(t_m))$ have similar formulas but not the same meaning.

[2] $H_s(f)$ represents system filtering that is included in the t-domain variables $v(t)$, $v_r(t)$, and $v_e(t)$ [5][7]. Thus, the single sideband power spectral density (PSD) of $v_r(t)$ is $|H_s(f)|^2 L_v(f)$, where $L_v(f)$ is the pre-filtered PSD of the pre-filtered noise process, i.e., for neg-p noise this PSD is $L_v(f) = K_p|f|^p$ [5][6][7].

Table III lists further properties of M^th order Δ-measures. The first property (30) is the well-known insensitivity of M^th order Δ-measures to $(M-1)^{th}$ or lower order polynomial drift. This follows directly from (27). The next property (34) relates Δ-measures to polynomial prediction error after an ideal M-point calibration. General prediction error $v_{e,M,M'}(t_{m'},v(t_m))$ is defined in (32) as the difference at an *unmeasured* point $t_{m'}$ between the true value $v(t_{m'})$ and a prediction based on $v_{cal,M'}(t_{m'},v(t_m))$ an M'-parameter *calibration* function somehow generated from M *measured* calibration points $v(t_m)$. Note that $v_{cal,M'}(t_{m'},v(t_m))$ is essentially the same as the fit $v_{a,M'}(t_{n'},v(t_n))$, except that the points and functions may be different. As shown in Figure 2, when $t_{m'}$ is the last point t_M, the prediction error is an extrapolation error, and when $t_{m'}$ is an internal point, the prediction error is an interpolation error. Finally, an ideal M-point calibration $v_{cal,M}(t,v(t_m))$ is defined as an M-parameter calibration function that exactly passes through all M measured points. Note that this is always possible here for a well-formed function, because there are zero degrees of freedom (0-DOF) in the fit.

Theorem (34) states that the prediction error at an unmeasured $(M+1)^{th}$ point $t_{m'}$ using an ideal $(M-1)^{th}$ order polynomial calibration is proportional to $\Delta(\tau)^M v(t_0)$ when all points are spaced by τ. The proof of (34) is as follows [5]. First from (25), note that

$$\Delta(\tau)^M v(t_0) = \Sigma_{m \ne m'}^M (-1)^{M-m} c(M,m) \Theta(\tau)^m v(t_0) + (-1)^{M-m'} c(M,m') v(t_{m'}) \quad (40)$$

Second, note that $v_{ply,M}(t_m,\mathbf{a})$ can always be made to pass through M data points, because it is a 0-DOF fit. Thus, one can substitute $v_{ply,M}(t_{m'},v(t_m))$, the $(M-1)^{th}$ order polynomial that passes though the measured $v(t_m)$, for $v(t_m)$ in the right term of (40) to obtain

$$\Delta(\tau)^M v(t_0) = \Sigma_{m \ne m'}^M (-1)^{M-m} c(M,m) \Theta(\tau)^m v_{ply,M}(t_0,v(t_m)) + (-1)^{M-m'} c(M,m') v(t_{m'}) \quad (41)$$

Reversing the binomial expansion, we can then write this as

$$\Delta(\tau)^M v(t_0) = \Delta(\tau)^M v_{ply,M}(t_0,v(t_m)) + (-1)^{M-m'} c(M,m')(v(t_{m'}) - v_{ply,M}(t_{m'})) \quad (42)$$

Finally from (30), we note that $\Delta(\tau)^M v_{ply,M}(t_0,v(t_m)) = 0$, which proves (34). For extrapolation error, also note that (34) has the simple form $v_{e,M,M}(t_M,v(t_m)) = \Delta(\tau)^M v(t_0)$.

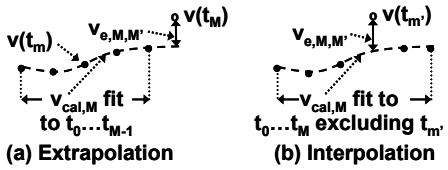

Figure 2. Extrapolation and interpolation prediction error.

(36) was first demonstrated by the author using combination of analytical and Monti Carlo techniques [5], but Charles Greenhall later provided the author with a totally analytical proof in an unpublished communication [10]. We reproduce this proof here as follows with some modifications.

TABLE IV. MATRIX EQUATIONS FOR M+1 DATA POINTS

$\mathbf{v} = (v(t_0),\ldots,v(t_M))^\dagger$ (43)

$\mathbf{v}_j = (v_j(t_0),\ldots,v_j(t_M))^\dagger$ (44)

$\mathbf{v}_{ply} = (v_a(t_0),\ldots,v_a(t_M))^{(T)} = \mathbf{ua}$ (45)

$\mathbf{a} = (a_0,\ldots,a_{M-1})^\dagger$ (46)

$\mathbf{u}_{nm} = (t_n - t_0')^m$ [n = 0 to M, m = 0 to M-1, t_0' arbitrary] (47)

Un-weighted least squares fit (ULSF) solution:

$\mathbf{a} = (\mathbf{u}^\dagger\mathbf{u})\mathbf{u}^\dagger\mathbf{v}$ $\mathbf{v}_{ply} = \mathbf{g}_w\mathbf{v}$ $\mathbf{v}_j = (\mathbf{I} - \mathbf{g}_w)\mathbf{v}$ $\mathbf{g}_w = \mathbf{u}(\mathbf{u}^\dagger\mathbf{u})\mathbf{u}^\dagger$ (48)

$\Delta(T/M)^M v(t_0) = \boldsymbol{\delta}^\dagger\mathbf{v}$ [from (25)] (49)

$\boldsymbol{\delta} = ((-1)^M c(M,0),\ldots,(-1)^{M-n} c(M,n),\ldots c(M,M))^\dagger$ (50)

$(\boldsymbol{\delta}^\dagger\mathbf{u})_m = \Delta(T/M)^M t_0^{m-1} = 0$ [from (27)] (51)

$\mathbf{v}_j = \mathbf{g}_\delta\mathbf{v}$ [(36) in matrix notation] $\mathbf{g}_\delta = \boldsymbol{\delta}(\boldsymbol{\delta}^\dagger\boldsymbol{\delta})^{-1}\boldsymbol{\delta}^\dagger = \lambda_M^{-1}\boldsymbol{\delta}\boldsymbol{\delta}^\dagger$ (52)

$\lambda_M = \boldsymbol{\delta}^\dagger\boldsymbol{\delta}$ [from (15) and (50)] (53)

Table IV defines the matrix notation used to prove (36). In the table, we write the M+1 the values of $v(t_m)$, $v_j(t_m)$, and

$v_{ply,M'}(t_{m'},v(t_m))$ as M+1 dimensional vectors $\mathbf{v}$, $\mathbf{v}_j$, and $\mathbf{v}_{ply}$ (43), (44), and (45). In (45), $v_{ply,M'}(t_{m'},v(t_m))$ is defined using both the M-dimensional parameter vector $\mathbf{a}$ (46) and a power law basis function matrix $\mathbf{u}$ (47). In this notation, an un-weighted least squares fit (ULSF) solution is given by (48) [11]. In this form, it is well known that $\mathbf{g}_w$ the solution matrix for $\mathbf{v}_{ply}$ in terms $\mathbf{v}$ is an operator that projects $\mathbf{v}$ into an M-dimensional manifold defined by the set of basis vectors in $\mathbf{u}$ [11]; that is, $\mathbf{g}_w\mathbf{v}_{ply} = \mathbf{v}_{ply}$ for any $\mathbf{a}$. It is also well-known that $\mathbf{v}_j = (\mathbf{I} - \mathbf{g}_w)\mathbf{v}$, and $(\mathbf{I} - \mathbf{g}_w)$ is an operator that projects $\mathbf{v}$ into the normal to this $\mathbf{u}$-defined manifold (the orthogonality theorem) [11]. Since, there are only M+1 dimensions in the total space, $\mathbf{v}_j$ can thus be represented by a constant b times a single vector orthogonal to all the vectors in $\mathbf{u}$.

To find such a vector, consider $\Delta(T/M)^M v(t_0)$ given in (49) as $\boldsymbol{\delta}^\dagger\mathbf{v}$, where $\boldsymbol{\delta}$ is defined in (50). From (27), we note in (51) that $\boldsymbol{\delta}^\dagger\mathbf{u} = \mathbf{0}$. Thus, $\boldsymbol{\delta}$ is a vector orthogonal to the basis $\mathbf{u}$, and we can write $\mathbf{v}_j$ as $b\boldsymbol{\delta}$. We further note that $\mathbf{g}_\delta$ in (52) is the projection operator into the direction of $\boldsymbol{\delta}$; that is, $\mathbf{g}_\delta\mathbf{v}_j = b\boldsymbol{\delta}(\boldsymbol{\delta}^\dagger\boldsymbol{\delta})^{-1}\boldsymbol{\delta}^\dagger\boldsymbol{\delta} = b\boldsymbol{\delta} = \mathbf{v}_j$. Finally, noting $\lambda_M = \boldsymbol{\delta}^\dagger\boldsymbol{\delta}$ in (53), we prove (36).

The final property of M^{th} Order Δ-Measures in Table III relates to the wide-sense stationary (WSS) spectral integral representation of σ_{stat}^2 [5][7], where σ_{stat}^2 is some MS statistic of $\Delta(\tau)^M v_r(t)$. This spectral representation is given here and in Table III (38) as

$$\sigma_{stat}^2 = \int df\, K_{stat}(f)|H_s(f)|^2 L_v(f) \tag{38}$$

where

(a) $L_v(f)$ is the pre-system-filtered single sideband power spectral density (PSD) of $v_r(t)$ [5][7] (see Table III Note 2),

(b) $H_s(f)$ is a system response function [5][7], which is a generalization of a high frequency spectral cut-off f_h [1], and

(c) $K_{stat}(f)$ is a spectral kernel that defines the spectral properties of the statistic independent of $H_s(f)$ [5][7].

For $\sigma_{stat}^2 = \sigma_{\Delta,M}(\tau,v_r(t_0))^2$, (39) notes that $K_{stat}(f) = |H_{\Delta,M}(f)|^2$ [5]. This $|H_{\Delta,M}(f)|^2$ has the well-known f^{2M} highpass filtering property of an M^{th} order Δ-variance with respect to $L_v(f)$ [1][5][7]. We finally note that $K_{stat}(f)$ for $\sigma_{\Delta,M}(\tau,v_r(t_0))^2$ is a response function squared, because $\Delta(\tau)^M$ is a time translation invariant operator. We finally note that $K_{stat}(f)$ cannot be represented as a response function squared for all error measures or statistics [5][7].

III. M^{TH} Order Random Stability (Instability)

Intuitively, random stability (or instability) is a measure of the temporal variation of v(t) solely due to the random data component $v_r(t)$. In this section, we precisely define the concept of M^{th} order random stability and explore the issues associated with implementing this definition when $v_c(t)$ as well as $v_r(t)$ is present in data.

Table V (54) defines general M^{th} order random stability $v_{s,M}(t_{m'},v_r(t_m))$ as the prediction error $v_{e,M,M}(t_{m'},v_r(t_m))$ when

(a) the data consists solely of random error $v_r(t_n)$, and

(b) the M-parameter calibration function $v_{cal,M}(t,v_r(t_m))$ is fit to pass through M measured calibration points $v_r(t_m)$.

Similarly, Table V (56) is the equation for polynomial M^{th} order random stability, which is defined as M^{th} order random stability when

(a) the model function $v_{cal,M}(t,\mathbf{a})$ is $v_{ply,M}(t,\mathbf{a})$, and

(b) all points are equally spaced by τ.

Note here that (34) is also used to write polynomial random stability in terms of an M^{th} order Δ-measure. Their MS forms are given in (55) and (57) (using (35)). Furthermore, applying (30) to (56) and (57), we note in (58) that $\Delta(\tau)^M v(t_n)$ and $\sigma_{\Delta,M}(\tau,v(t))^2$ the Δ-measure and Δ-variance acting on the raw (non-fit removed) data are unbiased measures of M^{th} order polynomial random stability when the drift is of the form $v_{ply,M'}(t,\mathbf{a})$ for $M' \le M$ over the data interval T (because $\Delta(\tau)^M v_c(t) = 0$). This is a generalization of the well-known fact that Hadamard variances are insensitive to constant frequency drift [2].

TABLE V. M^{TH} ORDER RANDOM INSTABILITY

General M^{th} order random stability at uncalibrated point $t_{m'}$	
$v_{s,M}(t_{m'},v_r(t_m)) = v_{e,M,M}(t_{m'},v_r(t_m))$	(54)
$\sigma_{s,M}(t_{m'},v_r(t_m))^2 = \mathcal{E}v_{s,M}(t_{m'},v_r(t_m))^2$	(55)
Polynomial M^{th} order random stability, $v_{cal,M}(t,\mathbf{a}) = v_{ply,M}(t,\mathbf{a})$, $t_m = t_0+m\tau$	
$v_{s,M}(\tau,t_{m'},v_r(t_m)) = \Delta(\tau)^M v_r(t_0)\,(-1)^{M-m'}/c(M,m')$	(56)
$\sigma_{s,M}(\tau,t_{m'},v_r(t_m))^2 = \sigma_{\Delta,M}(\tau,v_r(t_0))^2\,\lambda_M/c(M,m')^2$	(57)
When $v_c(t) = v_{ply,M'}(t,a)$ for $M' \le M$	
$\Delta(\tau)^M v(t_0)$ and $\sigma_{\Delta,M}(\tau,v(t_0))^2$ (acting on data with no fit removal) are natural unbiased measures $v_{s,M}(\tau,t_{m'},v_r(t_m))$ and $\sigma_{s,M}(\tau,t_{m'},v_r(t_m))^2$.	(58)
When $v_c(t) \ne v_{ply,M'}(t,a)$ for $M' \le M$ & linear fit over N points t_n	
$\Delta(\tau)^M v_{j,M'}(t_{n'},v(t_n)) = \Delta(\tau)^M v_r(t_{n'}) - v_{c\text{-}bias}(t_{n'}) - v_{r\text{-}bias}(t_{n'})$	(59)
$v_{c\text{-}bias}(t) = \Delta(\tau)^M v_{w,M'}(t,v_c(t_n))$ = bias due to $v_{a,M'}(t,v_c(t_n)) \ne v_c(t)$ over T	
$v_{r\text{-}bias}(t) = \Delta(\tau)^M v_{ply,M'}(t,v_r(t_n))$ = bias that changes kernel $K_{stat}(f)$	
Note $v_{ply,M'}(t_{n'},v(t_n)) = v_{ply,M'}(t_{n'},v_r(t_n)) + v_{ply,M'}(t_{n'},v_c(t_n))$	(60)

When $v_c(t)$ is not equal to $v_{ply,M'}(t,\mathbf{a})$ for $M' \le M$ over T, $\Delta(\tau)^M v_c(t_n)$ is not zero, and thus $\Delta(\tau)^M v(t_n)$ and its various MS statistics $\sigma_{stat}(v(t_n))^2$ are no longer unbiased measures of M^{th} order polynomial random stability. This is a generalization of the well-known fact that Allan variances acting on raw data are sensitive to frequency drift in the data and are thus biased measures of purely random stability. When utilizing Δ-variances as measures of random stability in the presence of such drift, standard practice is to minimize the bias by attempting to remove the drift with some fit $v_{a,M'}(t_{n'},v(t_n))$ and then utilizing $\Delta(\tau)^M v_{j,M'}(t_{n'},v(t_n))$ to generate the Δ-variance [1]. However, it is recognized that this is an imperfect process, and drift removal methodologies have been developed to minimize the bias for constant frequency drift [12].

In such imperfect cases, Table V (59) separates the bias or difference between $\Delta(\tau)^M v_{j,M'}(t_{n'},v(t_n))$ and $\Delta(\tau)^M v_r(t_{n'})$ the true measure of polynomial random stability into two terms as follows. $v_{c\text{-}bias}(t)$ in (59) is the direct bias component that occurs when the fitted model function $v_{a,M'}(t,v_c(t_n))$ does not completely track $v_c(t)$ over T. The form shown in (59) in terms of $v_{w,M'}(t,v_c(t_n))$ is obtained by using (9), (10), and (60). In this case, we also note that (38) no longer completely

specifies σ_{stat}^2; that is, one must add a second spectral integral term that is a function of the PSD of $v_c(t)$ (or its non-WSS equivalent) to completely specify σ_{stat}^2 [5][7]. The second bias component in (59) $v_{r\text{-}bias}(t)$ is the bias effect of the drift removal fitting process on $K_{stat}(f)$. It is noted that the fitting process changes $K_{stat}(f)$ from its non-fit-removed form even when the drift removal makes $v_{c\text{-}bias}(t) = 0$, because the fitting process filters $v_r(t)$ as well as $v_c(t)$ [5][7].

To analytically compute this fit-removed $K_{stat}(f)$, one can use the spectral theory developed in [5] and [7]. In addition, there is a simple numerical method for generating $K_{stat}(f)$ for any σ_{stat}^2 of the form $\Sigma_{n'}\xi_{n'}v_{stat}(t_{n'},v(t_n))^2$ as follows. One first generates code to compute $v_{stat}(t_{n'},v(t_n))$ starting with two input data sets $v(t_n) = \cos(2\pi f_o t_n)$ and $v(t_n) = \sin(2\pi f_o t_n)$ over the desired range of f_o. One then computes $\sigma_{stat}^2(f_o)$ for each f_o from these $v(t_n)$ and adds the resultant $\sigma_{stat}^2(f_o)$ values together to produce a net $\sigma_{stat}^2(f_o)$. We note for this input that $\sigma_{stat}^2(f_o) = K_{stat}(f_0)$, because

(a) $v(t_n)$ includes the system filtering, so $\sigma_{stat}(f_o)^2 = \int df\, K_{stat}(f)L_v(f)$,

(b) $L_v(f)$ in this case consists of Dirac δ-functions at $\pm f_o$,

(c) $K_{stat}(f)$ is symmetric about f, and

(d) summing $\sigma_{stat}(f_o)^2$ for cosine and sine inputs is equivalent to randomizing the phase of the input to make the output result WSS.

In using this numerical technique, a word of caution is warranted. Numerical truncation error can generate misleading results at small f when a high degree of cancellation from many terms is responsible for the result. Thus, one should always check for proper theoretical asymptotic behavior before relying on the numerical result.

As an illustration, let us now consider the $K_{stat}(f)$-biases introduced by various drift removal methods in the generation of the overlapping statistic of $\sigma_{\Delta,3}(\tau,x_j(t_{n'},x(t_n)))^2$, the drift-removed $\sigma_x(\tau)^2$ the unmodified Allan variance of x(t) [1]. The drift estimators we will consider are

(a) a 2nd order polynomial ULSF,

(b) the Greenhall frequency drift estimator $\hat{c}(r)$ [12], and

(c) a 6th order polynomial ULSF.

$K_{stat}(f)$ results for these drift removal methods are shown in Figure 3 for $\tau/T = 0.5$, where bias effects on $K_{stat}(f)$ are maximized. We note that bias effects on $K_{stat}(f)$ for all these drift estimators quickly disappear as τ/T becomes smaller than 0.5. For reference, the non-drift removed $K_{stat}(f)$ is also shown.

In Figure 3, only the lower portion of the spectrum near $f\tau = 0.5$ is shown. This is because drift-removed $K_{stat}(f)$ bias changes are negligible at higher spectral frequencies. In [12], Greenhall noted that the effect of kernel bias on the Allan variance varies drastically with the noise type. From Figure 3, one can see why this occurs; as p in $L_x(f) \propto |f|^p$ changes from white noise to more negative power law orders, the region near $f = 0.5/\tau$, where the maximum $K_{stat}(f)$ bias change occurs, is more and more heavily weighted in the σ_{stat}^2 integral (38). Note for white noise, that bias changes to σ_{stat}^2 are minimal if $f_h >> 1/\tau$, because white noise equally weights the whole spectrum up to f_h. In fact, for this white noise case in the limit of $f_h\tau \to \infty$, the fit-removed σ_x^2 is the same as the non-fit removed one. This is the source of the misconception that fit removal for large N can completely remove frequency drift effects without biasing σ_x^2.

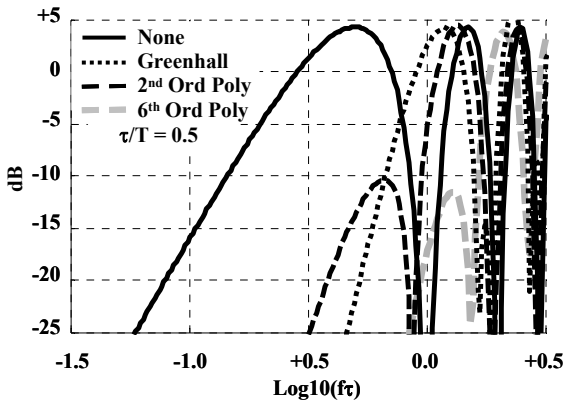

Figure 3. The Kernels $K_{stat}(f)$ for the unmodified Allan variance of x(t) with various forms of drift removal at $\tau/T = 0.5$.

Figure 3 shows the alteration in $K_{stat}(f)$ for 6th order polynomial ULSF removal, as well as 2nd order polynomial ULSF removal. This case is important in understanding bias effects when dealing with long term data where a constant frequency drift model is no longer valid. This is true for long term crystal oscillator aging, which has long term frequency aging behavior given by a sum of $A\cdot\ln(1+Bt)$ terms, and for environmentally induced drift large T, which typically has quite complicated behavior over long observation intervals.

One can see from Figure 3 that $K_{stat}(f)$ bias changes due to 6th order polynomial ULSF removal are quite drastic for large τ/T. One can also show that this 6th order polynomial case is typical for polynomial removal with orders greater than 3. We note that such (M'-1)th order polynomial USLF drift removal highpass filters the non-fit removed $K_{stat}(f)$ with $|f|^{2M'}$ HP behavior and a highpass knee of about $f = 1/T$ [5][7]. An importance consequence of this is that a Δ-variance that is a natural random stability measure without drift removal for intrinsic aging will have significant $K_{stat}(f)$ bias, if environmental factors contribute significantly to the drift over T and have complicated temporal behavior.

A final approach utilized in removing drift from long term data is piece-wise drift removal over portions T/N' of the total data interval T. One can show, however, that this causes the highpass filtering knee frequency that alters the drift-removed $K_{stat}(f)$ to move from 1/T to N'/T. This not only increases the $K_{stat}(f)$ bias for τ values on the order of 0.5T, but also causes this increase to remain appreciable for τ values down to 0.5T/N'.

IV. Summary and Conclusions

This paper has introduced a physical definition of Mth order random stability as the prediction error from an ideal M-

point calibration solely due to random noise. This definition allows one to define M^{th} order random stability, not only for polynomial fit prediction with uniform sampling intervals, but also for non-polynomial fit prediction with non-uniform sampling intervals. Using this definition and the properties of M^{th} order Δ-measures derived in the text, we have shown that M^{th} order Δ-measures and their variances without drift removal are natural measures of M^{th} order polynomial random stability when the drift over T is in the form of an $(M-1)^{th}$ or lower order polynomial. We have also provided a quantitative method for determining the bias in a fit-removed M^{th} order Δ-measure used to estimate M^{th} order polynomial random stability when the drift over T is not in the form of an $(M-1)^{th}$ or lower order polynomial. An important conclusion of the paper is that a Δ-variance that is a natural random stability measure without drift removal for intrinsic aging will have significant $K_{stat}(f)$ bias, if environmental factors contribute significantly to the drift over T and have complicated temporal behavior.

***Abstract*— We are presenting a novel concept of the time interval measurement which uses a surface acoustic wave (SAW) filter as a time interpolator. Based on our previous results we have designed and constructed a timing device which allows registration of times of arrival of pulses with a single shot precision of 800 fs RMS, the time interpolation nonlinearity bellow 200 fs, and the stability in sense of TDEV <10 fs for averaging times from 300 s to 3000 s. Two identical timing devices above have been used in an experiment, in which the frequency outputs of two Hydrogen masers were compared. The experiment proofed that one of possible applications of the timing device is a comparison of high performance low-noise frequency sources and measurement of their frequency stability in the time-domain. The noise background of the timing system was negligible for averaging intervals on the order of 100 ms and longer.**

I. INTRODUCTION

A novel time interval measurement method that makes use of a SAW filter as a time interpolator has been introduced in [1]. The method is based on the fact that a transversal SAW filter excited by a short pulse generates a finite-time signal with highly suppressed spectra outside a narrow frequency band. It results from the sampling theorem that if the responses to two excitations are sampled at clock ticks, they can be precisely reconstructed from a finite number of samples and then compared so as to determine the time interval between the two excitations.

A detailed analysis of measurement errors of this method has been given in [1] and [2]. It results from this analysis that the method excels in time interpolation efficiency since the time interpolation error relative to clock period is very small. It means that an accurate measurement can be achieved even with relatively low clock frequency. Also random errors caused by noises generated in different parts of the timing device are very low thanks to averaging effect as the interpolation process is not based on the only one but many observations. A special care has been given to minimization of non-linear effects in the timing device [3]. The experimental results [4], [5] proofed the new concept. The extreme single-shot precision, time interpolation linearity as well as the timing stability were in agreement with the expectations.

II. TIMING DEVICE

Based on the previous results we have designed and constructed a timing device which allows measurement and registration of times of arrival of input pulses with respect to a local time base. The block scheme of the timing device is in Fig. 1. An input pulse excites a SAW filter whose output is sampled at clock ticks and converted by an analog-to-digital converter (ADC) and buffered. Once the response to the input pulse has been processed, an internally generated pulse is applied to the same circuit. This internal pulse is generated synchronously with the time base reference. After both responses have died out, they are reconstructed from the samples and compared by means of cross-correlation to determine the time interval between the two pulses. All the processing is integrated into a simple algorithm based on the fast Fourier transform. The device uses the clock sampling frequency of 100 MHz. The SAW filter central frequency is of 525 MHz, and the filter bandwidth is of 18 MHz.

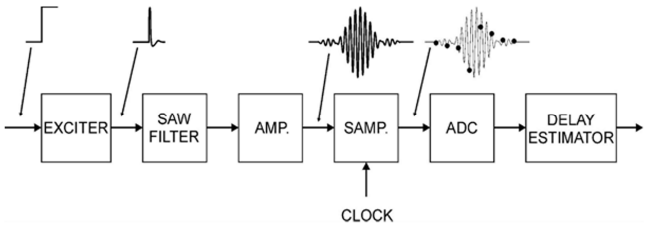

Figure 1. The block scheme of the timing device.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

The application of the internally generated time mark ensures calibrating the internal delays on a shot-by-shot basis hence the extreme timing stability and reproducibility of the measurements is achieved.

The internal time base is based on an external frequency multiplier providing spectrally pure 200 MHz sine wave multiplied from a 10 MHz frequency reference. The conversion of the 200 MHz sine wave to a pulse clock signal and its distribution to the ADC and the excitation circuit use high speed SiGe comparators and buffers.

To be able to check the measurement performance and do different experiments a reference time mark generator has been included into the timing device. It generates low jitter pulses synchronously to the local time base. The repetition frequency of these pulses is $100\ \text{MHz}/2^{17} = 763$ Hz and their jitter is below 300 fs RMS which is practically negligible with respect to the single-shot precision of the timing device itself.

The timing device is constructed on a single PCB (Fig. 2) which is installed in an Aluminum box (Fig. 3) to ensure the proper passive heat transfer and high timing stability. The box dimensions are 250 x 140 x 45 mm. Two identical timing devices described above together with a power supply unit are placed in a 19" case and create a two-channel NPET timing device (Fig. 4). The other 19" case includes the frequency multiplier 10 MHz to 200 MHz. The NPET communicates with a personal computer via USB. The input signals are connected through SMA connectors.

The performance of the timing device has been extensively tested using the reference time marks generated synchronously to the local time base as described above. The resulting histogram of the TOAs is in Fig. 5. The single-shot precision evaluated from these measurements was nearly 800 fs RMS.

Thanks to the device concept and construction an excellent timing stability has been obtained. Operating the device in a common laboratory environment without temperature stabilization, the TDEV better than 4 fs was routinely achieved for averaging times from 300 s to 3000 s (Fig. 6).

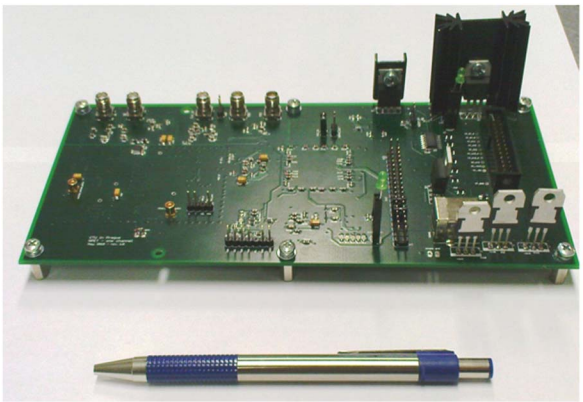

Figure 2. The timing device is constructed on a single PCB.

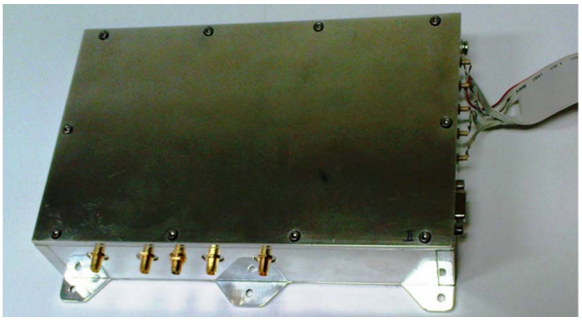

Figure 3. The timing device PCB is installed in an Aluminium box.

Figure 4. Two identical timing devices together with a power supply unit are placed in a 19" case and create a two-channel NPET timing device. The other 19" case includes the frequency multiplier 10 MHz to 200 MHz.

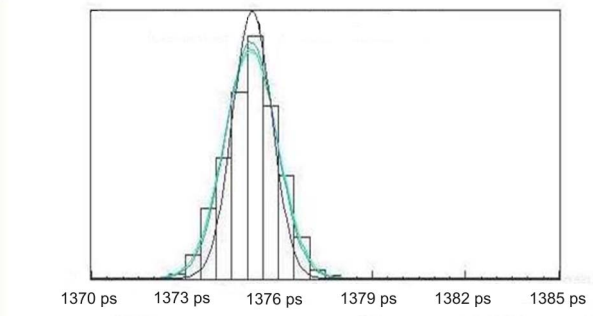

Figure 5. The resulting histogram of TOAs, 500 fs per bin. The single-shot precision evaluated from these measurements is nearly 800 fs RMS.

The timing stability can also be demonstrated on the 256 s moving average of the TOAs (Fig. 7) which did not leave the +/- 4 fs range within the period of 3 hours.

We further completed a series of measurements focused on the linearity of the time interpolation. In this case we used an external pulse generator not synchronous with the local time base. The pulses were connected to inputs of two identical timing devices through cables with different delays and the difference of TOAs in dependence on the TOA was measured. Several such measurements with different differential delay of the input pulses were completed. The resulting nonlinearity was evaluated below 200 fs.

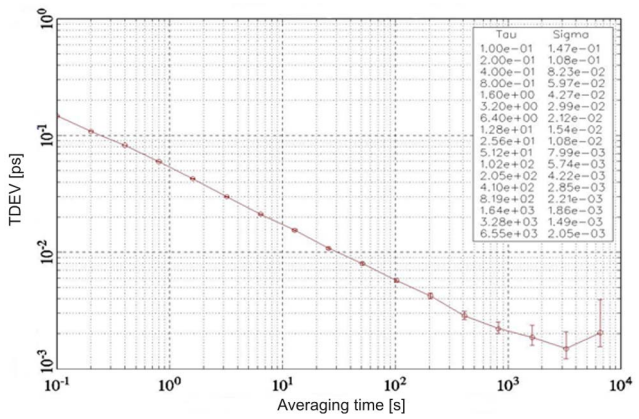

Figure 6. Operating the device in a common laboratory environment, the TDEV better than 4 fs was routinely achieved for averaging times from 300 s to 3000 s. The instability can be considered as a white phase noise for averaging times up to ~1000 s.

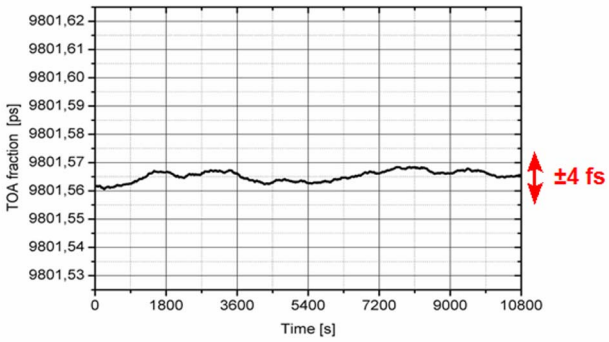

Figure 7. The 256 s moving average of the TOAs did not leave the ± 4 fs range within the period of 3 hours.

III. EXPERIMENTS

Two timing devices described above have been used in an experiment in which the frequencies of two H-masers were compared. The experiment was performed in the underground time and frequency laboratory at the Geodetic Observatory Wettzell, Germany. The experimental setup is in Fig. 8. There are from left to right the hydrogen maser EFOS SN 60, the data acquisition PC #1, the NPET timing device (channels #1 and #2), frequency multiplier #1, and the data acquisition PC#2. The other maser EFOS SN 39 and the frequency multiplier #2 were located in the next room.

At first both the timing devices were connected to the same frequency reference (H-maser SN 39 and frequency multiplier #1) according to the block scheme in Fig. 9a. The aim of this measurement was to prove the jitter and time stability of the experimental setup including the cables. The jitter was on the expected level of 800 fs RMS. The resulting TDEV is in Fig. 10.

Figure 8. The experimental setup. There are from left to right the hydrogen maser EFOS SN 60, the data acquisition PC #1, the NPET timing device (channels #1 and #2), the frequency multiplier #1, and the data acquisition PC#2. The other maser EFOS SN 39 and frequency multiplier #2 were located in the next room.

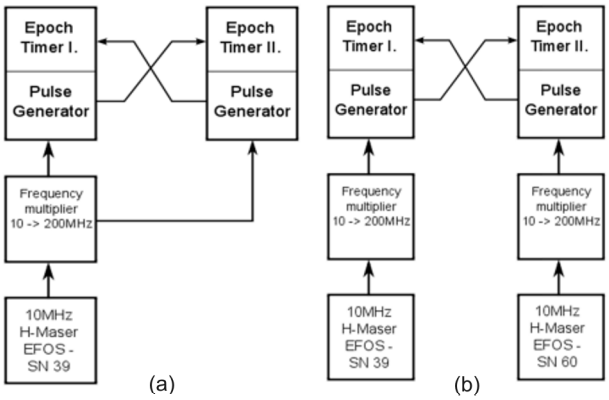

Figure 9. The block scheme for the first measurement (a) when both the timing devices were connected to the same frequency reference and the second measurement (b) when each timing device was connected to another H-maser.

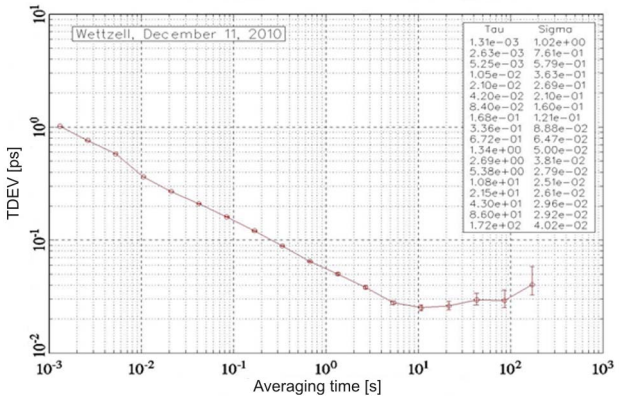

Figure 10. The resulting TDEV of the experimental setup when both the timing devices were connected to the same frequency reference.

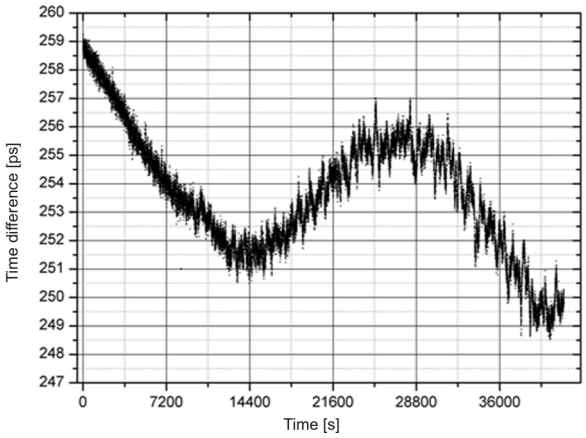

Figure 11. The record of the phase difference between two H-masers.

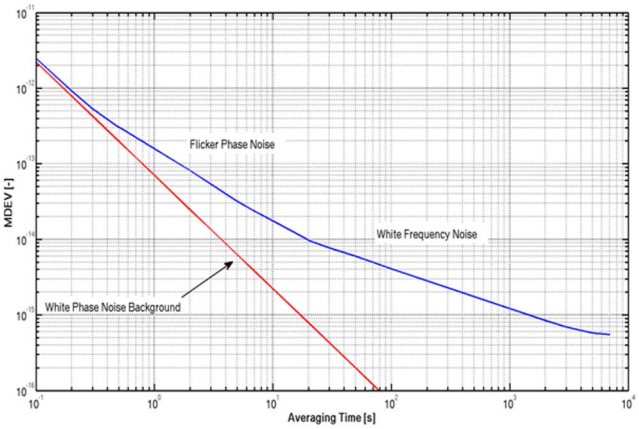

Figure 12. The evaluated MDEV of the phase difference between two H-masers. The red line represents the white phase noise background caused by the timing device. It is negligible for averaging times greater than ~400 ms. For longer averaging times the MDEV follows the slopes of flicker phase noise and white frequency noise as expect

After that each timing device was connected to another frequency reference according to the block scheme in Fig. 9b and the phase difference between the H-masers was measured. The resulting record of the phase difference is in Fig. 11 and the evaluated MDEV is in Fig. 12. The white phase noise background caused by the timing device (red line) was computed from the results of the previous measurement. It is negligible for averaging times greater than ~400 ms. For longer averaging times the MDEV follows the slopes of flicker phase noise and white frequency noise as expected [6].

IV. Conclusion

Two timing devices of a novel concept have been used in a timing experiment in which the frequency outputs of two H-masers were compared. The experiment proofed that one of possible applications of the timing device is a comparison of high performance low-noise frequency sources and measurement of their frequency stability in the time-domain for a wide range of averaging intervals. The noise background of the timing system was negligible for averaging intervals on the order of 100 ms and longer. The excellent timing precision near 800 fs RMS and stability well below 10 fs of the novel principle timing system has been demonstrated.

Abstract- *The paper proposes a digital compensation by imposing real-time compensation voltage to Vin Pin of VCOXCO while device vibrating. The embedded digital compensating circuit includes a MEMS three-axes acceleration sensor, a FPGA and a D/A converter. G-sensitivity vector can be computed based on the MEMS sensor. A proportion digital compensation model is built to generate voltage which can compensate frequency drift and perturbation caused by acceleration.*

□. INTRODUCTION

Quartz crystal oscillator is sensitive to temperature and acceleration[1]. OCXO can maintain temperature stable to increase stability of output frequency, so OCXO is widely applied at precise equipment. Most OCXO are VCOCXO whose frequency can be adjusted from 10^{-7} to 10^{-5} by controlling voltage. OCXO is sensitive to acceleration which causes equipment performance deterioration at moving applications. The range of typical g-sensitivities spans from 1×10^{-10} Hz/g for precision SC cut to greater than 1×10^{-7} Hz/g for a low cost AT cut.

At present, to decrease g sensitivity, the way used most is mechanic cushion which is useful only to high frequency vibration. It can't operate effectively when the device suffers low frequency vibration or continual g movement. Additionally, mechanic cushion increases the volume and weight of devices, which is harmful to miniature devices.

Gagnepain uses two resonators in series electrically and reverses parallel connection mechanically, so g sensitivity was counteracted[2]. Owing to lack of repeatability in the acceleration sensitivity, it's difficult to make alignment. Greenray corp manufactures dual-resonator oscillators using AT-strip quartz whose g sensitivity is repeatable in both magnitude and direction, so the g sensitivity can be below 1×10-11.[3]

Przyjemski[4] and Emmons[5] used an accelerometer aligned with the g sensitivity direction. The accelerometer signal was fed into a tune circuit to decrease g sensitivity. As the circuit was analog, it's hard to be linear at all point. Some scholars[6] proposed three accelerometers mounting with the oscillator and aligned on mutually perpendicular axes and a DSP was applied to generate compensation voltage to VCOCXO. But it was complicated to install three accelerometers and it would take some time for DSP to compute and generate compensation value.

This paper proposes real time digital compensation based on FPGA process. A MEMS three axes acceleration sensor whose package is less than 3mm×3mm×0.9mm is applied to get the acceleration vector. A FPGA is employed which can realize computation in one clock period. Because of the integration and miniaturization of digital device, the whole compensation system is flexible, low-cost and easy to be applied.

Ⅱ. PRINCIPLE OF DIGITAL COMPENSATION

The research is carried out on the basis of Voltage Controlled OCXO for several reasons. First, the temperature of OCXO is stable so temperature sensitivity can be substantially reduced. Second, with the big dimension, digital controller can be embedded into OCXO. At last it's easy to realize the compensation by adjusting the "Vin" pin of VCOCXO. So little change is needed to be made to the original OCXO.

A. Frequency domain analysis

When sinusoidal vibration is imposed on OCXO, there will be vibration-induced sideband in the carrier, the ratio of the power can be denoted as follows[1]:

$$L_V^n(dBc) = 20\log(J_n(\beta)/J_0(\beta)) \tag{1}$$

Where $J_n(\beta)$ is the Bessel function of nth sideband.

$$\beta = \Delta f / f_V = (\vec{\Gamma}\cdot\vec{A}) f_0 / f_v \tag{2}$$

is the modulation index.

Where f_0 : output frequency of resonator; f_v : vibration frequency; $\vec{\Gamma}$ is g sensitivity vector and $\vec{A}$ is acceleration g vector.

Several approximations can be made if $\beta < 0.1$. The approximation is

$$J_0(\beta) = 1, \quad J_1(\beta) = \beta / 2, \quad J_n(\beta) = 0 , \text{ so}$$

$$L_v^1(\beta) \approx 20 * \log((\vec{\Gamma} \cdot \vec{A}) f_0 / (2 f_v)) \tag{3}$$

B. Building acceleration sensitivity vector model

When acceleration exists, the quartz resonator will generate stress which would corrupt its RF outputs. The package type of resonator would also affect g-sensitivity. Resonators would be distorted when large-scale g, which causes non-linear g-sensitivity, is imposed on.

The direction of g-sensitivity vector was fixed for each OCXO. A MEMS three dimension g sensor was installed at the package of OCXO to sense the acceleration. Supposing that axes of g sensor was x,y,z and g sensitivity angle of each axis was $\varphi_x, \varphi_y, \varphi_z$, it's shown as Fig.1.

The value of g sensitivity vector can be described as

$$a_m = a_x \cdot \cos\varphi_x + a_y \cdot \cos\varphi_y + a_z \cdot \cos\varphi_z \tag{4}$$

a_x, a_y, a_z was measured by sensor, so if $\varphi_x, \varphi_y, \varphi_z$ were known, a_m could be computed.

If the vibration was imposed only along one axis, g sensitivity would be only caused by one axis. Supposed that vibration was imposed on x axis, so

$$a_m = a_x \cdot \cos\varphi_x = \vec{A} \tag{5}$$

We imposed sinusoid vibration at fixed frequency, so from equation (2),(3) we could get

$$\cos\varphi_x = \vec{A} / a_x = 10^{L_v^1(\beta)/20} \cdot 2 f_v / (f_0 \cdot k_a) \tag{6}$$

Where g-sensitivity coefficient is k_a .

By using this method, $\cos\varphi_x, \cos\varphi_y, \cos\varphi_z$ could be obtained. Fig.2 shows g-sensitivity test platform. We impose sine wave vibration upon one axis. Output of resonator was multiplied to increase the acceleration effect. The ratio power $L_v^1(\beta)$ could be provided by a spectrum analyzer.

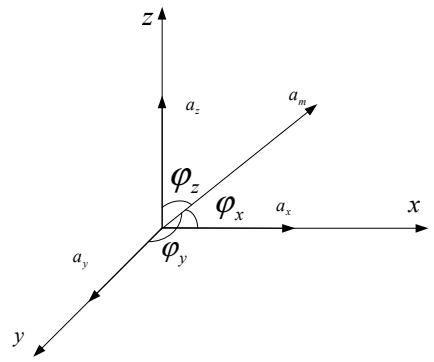

Figure 1. G-sensitivity vector with three axes of sensor

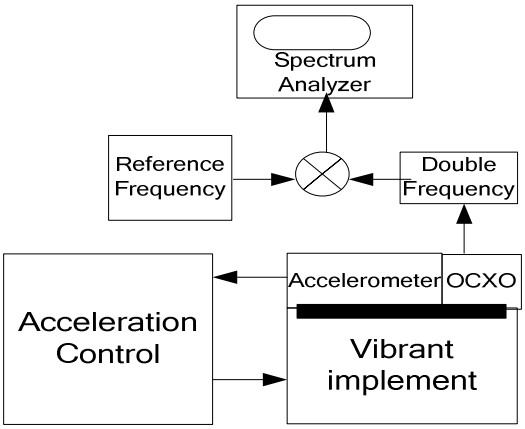

Figure 2. G-sensitivity test platform

C. Proportion digital real-time compensation

Supposed that voltage control coefficient was k_v (Hz/v), g-sensitivity coefficient was k_a and the real-time generated compensation voltage was

$$\Delta v = k_p \cdot \frac{k_a \cdot a_m}{k_v} \tag{7}$$

Where k_p was proportion coefficient which would determine the compensation effect.

The algorithm diagram is shown in Fig.3. Fig.4 shows the compensation result. f_{v1} is frequency drift caused by acceleration, f_{v2} is frequency drift caused by imposed voltage Δv which counteracts f_{v1} . f_{vc1} is frequency drift after compensation which is much less than itself before compensation.

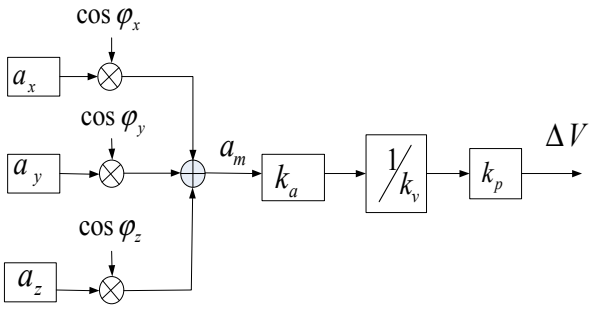

Figure 3. Algorithm diagram

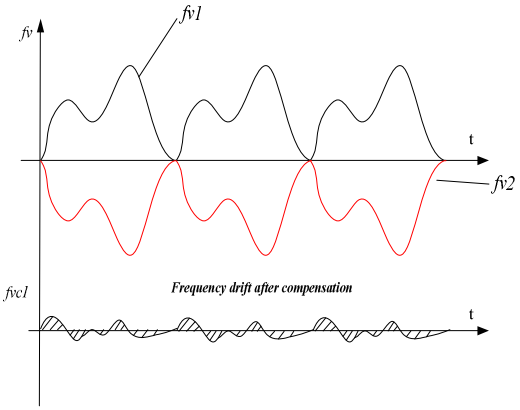

Figure 4. Frequency drift after compensation

D. Time delay effect

Suppose that a time delay Δt exists at compensation for it costs time to sense and compensate. If sinusoidal wave vibration is imposed, the RF output after compensation can be described as follows

$$V(t) = V_0 \cos(2\pi f_0 t + (f_0 \cdot \vec{\Gamma} \cdot \vec{A} / f_v) \sin 2\pi f_v t - (f_0 \cdot k_v \cdot \Delta v / f_v) \sin 2\pi f_v (t - \Delta t)) \quad (8)$$

When there is an ideal compensation, $k_v \cdot \Delta v = \vec{\Gamma} \cdot \vec{A}$, so

$$V(t) = V_0 \cos(2\pi f_0 t + (f_0 \cdot \vec{\Gamma} \cdot \vec{A} / f_v)(\sin 2\pi f_v t - \sin 2\pi f_v (t - \Delta t))) \quad (9)$$

III. DIGITAL COMPENSATION SYSTEM DESIGN

For acceleration device experience varies with high amplitude, it is hard to maintain linear in any work state when analog circuit is employed. What is more, it is hard to compute the sensitivity vector with analog circuit.

We designed digital compensation circuit based on FPGA circuit shown as Fig.5. A MEMS triaxial sensor was applied which could output three axes acceleration values and a FPGA with 45nm low-power copper process technology is also employed. FPGA got the value from sensor by SPI interface. A serial D/A converter was applied to generate the compensation voltage. Dc-dc converter and voltage regulating module provided necessary voltage for FPGA. The board size of digital circuit was designed based on OCXO, so it could be installed just on the pin of OCXO shown as Fig.6. Furthermore, the total circuit could be embedded in the OCXO, which made it easy being widely applied.

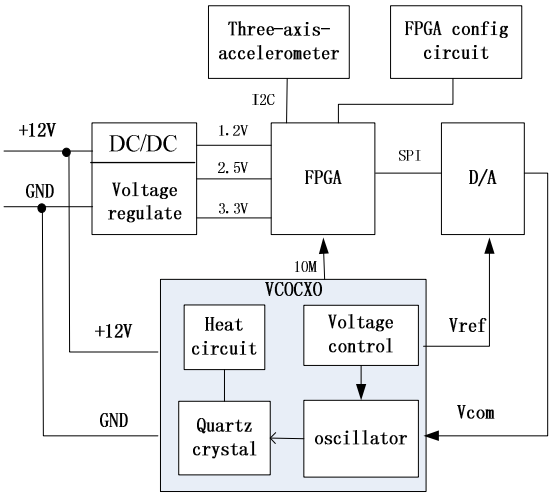

Figure 5. Digital compensation scheme

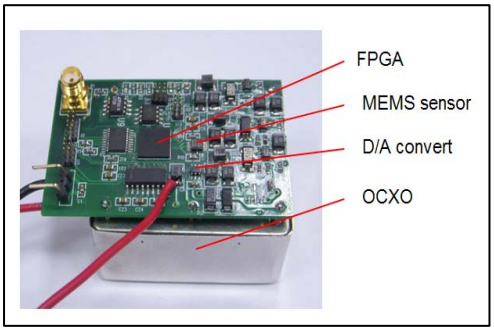

Figure 6. Experiment prototype

IV. EXPERIMENT

An embodiment of proposed compensation circuit is designed which consists of a MEMS acceleration sensor, a FPGA system and a 12 bit D/A converter. The parameter of OCXO can be described as follow: $f_0 = 10MHz$, $k_g = 5.06 \times 10^{-9}$, $k_v = 8 \times 10^{-8}$. With the 12bit D/A, the frequency controlling resolution is $k_v / 4096 = 1.95 \times 10^{-11}$ which is much less than k_g.

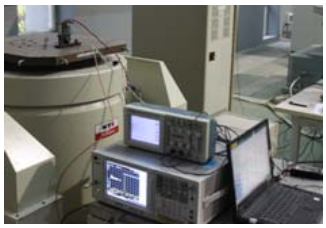
And experiment platform is also built. It includes:

1) DC power supply;
2) digital storage oscilloscope TDS1012;

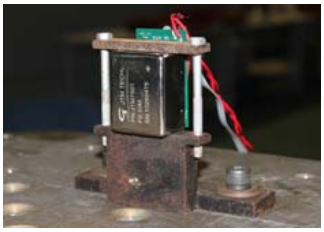
3) Spectrum Analyzer E4443A;

4) vibration controlling system;

The experiment environment is shown in Fig.7(a). The OCXO is installed on the platform of vibration system as shown in Fig.7(b). Compensation delay is 7.5us.



(a) Experiment platform

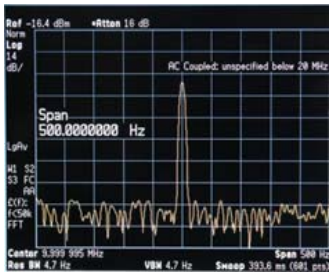


(b) OCXO fixed by clamp

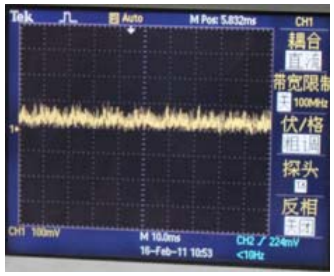
Figure 7. Experiment environment

The output spectrum of OCXO at rest is shown in Fig.8(a). Then 15Hz 4g sine wave vibration is imposed and output spectrum is shown in Fig.8(c). Fig.8(b) shows the compensation voltage and Fig.8(d) shows the output spectrum after compensation while kp=4. We can see 11.9dB attenuation is gotten. Then 30Hz, 300Hz experiments were also carried out. From recorded data we can see that g sensitivity is much decreased after compensation.

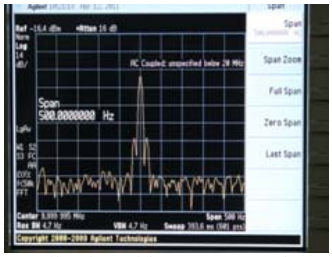
We can see from Tab.1 that the digital compensation gets good result when low frequency vibration is imposed. But it is less effective when high frequency vibration is imposed. The reason is that delay may cause this problem.



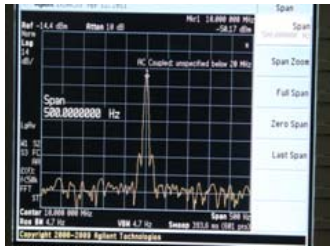
(a) Output at rest



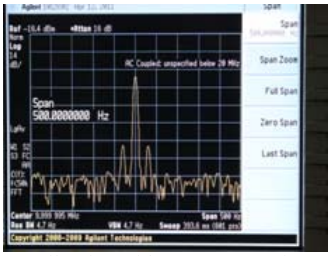
(b) Compensation voltage



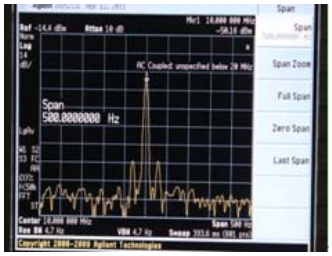
(c)Vibration without compensation Gmax=4g, f=15Hz



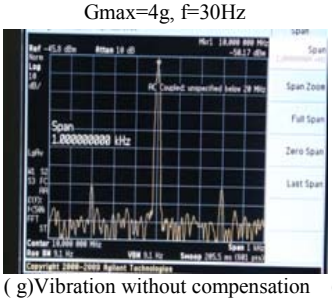
(d) Vibration with compensation kp=4 Gmax=4g, f=15Hz



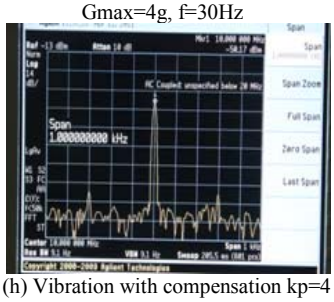
(e)Vibration without compensation Gmax=4g, f=30Hz



(f) Vibration with compensation kp=4 Gmax=4g, f=30Hz



(g)Vibration without compensation Gmax=6g, f=300Hz



(h) Vibration with compensation kp=4 Gmax=6g, f=300Hz

Figure 8. Experiment result

TABLE I. COMPARISON AFTER COMPENSATION

$g_{\max}$ *(g)*	f_v *(Hz)*	$L_v^1(\beta)$ *(dB)*	$L_v^1(\beta)$ *(dB) With compensation*
4g	15	-47.6	-59.5
4g	30	-54.6	-60.2
6g	300	-66.2	-71.5

V CONCLUSION

A new acceleration compensation technique which can substantially reduce the acceleration sensitivity with low cost is proposed. The total cost of digital circuit is less than $20 and the compensation makes very little change to OCXO. It is easy to realize digital compensation for VCOCXO. The method has good future for high accuracy OCXO.

***Abstract*—In this paper, we demonstrate synchronization of two electrically coupled MEMS oscillators incorporating nearly identical silicon tuning fork microresonators. It is seen that as the output of the oscillators are coupled, they exhibit a synchronized response wherein the output amplitudes and signal-to-noise ratios of the two oscillators are improved relative to the case where the two oscillators are uncoupled. The observed output frequency of each oscillator before coupling is 219402.4 Hz and 219403.6 Hz respectively. In contrast, when the oscillators are driven simultaneously, they lock at a common output frequency of 219401.3 Hz and their outputs are found to be out-of-phase with respect to each other. A 6 dBm gain in output power and a reduction in the phase fluctuations of the output signal are observed for the coupled oscillators compared to the case when the oscillators are uncoupled.**

I. INTRODUCTION

Over the last two decades, advancements in design, fabrication and packaging of silicon MEMS oscillators have resulted in their commercialization with the potential to replace quartz crystal oscillators from certain market sectors due to their smaller sizes, scalability to VHF-UHF frequencies and the potential for integration with CMOS electronics. However, MEMS oscillators are currently limited in their noise performance and output power capabilities, in part due to their smaller dimensions and the associated onset of non-linear self-limiting behaviour at relatively modest oscillation amplitudes.

Several methods have been previously employed to address these limitations. Of these, perhaps the most notable is the effort to enhance the noise performance of silicon MEMS oscillators by increasing the output power using array-coupled silicon microresonators [1]. In this work, an array of nine identically designed mechanically coupled wine-glass disk resonators operating in a combined resonant mode were embedded in an oscillator feedback loop to enhance the output motional current, thereby improving the phase noise performance. While it can be inferred from their results that the use of multiple resonators, enhances the oscillator response relative to the typical use of a single resonator, the use of multiple resonators also changes the modal dynamics, as each resonator adds an additional degree of freedom, making the system more susceptible to excitation of spurious modes. Moreover, electrostatic transduction of the resonator array in order to excite a particular combined vibration mode for an array coupled system can impose constraints on transducer geometry and routing interconnect as well as increase the effects of capacitive feedthrough parasitics.

Various noise sources with electrical, mechanical and environmental origins result in amplitude and phase fluctuations in the output of the MEMS oscillator [2]. Phase fluctuations are accumulated over time and are of particular interest in timing and frequency control applications [3]. In an attempt to address the phase stability of MEMS oscillators, we propose the utilization of the phenomenon of synchronization wherein synchronized oscillators lock at a common output frequency and a constant relative phase difference.

One of the first observations of synchronization was reported by the Dutch researcher Christiaan Huygens in the 17^{th} century. He observed that when two symmetric pendulum clocks were suspended from a common frame, they began to oscillate at a common frequency and out-of-phase with respect to each other due to the weak coupling that caused by the imperceptible motion of the frame [4].

More recently, Bennett *et al.* re-examined the phenomenon using two symmetric pendulum clocks and showed that the onset of synchronization was related to the extent of mismatch of their uncoupled oscillation frequencies and the strength of coupling between them [5]. The oscillation frequency for a MEMS oscillator is determined by the resonating element which is a MEMS resonator in our case. Tolerances in fabrication processes often result in variations in the dimensions of the resonator and in their material properties. Due to these variations, the nominal resonant frequencies across identically designed resonators are usually different. MEMS resonators can be coupled by mechanical or electrical methods [6]. As opposed to mechanical resonators in more conventional technologies, electrical coupling of MEMS resonators can be implemented by parallel-plate capacitive coupling elements that can be readily implemented in a standard micromachining process. In this work, the synchronization of two electrically coupled silicon MEMS oscillators is demonstrated.

II. Device Description And Operation

A. Device Configuration

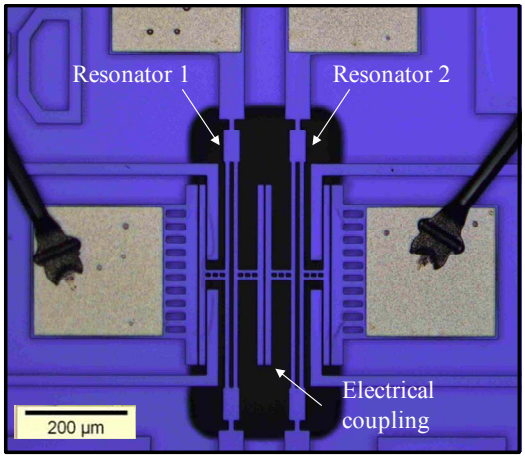

Figure 1. Optical micrograph of electrically coupled DETF resonators.

Fig. 1 shows an optical micrograph of two electrically coupled identically designed silicon double-ended-turning-fork (DETF) resonators [6]. The device is fabricated in a commercial foundry process using the silicon-on-insulator MEMS process through MEMSCAP Inc., USA. The two resonators are separated by a coupling gap as can be seen in Fig. 1. In this device, each tine is 350 µm long, 7 µm wide and 25 µm thick. Additional parallel plates are added at the point of maximum displacement to ensure uniform electrostatic actuation of the fundamental vibration mode. Each added electrode is 280 µm long, 10 µm wide and 25 µm thick. All the actuation gaps in both the resonators are 2 µm including the coupling gap. The out-of-phase normal mode of the resonator is of interest, as it offers a higher quality factor compared to the in-phase normal mode, due to the cancellation of stress at the anchor points. It is to be noted that any potential difference across the coupling gap generates an attractive electrostatic force which is displacement dependent and results in a negative mechanical spring like behaviour. The electrostatic coupling force (F_c) between two resonators can be determined by:

$$F_c = -\frac{\varepsilon_o A}{d^2}(V_{DC1} - V_{DC2})^2 \qquad (1)$$

Here V_{DC1} and V_{DC2} are the *DC* bias applied to each of the resonators. A is the actuation area, d is actuation gap and ε_o is permittivity of free space. It can be deduced from equation (1) that the change in potential difference across these resonators results in a modified coupling force.

B. Device Characterization

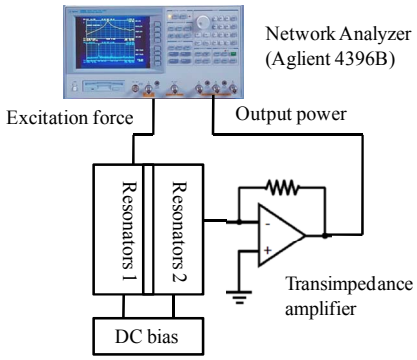

Figure 2. Schematic representation of open loop measurement setup for silicon DETF MEMS resonators.

A schematic representation of the measurement setup for open-loop experiments is shown in Fig. 2. The device is tested in a custom vacuum chamber at a pressure of ≈50 mtorr. Two-port electrostatic transduction is employed to detect the motion of the resonators. An *AC* excitation force is applied to the network analyzer to drive the resonators while *DC* bias is used to detect the motional current. The output motional current is amplified and converted to a voltage by a transimpedance amplifier and then sent to the network analyzer.

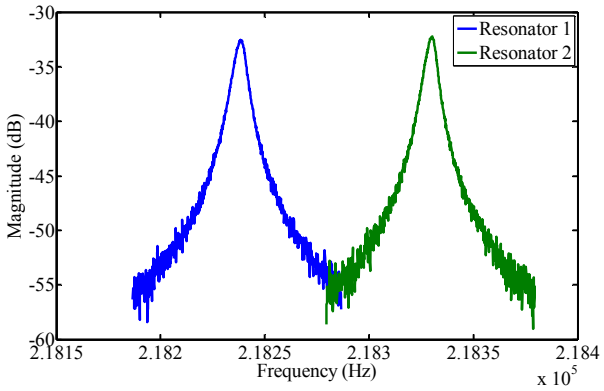

Figure 3. Open loop response of uncoupled DETF MEMS resonators.

The result of the measurements for the uncoupled response after feedthrough cancellation is shown in Figure 3. The feedthrough component is obtained by applying 0 V potential difference across the actuation gap. The quality factor and resonance frequency for each resonator are 31177, 32956 and 218238.3 Hz, 218330.0 Hz respectively. These values are determined by a nyquist circle fit to the measurements of the uncoupled response. Although, the resonators are designed to be identical, fabrication tolerances result in variations in dimensions and material properties, consequently leading to deviations in the resonance frequencies for identically

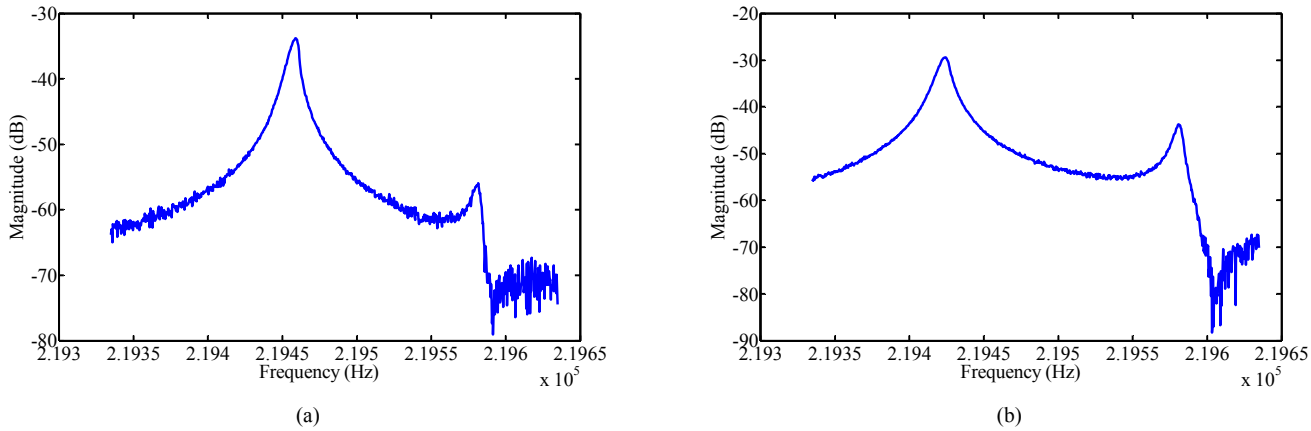

Figure 4. Open loop response of coupled DETF MEMS resonators observed at resonator 1 under two different conditions of electrical coupling (a) 4 V potential difference across the coupling gap (b) 8 V potential difference across the coupling gap.

TABLE I. SUMMARY OF EMPIRICAL RESULTS

Oscillator	**Frequency (Hz)**	**Output power (dBm)**	**Phase ratio (degrees)**	
			Mean	***Standard deviation***
Uncoupled Oscillator 1	219402.4	-55.6	169.4	41.4
Uncoupled Oscillator 2	219403.6	-57.6	156.5	54.9
Coupled Oscillator 1	219401.3	-50.8	180.4	18.2
Coupled Oscillator 2	219401.3	-50.9	178.8	20.4

designed structures.

The coupled response of the resonators is shown in Fig. 4(a) and (b) for two different coupling forces. In first case, the potential difference across the coupling gap is 4 V while it is 8 V in the second case. The coupled response is observed at resonator 1. The lower frequency mode is found to be out-of-phase normal mode which occurs first, due to the negative value of the electrical coupling spring.

III. IMPLEMENTATION OF ELECTRICALLY COUPLED OSCILLATORS

Fig. 5 illustrates the block diagram representation for the coupled MEMS oscillators. The two DETF resonators are embedded within the feedback loop of two distinct oscillator circuits. Each oscillator comprises a transimpedance amplifier for converting the motional current to a voltage and to meet the loop gain requirement for sustained oscillation. This block is followed by a band pass filter which removes unwanted normal modes. The filter output is then fed to a comparator. The comparator acts as a hard voltage limiter and limits the effect of amplitude fluctuations in the feedback signal. For both oscillators, output signals are observed at the output of the transimpedance amplifier as shown in Fig. 5. The response of the above configuration is compared for four different cases and the results are tabulated in Table I.

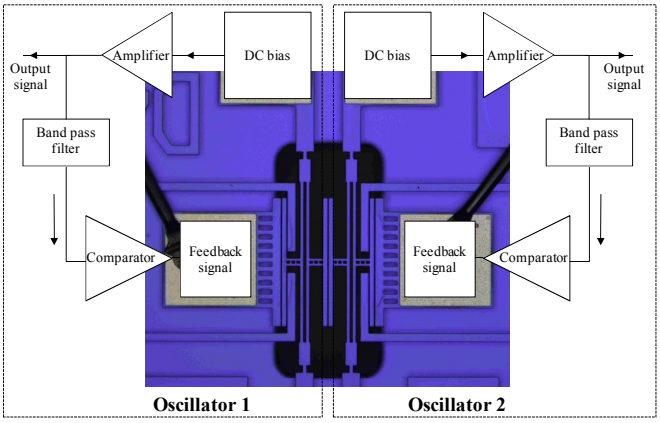

Figure 5. Schematic description of electrically coupled MEMS oscillators.

The first two cases are when both the oscillators are uncoupled (operated independently) and the next two cases when both are coupled (operated simultaneously). The observed output frequencies for oscillators 1 and 2 when operated independently, are 219402.4 Hz and 219403.6 Hz. When operated simultaneously, the oscillators lock at a common oscillating frequency of 219401.3 Hz as shown in Fig. 6(a) and (b) respectively.

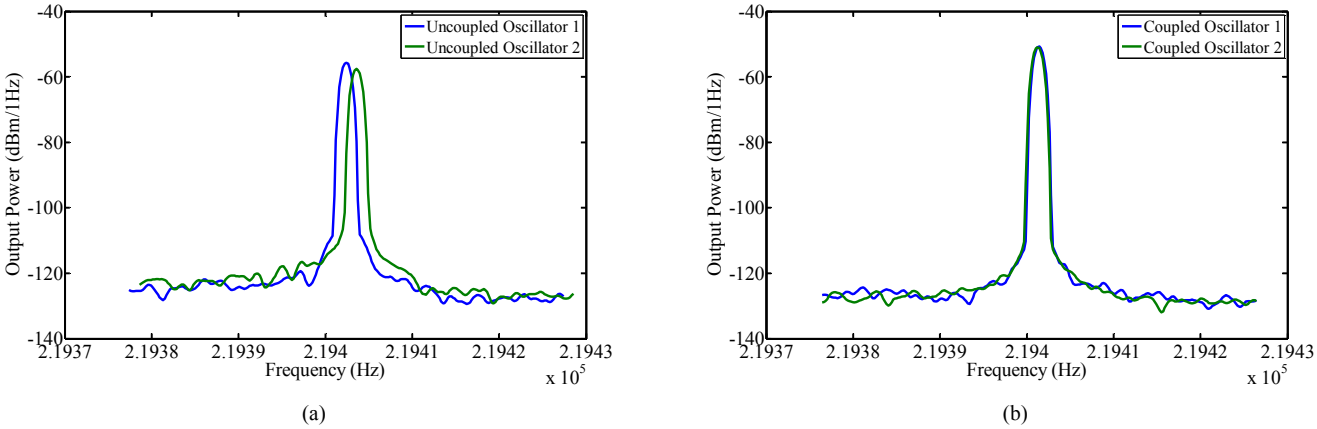

Figure 6. Output response of the MEMS oscillators compared before and after capacitive coupling (a) oscillators are uncoupled (b) oscillators are coupled.

In order to compare the oscillator response for uncoupled and coupled cases, a frequency normalized plot for oscillator 2 is shown in Fig. 7. A 6 dBm gain in the output power and a clear reduction in noise floor can be observed for the case when the oscillators are coupled relative to the case when the two oscillators are uncoupled. Both oscillators describe the same general behaviour.

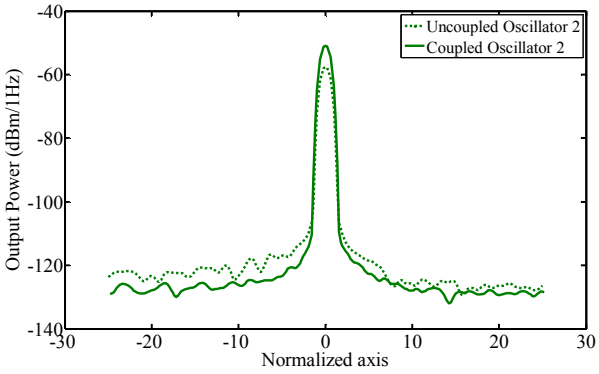

Figure 7. Frequency normalized response of oscillator 2 for uncoupled and coupled cases.

Table I summarizes the empirical results for the uncoupled and coupled MEMS oscillators. The phase ratio describes the relative phase of oscillator 1 with respect to oscillator 2. These measurements are done using a frequency counter (Agilent 53230A) at a sampling rate of 0.5 sec for a total measurement time of 250 sec. For each case, the mean and standard deviation of the data are provided. From Table I, it can be seen that the coupled MEMS oscillators are oscillating with the same frequency. Moreover, the phase difference between the coupled oscillators is found to be approximately 180^{o} demonstrating locking to a common oscillation frequency with a constant phase difference. Moreover, the relative phase fluctuation is clearly reduced when the oscillators are coupled as compared to the case when the oscillators are uncoupled.

Measurements of phase noise and long-term oscillator stability before and after coupling are ongoing.

IV. Conclusion

We propose the use of synchronization to enhance output signal power and enhance the signal-to-noise performance for coupled MEMS oscillators. The synchronized response of two coupled MEMS oscillators is demonstrated wherein the output amplitudes and signal-to-noise ratios of the coupled oscillators are clearly enhanced relative to the case before coupling. In addition, a reduction in relative phase fluctuations is observed for two coupled MEMS oscillators with the two oscillators locking 180^{o} out of phase. These initial results are promising and demonstrate that the phenomenon of synchronization can be extended to coupled MEMS oscillators resulting in improvements in oscillator noise performance. Future work includes more detailed investigations of noise and long-term stability in synchronized MEMS oscillators.

***Abstract*—Opto-electronic oscillators (OEOs) are based on a long optical fiber that acts as a high *Q* cavity. However, a long fiber is sensitive to the temperature fluctuation. The aim of this paper is to study the possibility of stabilizing the OEO cavity by employing the technology of radio frequency transfer over fiber links. We propose a scheme of a dual-loop OEO with a probe signal and experimentally demonstrate that the probe signal is useful for monitoring the fiber delay without observable interference. This paper will simulate the adjusting of the OEO optical cavity by a variable optical delay module and discuss its best long-term stability.**

I. INTRODUCTION

Ultra-stable frequency transfer over an optical fiber has been a state of art technology in the recent years [1]-[3]. By compensating the delay variation according to the phase information of the round-trip signal, a very stable optical delay line could be obtained. A radio frequency (RF) transfer using amplitude modulation of the laser carrier has demonstrated a frequency stability of the 10^{-15} level at 1-s averaging time and below 10^{-18} at 1 day [4].

An ultra-stable optical delay line is vey important component for many kinds of optical systems, such as the optoelectronic oscillator (OEO). This oscillator, based on optical fibers to act as a high quality factor (*Q*) cavity, is capable of generating radio-frequencies with very high spectral purity [5]. Very low phase noise of variant OEO architectures have been demonstrated, such as the dual-loop OEO [6][7], coupled OEO [8], and OEOs with photonic resonator-based filters [9]. However, the long-term instability of OEO is still a challenge due to its sensitive to the surrounding temperature variations. It is still a challenge for OEO to reach a good long-term frequency stability without a thermally stabilized chamber [10].

The aim of the paper is to study whether the technologies of RF frequency transfer can be adequate for stabilizing the optical fiber loop of OEO. We experimentally demonstrate the use of a probe signal for monitoring the fiber delay and evaluate the performance of OEO with stabilizing its delay.

II. BACKGROUND

There are two fiber paths with different time delays in the dual-loop OEO as illustrated in [6]. If we assume the delay of the long fiber loop is τ_1, and that of the short fiber loop is τ_2, the oscillation frequency is given by

$$f_o = \frac{m}{\tau_1} = \frac{k}{\tau_2}, \tag{1}$$

where *m* and *k* are integers. The mode spacing of the OEO is then determined by the short loop delay τ_2, and the phase noise is determined by the long loop delay τ_1. This leads to the oscillation signal having narrow spectral linewidth with the suppressed unwanted modes. Because of the frequency pulling effect between a narrow spectral width of the long loop and a broader one of the short loop, a small tuning of oscillation frequency is chiefly determined by the long loop delay variations unless a frequency hopping happens [6][11].

If the long loop delay varies $\Delta\tau_1$, the oscillator frequency is then tuned by an amount Δf_o, and the relation is expressed as

$$\frac{\Delta f_o}{f_o} = \frac{-\Delta\tau_1}{\tau_1}. \tag{2}$$

The frequency stability is then negatively related to the stability of long loop delay. If there is a possible to monitor the loop delay, one can stabilize the fiber delay by the techniques of RF frequency transfer. An approach to precisely monitoring the long fiber delay is demonstrated as follows.

III. Experimental Setup

Fig. 1 shows the scheme of a dual-loop OEO with a probe signal. These devices are commonly available in time keeping institutes for the purpose of time and frequency transfer. In order to add a probe signal, a RF coupler is used in front of the optical modulation. Our light source is a 1310 nm single-mode laser. After the direct modulation, the optical signal is divided into two loops by a 50/50 optical coupler. The longer one is a 10 km spool of standard single-mode fiber (SMF), and the short one is a 30 m SMF pigtail. An additional RF power splitter, followed after the photodetector of the long fiber, provides the output port of the probe signal. Since the loss of the short fiber is much small than the long one, the additional attenuator is essential to balance the loop gains. After combining the signals from these two loops, two cascaded RF amplifiers provide a high gain to compensate the loss of components for reaching the oscillation condition. A RF band-pass filter, having a 4 MHz bandwidth centered at 70 MHz, selects an oscillation around the intermediate frequency. Finally, a half of the RF power is taken off by a power splitter and used as an OEO output. The other part of RF signal is combined with the probe tone and sent back to form the feedback loops. The output is measured by a spectrum analyzer and a frequency counter (SR 620).

A pseudo-random noise (PRN) encoded signal is employed to monitor the long fiber loop delay of the OEO. The PRN signal is based on the spread-spectrum techniques, resulting in a signal with a wider bandwidth and a lower spectral power density. The probe signal is generated by a modem (TimeTech SATRE), usually used for two-way satellite time and frequency transfer (TWSTFT) [12]. The modem acts as a time interval counter to measure the propagation time when the probe signal passing through the long fiber and returning back to the modem.

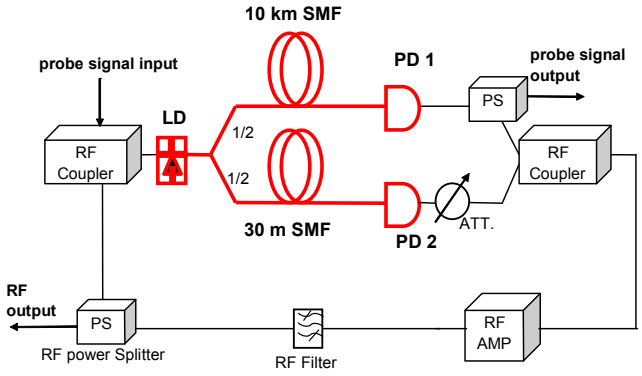

Figure 1. Experimental setup. LD: direct modulation laser diode; PD: photo detector; ATT: variable power attenuator; SMF: single mode fiber.

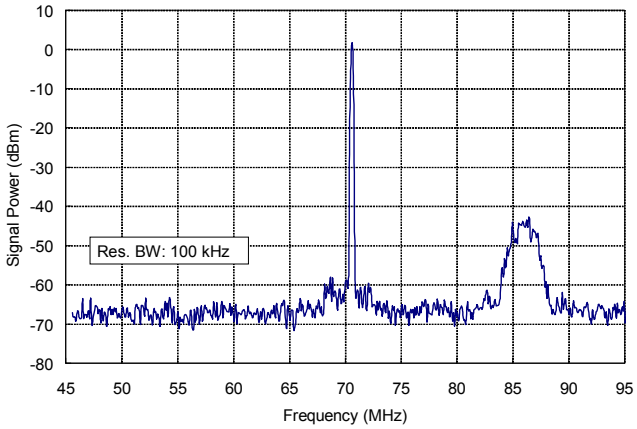

Figure 2. RF spectrum of OEO tone at 70.6 MHz and probe signal centered at 86 MHz.

To avoid the interference between the oscillation and the probe signal, the frequency of the probe signal should lie outside of the bandwidth of the band-pass filter, and far away the oscillation frequency. Moreover, its power intensity must be much lower than that of the oscillation to avoid the beats between them. However, the probe signal should maintain its carrier-to-noise ratio for the monitoring precision. Fig. 2 shows the spectrum of the RF output. The oscillation frequency is at 70.6 MHz with a peak power of 1.7 dBm. The center frequency of the probe signal is placed at 86 MHz, which is 15.4 MHz far from the oscillation. While the chip rate of the probe signal is 2.5 MHz, the actual bandwidth larger than -60 dBm is 4 MHz. The peak power occurred near the 86 MHz is -42.3 dBm, which is about 44 dB lower than the oscillation signal. The carrier-to-noise ratio of the received probe signal reaches 69 dB/Hz. In the observation of the frequency counter, the existence of this probe does not affect the stability for the period larger than 1 s. In addition, the probe signal can be easily eliminated by an additional filter following the RF output.

IV. Results

For focusing on the long term behavior, the frequency measurements were recorded every second by counter, and there was no frequency hopping during our observation. Meanwhile, the delay of the long fiber was monitored every second by the probe signal from a modem. To reduce the short-term measurement noise of the monitored data, we used the 600-s moving averages of the monitored data to represent the delay of the fiber in this study. Fig. 3 shows the measured frequency variation and the negative value of the monitored delay variation. It is clear that the frequency varied with the delay variation.

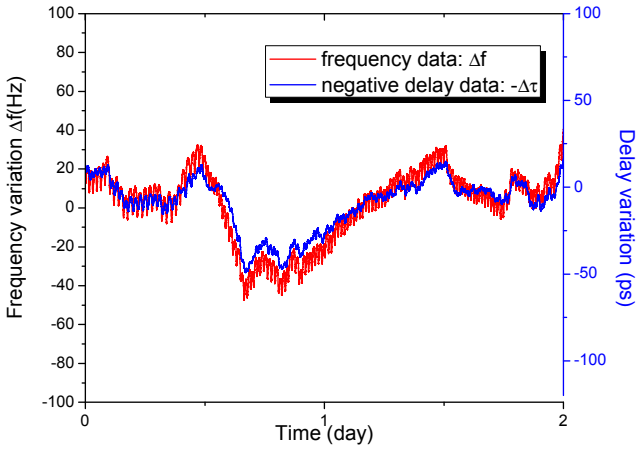

Figure 3. Frequency variation of the OEO versus the negative delay data of the long fiber loop.

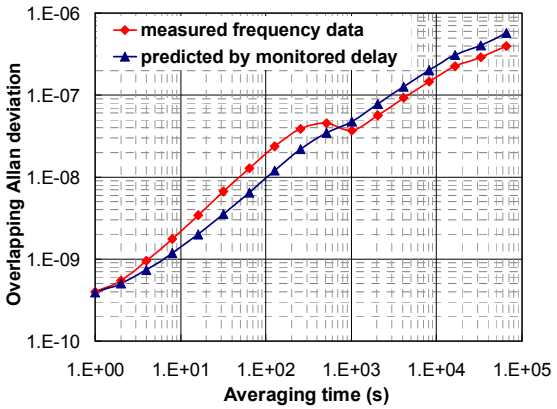

Figure 4. Measured and predicted Allan deviation of the OEO.

Fig. 4 shows the Allan deviation results. The measured frequency fluctuation is represented by red line. The frequency stability is 3.9×10^{-10} at a 1-s averaging time. Due to the thermal drift, the curve has no descending or flat part, and ascends to 10^{-7} after 4000-s averaging times. The other blue curve is the predicted results according to the delay data. As the relationship described by (2), we treated the negative fractional delay fluctuation (i.e. $-\Delta\tau/\tau$) as the fractional frequency data, and calculated their frequency stability. These two curves have the same tendency and were tied to a similar level. This means that the predicted results are in certain agreement with the measured frequency data. Nevertheless, the measured data in the short term were a little worse than the predicted one because the delay of the non-monitored filter rapidly responded to the temperature fluctuation. However, for the long term (τ > 700 s), the stability of the measured frequency is lower than the predicted value.

V. Performance Evaluation of Active Tuning

According to the monitored fiber delay data, we are able to stabilize the fiber delay by compensating its variation. To carry out the active optical compensation, the long fiber delay would be controlled by inserting an available fiber device, such like a motorized variable optical delay line and a piezoelectric fiber stretcher. Based on the specification of commercial devices, we simulated the delay of active tuning fiber loop of an OEO. The delay varying speeds are classified as none, ±0.01 ps/sec, and ±0.05 ps/sec; and the control dynamic range is 600 ps. We steered the delay line according to the difference between the typical value and the value of the past 600-s moving average of the monitored data. Finally, we got a simulated result of a stabilized loop delay.

Fig. 5 shows the Allan deviations of the monitored delay and the simulated stable delay after the tuning. Since the delay data were actually the time interval readings of the phase differences, the results were calculated as the phase data. The long-term stability of the delay of the free running fiber loop was almost limited to the level of 10^{-15}. Through the active compensation, the stability of the fiber delay could be below 10^{-18} after 3×10^{4} s averaging.

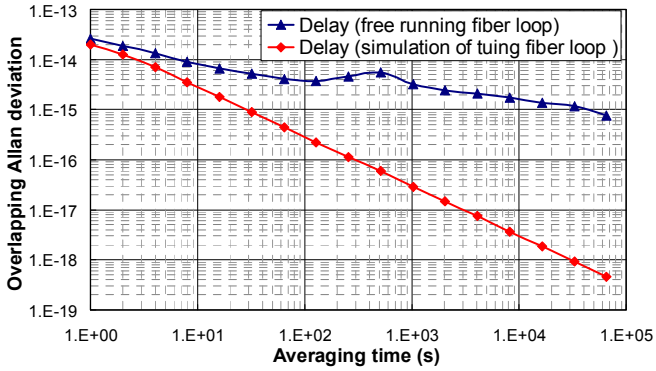

Figure 5. Comparison between delay stabilities of the measured free-running fiber loop and simulated tuning fiber loop.

By reading the stabilized delay data as frequency data, we could evaluate the frequency stability for a cavity stabilized OEO. Fig. 6 shows the evaluated results of the simulated delay data. The long-term frequency stability of the OEO could be kept within 10^{-10} after 600-s averaging times. Compared with the free running OEO, the results show that the frequency stability was reduced from 10^{-7} to 3×10^{-11} at a 10^{4}-s averaging time. This would be a great improvement.

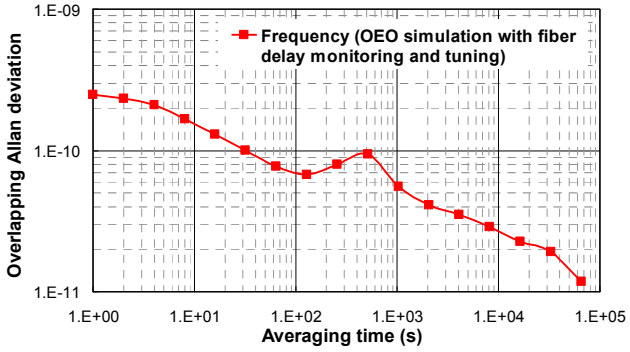

Figure 6. Frequency stability of an OEO from the simulation of tuning fiber loop delay.

VI. CONCLUSION

We have demonstrated a probe-signal method for monitoring the fiber delay of a dual-loop OEO. Since the probe signal can keep a good carrier-to-noise ratio with a much lower power level than that of the oscillated signal, there is no observable interference in the oscillation loop.

The measurement noise of the monitored data is not precise enough that we have to use their 600-s moving averages to represent the fiber delay. In the future work, we plan to carry out the active stabilizing of a fiber delay loop according to the monitored data. Then, more precise monitoring is necessary for real-time phase correction. Through the better selection of components, we may employ a higher chip-rate PRN signal, which requires a broader bandwidth, to increase the precision of monitored data.

***Abstract*— This paper presents a critical review of different acoustic resonator models exposed in the past, in the light of recent experimental results. Among the few models attempting to explain the 1/*f* behavior of the quartz crystal resonator, the *1/f* quantum noise theory of P. Handel and the thermal boson theory of M. Planat, are recalled. The latest published experimental results are analyzed taking into account these models. In the case of Handel's model, the noise depends on the resonator volume under the electrodes and the unloaded quality factor of the resonator. Handel's model is supposed to give an order of magnitude of the lowest possible noise level, but now some experimental results are under its prediction. An approach using the vibrating volume of the resonator is proposed to renew the lowest noise level estimation and found to be compatible with the latest experimental results.**

I. INTRODUCTION

High-precision quartz oscillators are mainly used in telecommunications, metrology and space applications such as local oscillators in satellites. The short-term stability of such oscillators is essential.

In 1994, J. Norton [1] has measured the best result of short-term stability of a quartz crystal resonator. It was a 5 MHz SC cut mounted in a BVA structure. The result in term of Allan standard deviation was $3.74 \cdot 10^{-14}$ for τ equals to 10 s. In 1999, at 10 MHz, R.J. Besson [2] measured two BVA quartz crystal oscillators with $5 \cdot 10^{-14}$ Allan standard deviation. Then, for ten years, there had been no significant improvement of quartz oscillators in the short term stability domain and no real solution had been found to improve the phase noise of BAW resonators. J. Norton's result represented the best acoustic resonator noise performance that could be found in the literature, pretty close to the lowest theoretical estimates. However, recently, better experimental results [3-4] have shown that quartz crystal oscillators may still have not said their last word in the short-term stability domain.

The oscillator limitation is theoretically imposed by the resonator. However, few models attempt to explain the *1/f* behavior of the quartz crystal resonator. In this paper, we will briefly recall the *1/f* quantum noise theory of P. Handel and the thermal boson theory of M. Planat in order to compare the latest published experimental results to the lower limitations computed with these two models. In the case of Handel's model, the noise depends on the resonator volume under the electrodes and the unloaded quality factor (Q) of the resonator. It gives an order of magnitude of the noise, but now some experimental results are below its prediction. In this paper, we will show that a lower theoretical estimate can nonetheless be extracted from Handel's model provided one uses the vibrating volume of the resonator instead of the volume under the electrodes.

II. MODELS

The following part presents a summary of the two models trying to elucidate the physical origin of the *1/f* flicker noise of a quartz crystal resonator with a focus on the origin of the *1/f* formula. We note, that both models can be seen as the two opposite sides of the fluctuation-dissipation theorem [5], since Planat studies the energy fluctuations around statistical equilibrium of a population of massless degenerate thermal bosons, whereas Handel proposes an origin for the dissipation occurring when the oscillator comes back to its mode after a small perturbation.

A. Planat's Model

In 2003, M. Planat proposed a statistical thermodynamics based model to explain the *1/f* noise in quartz crystal resonators [6]. In this paper, Planat considered the case of a population of massless bosons with a degenerate quantum harmonic oscillator energy spectrum which predict a hyperbolic fluctuation spectrum at low frequencies. According to the equipartition law of statistical mechanics, the partition function is introduced using a degeneracy parameter of the

978-1-61284-110-6/11/$26.00 ©2011 IEEE

energy level nhf with n the number of bosons, h the Planck constant and f the frequency. The free energy F may be approximated in the low frequency part of the spectrum by:

$$\frac{F}{kT} \approx -\frac{\pi^2}{6x} - \frac{1}{2} ln\left(\frac{x}{2\pi}\right) + \frac{x}{24} \qquad (1)$$

with $x = hf / kT$

Subsequently, the exposed model keeps only the first term of (1).

According to the Einstein's conventional approach, the energy fluctuations of a system in equilibrium within a larger system of temperature T are:

$$\varepsilon^2 = \left\langle \left(E - \langle E \rangle\right)^2 \right\rangle = kT^2 \frac{\partial \langle E \rangle}{\partial T} \qquad (2)$$

One can reformulate this relation for the fluctuations of the energy dE = u(f,T)df in the bandwidth df:

$$d\varepsilon^2 = kT^2 \frac{\partial u}{\partial T} df = S_u(f) df \qquad (3)$$

with u the energy spectral density and $S_u(f)$ the power spectral density of the fluctuations of u.

Thus, energy fluctuations in the bandwidth df are given by:

$$\left[\frac{S_u(f)}{u^2}\right]_{LF} = \frac{9hc_{ph}^3}{4\pi^3 V} \frac{1}{kTf} = \frac{A_{ph}}{Vf} \qquad (4)$$

With $3 / c_{ph}^3 = 1 / c_C^3 + 1 / c_B^3 + 1 / c_A^3$, c_A, c_B and c_C the velocities of the longitudinal mode A and the shear modes B and C, respectively.

Considering [7-8], the fractional frequency fluctuations in a quartz crystal resonator are:

$$S_y(f) = \frac{S_\omega(f)}{\omega^2} = \frac{1}{Q^4} \frac{A_{ph}}{Vf} = \frac{h_{-1}}{f} \qquad (5)$$

(5) has been used to give an order of magnitude of the power spectral density of the fractional frequency fluctuations of a 5 MHz 5th overtone (OT 5), AT-cut quartz crystal resonator.

B. Handel's Model

P. H. Handel proposes in [9] a summary of his *1/f* quantum noise theory. According to him, the general origin of the intrinsic *1/f* noise is due to a quantum self-interference process caused by very small spontaneous bremsstrahlung energy losses. The rate Γ of phonon interactions which remove phonons from the main quartz resonator mode is modulated by the quantum *1/f* effect. The time-derivative of the polarization vector P of the quartz crystal is affected. According to bremsstrahlung, when the phonon is removed, a constant energy is radiated away per unit frequency interval at any frequency, its expression is:

$$E = \frac{1}{(4\pi\varepsilon_0)} \frac{\left(\Delta\dot{P}\right)^2}{3c^3} \qquad (6)$$

With $\Delta\dot{P}$, the variation of current density of the quartz crystal.

Then the number of photon emitted as bremsstrahlung of frequency f, per Hertz is given by dividing (6) by the energy of photon hf:

$$Z = \frac{2\alpha\left(\Delta\dot{P}\right)^2}{3\pi f e^2 c^2} \qquad (7)$$

With $\alpha = (1 / 4\pi\varepsilon_0)(2\pi e^2 / hc) = 1 / 137$, the Sommerfeld's fine structure constant.

Thus the one side spectrum is inversely proportional to f:

$$S_{\delta\Gamma / \Gamma}(f) = \frac{4\alpha\left(\Delta\dot{P}\right)^2}{3\pi f e^2 c^2} \qquad (8)$$

If the main resonant mode is described as a forced harmonic oscillator with losses then the quantum *1/f* fluctuations are present in the loss coefficient Γ of the following equation:

$$\frac{d^2x}{dt^2} + 2\Gamma \frac{dx}{dt} + \omega_0^2 x = F(t) \qquad (9)$$

The quality factor of the resonator is defined as:

$$Q = \omega_r / 2\Gamma \qquad (10)$$

The resonant frequency is given by:

$$\omega_r^2 = \omega_0^2 - 2\Gamma^2 \qquad (11)$$

Thus

$$S_y(f) = \frac{1}{4Q^4} S_{\delta\Gamma / \Gamma}(f) \qquad (12)$$

Where $y = \Delta f / f_0$ is the relative frequency fluctuation.

The vibrational energy of the crystal can be written as:

$$W = n\hbar\langle\omega\rangle = 2\left(\frac{Nm}{2}\right)\left(\frac{dx}{dt}\right)^2 = \left(\frac{m}{Ne^2}\right)\chi^2\left(\dot{P}\right)^2 \qquad (13)$$

With m the reduced mass of the elementary oscillating dipoles, e their charge, N their number in the crystal, χ a polarization constant, <ω> the average circular frequency of a thermal phonon interacting with phonons in the main resonator mode and n the average number of phonons in that typical thermal phonon mode.

Thus with:

$$\left(\Delta\dot{P}\right)^2 = \frac{N\hbar\langle\omega\rangle}{n} \frac{e^2}{4\chi^2} \qquad (14)$$

We can write:

$$S_y(f) = \frac{\beta}{f}\left(\frac{V}{Q^4}\right) \qquad (15)$$

With: $\beta = n_0 \frac{\alpha\hbar\langle\omega\rangle}{12n\pi mc^2\chi^2} = 1/cm^3$, n_0 the number of dipoles per volume unit and V in cm^3.

III. ACOUSTIC VOLUME ESTIMATION

The acoustic volume estimation is carried out using Tiersten's definitions as *e. g.* in [10].

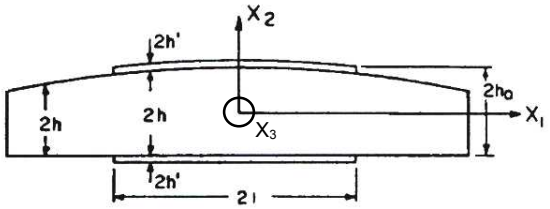

Figure 1. Geomeric definition of a plano-convex resonator

Due to the plano-convex shape, the thickness of the resonator $2h$ is given by the following expression (Fig. 1):

$$2h \cong 2h_0\left[1 - \frac{(x_1^2 + x_3^2)}{4Rh_0}\right] \qquad (17)$$

The amplitude of the mechanical displacement in the resonator is:

$$u_{nmp} = A \sin\frac{n\pi x_2}{2h} H_m\left(\sqrt{\alpha_n}x_1\right)H_p\left(\sqrt{\beta_n}x_3\right) \cdot e^{-\alpha_n(x_1^2/2)}e^{-\beta_n(x_3^2/2)}e^{j\omega_{nmp}t} \qquad (18)$$

with:

$$\alpha_n^2 = \frac{n^2\pi^2\hat{c}}{8Rh_0^3M_n} \text{ and } \beta_n^2 = \frac{n^2\pi^2\hat{c}}{8Rh_0^3P_n} \qquad (19)$$

Where n = 1, 3, 5, … the overtone number, m, p = 0, 2, 4, …, label the different mode shapes in the plane of the resonator, H_m *and* H_p are Hermit polynomials, R is the curvature radius, $2h_0$ is the thickness of the resonator center, M_n and P_n are the dispersion constants and $\hat{c}$ is the effective elastic constant associated to the propagation of the (C) mode.

For the 3rd overtone (OT 3), we have:

$$u_{300} = A \sin\frac{3\pi x_2}{2h} e^{-\alpha_3(x_1^2/2)}e^{-\beta_3(x_3^2/2)}e^{j\omega_{300}t} \qquad (20)$$

$$\alpha_3^2 = \frac{9\pi^2\hat{c}}{8Rh_0^3M_3} \text{ and } \beta_3^2 = \frac{9\pi^2\hat{c}}{8Rh_0^3P_3} \qquad (21)$$

In the case of SC-cut quartz resonator [11], the cut is defined by a doubly rotation (φ = 22°45', θ = 34°) and in N/m^2:

$$\hat{c} \cong 34.6 \cdot 10^9, M_3 \cong 57 \cdot 10^9, P_3 \cong 67 \cdot 10^9$$

The energy of the acoustic wave is given by:

$$W_1 \cong \frac{1}{2}\hat{c}\left(\frac{3\pi}{2h}\right)^2 \iiint_V \left[\cos\left(\frac{3\pi}{2h}x_2\right)e^{-\alpha_3\frac{x_1^2}{2}}e^{-\beta_3\frac{x_3^2}{2}}\right]^2 dV \qquad (22)$$

To define the acoustic volume, we can consider the vibration amplitude which remains constant over the surface S_{eq}, then we compute a cylindrical volume that has the same energy than the acoustic wave.

$$W_2 \cong \frac{1}{2}\hat{c}\left(\frac{3\pi}{2h}\right)^2 \int\left[\cos\left(\frac{n\pi}{2h}x_2\right)dx_2\right]^2 \times S_{eq} \qquad (23)$$

Thus:

$$W_1 = W_2 \Rightarrow S_{eq} = \iint_S \left[e^{-\alpha_3\frac{x_1^2}{2}}e^{-\beta_3\frac{x_3^2}{2}}\right]^2 dx_1dx_3 \qquad (24)$$

Consequently, the acoustic volume is defined by:

$$V_{ac} = S_{eq}2h_0 \qquad (25)$$

IV. APPLICATION OF THE MODELS TO EXPERIMENTAL MEASUREMENTS

As seen in [4], the best measured resonators are the 5 MHz BVA SC-cut, OT 3, resonator from Oscilloquartz (Neuchatel, Switzerland). In [12], a succinct description of the resonator is given which allows us to compute an order of magnitude of our approach. The diameter of the resonant part of the resonator is around 20 mm, the electrodes diameter D is about 11 mm. The thickness of the resonator is chosen to vibrate on the OT 3 at 5 MHz. The acoustic velocity for the thickness shear C-mode of a SC-cut in quartz crystal is about 3610 m/s. Thus, the thickness at the center of the resonator $2h_0$ is given by 3λ/2 formula and is approximately equal to 1.15 mm.

The energy trapping is quasi-independent of the electrodes dimension, in contoured resonators. It influences the motional resistance and the static capacitor. The displacement can be computed from the center of the resonator to the external edge of the resonator. The radius of curvature is one of the most important parameter. Usually, sufficient energy trapping is obtained when the lateral boundary has no effect on the vibration. Thus, we will consider an attenuation of the mechanical displacement of about 10^{-7} between the center and the boundary of the resonator. This trapping corresponds to a curvature radius R of about 290 mm (fig. 2).

The Q factor of this kind of resonator can be found from the dissipative matrix η_{ij} of the quartz crystal [13]. These constants must be expressed in the SC-cut orientation. Then, the values are considered as the imaginary part of the effective elastic coefficients. Resolution of the Christoffel equations [11] gives the complex eigenvalue $\hat{c} + i\hat{\eta}$. Then, an order of magnitude of the Q factor can be obtained using the following equation:

$$Q = \frac{\hat{c}}{\hat{\eta} 2\pi f} \qquad (26)$$

In our case, $\hat{\eta} \cong 3.95 \cdot 10^{-4}\, Ns/m^2$. A SC-cut quartz crystal resonator, at 5 MHz, OT 3, gives a maximum of quality factor of about $2.8 \cdot 10^6$. This value corresponds with the one given in [3].

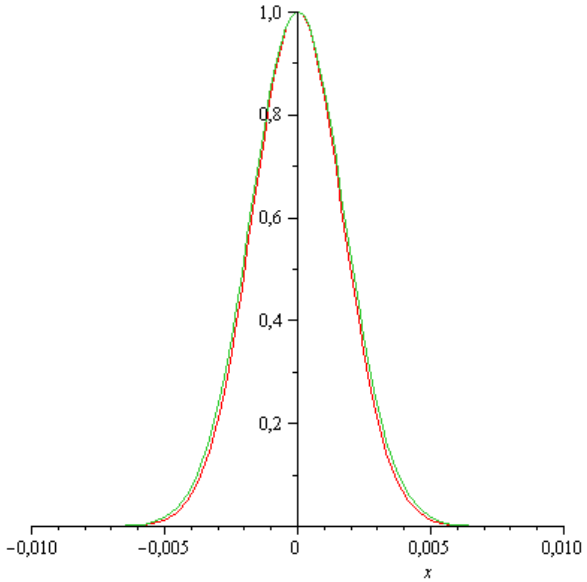

Figure 2. Energy trapping of a plano-convex resonator, SC-cut 5 MHz, OT3, R = 290 mm. (red curve: along x_3 axis, green curve: along x_1 axis).

Consequently, we can compute the motional resistor R_{mot} from the motional capacitance C_{mot} using:

$$R_{mot} = \frac{1}{QC_{mot} 2\pi f} = \frac{L_{mot} 2\pi f}{Q} \qquad (27)$$

In the case of OT 3, C_{mot} is given by [10]:

$$C_{mot} = \frac{64\hat{e}_{26}^2 \left(\int_0^{\frac{D}{2}} e^{-\alpha_3 \frac{x_1^2}{2}} dx_1 \int_0^{\frac{D}{2}} e^{-\beta_3 \frac{x_3^2}{2}} dx_3 \right)^2 \sqrt{\alpha_3}\sqrt{\beta_3}}{9\pi^3 h_0 \hat{c}} \qquad (28)$$

With D the electrode diameter, $\hat{e}_{26} \cong -0.0576\ C/m^2$ the effective piezoelectric constant.

The computing value of C_{mot} is around 280 fF. We obtain R_{mot} equals to 42 Ω, L_{mot} is about 3.6 H. These results are closed to the measured value in [3].

The static capacitor C_0 can be also computed with the following formula [9]:

$$C_0 = \frac{\pi D^2}{4}\left(1 + \frac{(D/2)^2}{8Rh_0}\right)\frac{\varepsilon_{22} + \frac{\hat{e}_{26}^2}{\hat{c}}}{2h_0} \qquad (29)$$

With $\varepsilon_{22} = 39.78 \cdot 10^{-12} F/m$ the permittivity constant in SC-cut.

We have C_0 around 3.4 pF.

Short-term stability is usually given in the time domain with an Allan variance. The Allan variance is computed from the Fourier frequency and from the power spectral density of the frequency fluctuations [14]:

$$\sigma_y^2(\tau) = \int_0^\infty S_y(f) \frac{2\sin^4 \pi f\tau}{(\pi f\tau)^2} df \qquad (30)$$

In the case of the flicker frequency noise (which is the resonator noise), relation between the Allan standard deviation and the power spectral density (PSD) of relative frequency fluctuations $S_y(f)$, is given by [15]:

$$\sigma_{y\_floor} = \sqrt{2\ln(2) S_y(1Hz)} \qquad (31)$$

Table 1 presents the comparison between measurements and the results proposed by both models. For Planat's model, only the velocity of the C-mode of the acoustic wave is used to the computation. The result is really higher than the experiment. Using the acoustic volume in this model is not relevant because of the invert proportionality.

TABLE I. COMPARISON OF THE SHORT-TERM STABILITY IN TERM OF ALLAN STANDARD DEVIATION σ_{Y_FLOOR} OF A SC-CUT, 5 MHZ, OT 3 RESONATOR

Frequency (MHz)	5
Quality factor Q (10^6)	2.8
R_{mot} (Ω)	42
C_{mot} (fF)	280
L_{mot} (H)	3.6
C_0 (pF)	3.4
Volume under electrodes V_{elec} (cm^3)	$1.093 \cdot 10^{-1}$
Acoustic volume V_{ac} (cm^3)	$1.076 \cdot 10^{-2}$
Volume ratio	10
$\sigma_{y\_floor\_planat}$ (vol. under electrodes)	$5.2 \cdot 10^{-12}$
$\sigma_{y\_floor\_Handel}$ (vol. under electrodes)	$5.4 \cdot 10^{-14}$
$\sigma_{y\_floor\_Handel}$ (Acoustic vol.)	$1.67 \cdot 10^{-14}$
$\sigma_{y\_floor\_exp\ [1]}$ (oscillator measurement)	$3.75 \cdot 10^{-14}$
$\sigma_{y\_floor\_exp\ [4]}$ (oscillator measurement)	$2.5 \cdot 10^{-14}$

The flicker noise seems to be the limit of the short-term stability of a quartz crystal resonator. An order of magnitude of this limit is given by the previous calculus around $1.6\ 10^{-14}$ with the Handel's model using the definition of the acoustic volume.

If it was possible to eliminate this noise, the noise limit should be given by the thermal noise of the resonator. In term of Allan standard deviation, its expression is usually [16]:

$$\sigma_{y\_therm}(\tau) = \frac{1}{Q_L}\sqrt{\frac{kT}{2P\tau}} \qquad (32)$$

With a loaded Q-factor Q_L around $1.6 \cdot 10^6$ for the previous resonator and a excitation power of 60 µW, we get around T = 80°C:

$$\sigma_{y\_therm}(\tau) \approx 4 \cdot 10^{-15} \cdot \tau^{-1/2} \qquad (33)$$

At 1s, without *1/f* noise, the short-term stability limit should be $4 \cdot 10^{-15}$.

V. Conclusion

Regarding the experimental results, the *1/f* story of the quartz crystal is not over. The considered models should be the fundamental limit of the flicker noise of a resonator. Values of Handel's model are under the experimental measurements if the volume is considered as the acoustic volume. The experimental results seem to be now very close to the fundamental limit. The model validity could be proved by varying the acoustic volume while keeping the Q factor of the resonator constant.

***Abstract*—This paper presents, for the first time, the analytical modeling and the experimental verification of the effects of volume and frequency scaling in AlN contour mode NEMS resonators (CMRs) on oscillator phase noise and associated limit of detection (LOD) when the device is used for sensing mass-induced frequency shifts. Both the analytical model and the experiments show that the LOD is improved by scaling the thickness of the AlN plate and by increasing the operating frequency of the device (*i.e.* implementing a high frequency resonant nano-plate). LOD values in the order of *10s of zg/μm²* are experimentally extracted.**

I. INTRODUCTION

The need to detect extremely small concentrations of analytes requires reliably measuring extremely small variations in the sensor output signal. In this perspective, gravimetric sensors, such as Quartz Crystal Microbalances (QCMs) [1-3], have a significant advantage over other sensor technologies (conductance-based sensors, Chem-FET, or optical sensors [4-6]) since they use frequency as the output variable, which is one of the physical quantities that can be monitored with the highest accuracy [7]. Nevertheless, smart, compact, portable and low cost electronic noses for multiple gas detection cannot be implemented with bulky and unintegrable QCMs. Even if QCMs have been successfully employed as gravimetric sensors thanks to their extremely high quality factors, which permit to obtain limits of mass detection in the order of few nanograms, their relatively large volume and their inability to be directly integrated on silicon render them unattractive for the fabrication of sensor arrays composed of a large number of mechanical elements.

In response to this growing demand for miniaturization, the use of micro and nano electromechanical (MEMS/NEMS) resonators for sensing applications has been extensively explored. The scaling of the device dimensions enables the fabrication of nanomechanical resonators whose mechanical resonance frequency is extremely sensitive to mass loading. Nevertheless, the greatly reduced dimensions of these devices render their transduction extremely difficult and require the use of cumbersome, complex and power inefficient read-out techniques. In addition, the enhancement in sensitivity associated to the scaling of the device dimension is in most cases offset by the reduced stability and power handling of the nanomechanical device, which result in a limited gain in limit of detection (LOD) [8, 9].

The LOD, or resolution [9], is defined as the minimum value of analyte concentration that can be detected. It depends on both device sensitivity as well as signal to noise ratio and it determines the ultimate performance of a gas sensor. For gravimetric gas sensors the LOD is strictly related to both the sensitivity of the device resonance frequency to mass adsorbed per unit area (not absolute mass) and the minimum frequency shift (induced by gas molecule adsorption) that can be resolved by the sensor readout. Although the device sensitivity is influenced exclusively by the mass and frequency of operation of the mechanical element (hence it is enhanced by scaling the device dimensions), the minimum measurable frequency shift is a function of the noise of the acoustic oscillator (*i.e.* resonant element and electronic circuitry), hence the power handling and the dimensions of the mechanical device.

Therefore, optimal sensor performance is attained by synthesizing an ultra-low mass resonant device (hence with ultra-high frequency sensitivity to mass loading per unit area) that can be efficiently excited into mechanical vibration (hence large surface area of the transducer is desirable since it facilitates efficient transduction) and that can handle input power levels high enough to guarantee very low noise performance. Suspended membranes with thickness in the nanometer range are therefore desirable. Flexural plates (instead of beams) are a good compromise [10, 11], but higher frequencies and power handling are achieved in bulk mode acoustic resonators [12-14].

In this perspective, the recently demonstrated Nanoscale AlN Contour Mode Resonant Sensor (nano-CMR-S)

This work was supported by NCMR/NSF grant no. IIS-07-15024.

technology [15] represents the best candidate for the implementation of high performance gravimetric gas sensors. In fact, this technology enables the fabrication of ultra-sensitive nanoscaled devices that can be efficiently actuated and sensed piezoelectrically directly on chip [15, 16]. The capability of this technology to maintain high Q and high coupling, k_t^2, despite the device volume reduction has been demonstrated [15, 16] and it represented the enabling feature for the demonstration of individual sensors [15, 16] and sensor arrays [17, 18], connected to compact, low power and low noise CMOS oscillator circuits for direct frequency readout.

In this work, for the first time, the noise performance of the AlN nano-CMR-S technology is studied from both analytical and experimental points of view. In particular the effects of volume and frequency scaling of the NEMS resonator on the sensor limit of detection are investigated. Both the analytical model and the experiments show that the LOD is improved by scaling the thickness of the AlN plate and by increasing the operating frequency of the device (*i.e.* implementing a high frequency resonant nano-plate). LOD values in the order of *10s of* $zg/\mu m^2$ are experimentally extracted.

II. Analytical Model

An AlN CMR-S is composed of an AlN film sandwiched between two patterned metal electrodes (Figure 1). When an AC voltage is applied across the thickness (T) of the device a contour-extensional mode of vibration is excited through the equivalent d_{31} piezoelectric coefficient of AlN.

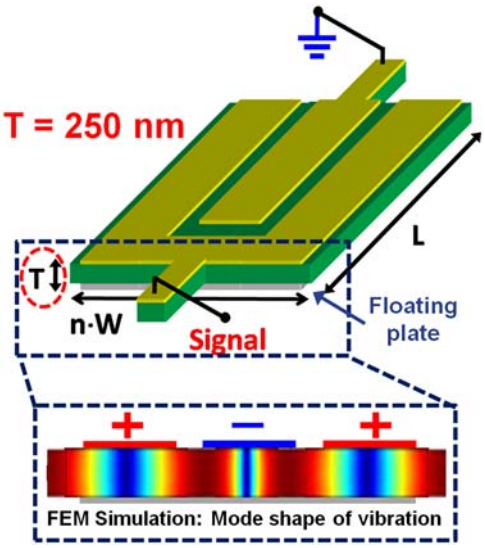

Figure 1 *Schematic representation of an AlN NEMS CMR-S: a number, n, of sub-resonators each of width, W, is mechanically coupled in order to excite a higher mode of vibration in the AlN nano-plate (f_0 is set by W) The inset shows a FEM simulation of the device mode of vibration.*

Given the equivalent mass density, ρ_{eq}, and Young's modulus, E_{eq}, of the material stack (AlN and metal electrodes) that forms the resonator, the center frequency, f_0, of this laterally vibrating mechanical structure, is univocally set by the periodic pattern of width W formed by the metal electrodes on the AlN plate [19]. The other two geometrical dimensions, thickness, T, and length, L, set the equivalent electrical impedance of the resonator [19] and can be designed independently of the desired resonance frequency.

The sensitivity, S, to mass per unit area of a CMR-S loaded on its top surface and its associated Limit of Detection, *LOD,* can be expressed as in Eq. (1) [20, 21].

$$S = -\frac{f_0}{2\rho_{eq}T} \qquad LOD = \frac{\Delta f_{\min}}{S_{CMR-S}} \tag{1}$$

Where Δf_{min} indicates the minimum frequency shift detectable by the sensor read-out. When the resonant sensor is connected to a self-sustained oscillator loop for direct frequency readout, the minimum detectable frequency shift, Δf_{min}, is limited by the noise induced frequency fluctuations of the oscillator output signal. Different types of noise (whose physical meaning and origin go beyond the focus of this paper) such as, white phase modulation (WPM), white frequency modulation (WFM), flicker frequency modulation (FFM) and random walk frequency modulation (RWFM) affect the oscillator signal and contribute to the generation of frequency fluctuations [22]. Such noise induced time domain frequency fluctuations are typically described by a statistical tool called Allan Deviation (square root of Allan Variance) [23]. The Allan Deviation (units of Hz) is commonly used to measure the time domain frequency fluctuation of clocks and oscillators for a given integration time, τ (measurement time).

For oscillator circuits composed of an acoustic resonator (such as the NEMS resonator of this work) connected in the positive feedback loop of a sustaining amplifier the Allan Deviation (hence the noise induced frequency fluctuations) can be expressed according to Eq. (2) [22].

$$\Delta f_{\min} = \sigma_y(\tau) = \left[\frac{f_0}{2\cdot Q\cdot\sqrt{P_C}}\right]\cdot\left[\alpha_{WP}\cdot\frac{1}{\tau}+\alpha_{WF}\cdot\frac{1}{\sqrt{\tau}}+\alpha_{FF}+\alpha_{RW}\sqrt{\tau}\right] \tag{2}$$

Where f_0 is the oscillator signal frequency; Q is the quality factor of the acoustic resonator; P_C is the power level at which the resonator is driven; α_{WP}, α_{WF}, α_{FF}, α_{RW} are respectively coefficients for white phase modulation, white frequency modulation, flicker frequency modulation and random walk frequency modulation; τ is the measurement time (inverse of the measurement bandwidth).

It is important to note that the value of Allan Deviation, $\sigma_Y(\tau)$, for a given measurement time, τ, can be lowered by increasing the driving power P_C. Therefore, in order to minimize the noise of the oscillator it is possible to drive the acoustic resonator with the maximum power level that it can handle. A mechanical resonator is characterized by a critical value of vibration amplitude (greatest displacement) after which non-linear phenomena occurs inducing a distorted admittance vs. frequency curve, which exhibits an infinite slope right at the point of bifurcation [24]. This critical value of vibration amplitude is associated to a critical value of drive power, P_{max}, (maximum power that the resonator can handle before bifurcation occurs) which is a function of the resonator geometry, quality factor, Q, and material properties.

For AlN Contour-Mode Resonators a simple analytical expression for the critical power, P_{max}, due to elastic non-linearity has been derived in [25]. Such expression is reported in Eq. (3) and can be employed to describe the maximum power level that the AlN nano-CMR-S can handle.

$$P_{\max} = K \cdot \frac{A}{\sqrt{\rho Q^2}} \cdot \frac{T}{W} \qquad K = \frac{2\pi^3 \sqrt{Y_0^3}}{\sqrt{3}\left|9Y_2 - 10Y_1^2\right|} \tag{3}$$

Where A is the device surface area ($n \cdot W \cdot L$); W the device frequency setting dimension; T the thickness of the material stack forming the AlN nano-CMR-S (Figure 1); ρ the device equivalent mass density; Q, the linear quality factor of the resonator; Y_0 the device equivalent Young's modulus; Y_1 and Y_2, the first-order, and second-order corrections of the strain dependent Young's modulus.

According to Eq. (3), the power handling, P_{max}, of an AlN nano-CMR-S (for a given value of device surface area, A) is directly proportional to the device resonance frequency, f_0, and inversely proportional to the square of the device quality factor, Q^2. Substituting Eq. (3) in Eq. (2) and dividing the result by the sensitivity (Eq. (1)) of the AlN nano-CMR-S it is possible to find an expression for the LOD of the AlN CMR-S technology as function of the device material and design parameters:

$$LOD(\tau) = \rho^{5/4} \cdot \sqrt{\frac{T \cdot W}{A \cdot K}} \cdot \left[\alpha_{WP} \cdot \frac{1}{\tau} + \alpha_{WF} \cdot \frac{1}{\sqrt{\tau}} + \alpha_{FF} + \alpha_{RW} \sqrt{\tau} \right] \tag{4}$$

Eq. (4) shows that the LOD of a NEMS AlN CMR-S connected to a self-sustained oscillator circuit and driven at critical power, P_{max}, improves by scaling the resonator thickness, T, and by increasing its surface area, A, and frequency of operation, f_0, ($W \propto 1/f_0$) independently of the device quality factor, Q.

Therefore, the analytical model suggests that optimum sensor performance can be achieved by designing an AlN nano-plate (with greatly reduced thickness, T, and relatively large area, A) and by exciting it into a high frequency bulk acoustic contour-extensional mode of vibration.

III. Experimental Verificaiton

In order to experimentally verify the proposed analytical model three nanoscale AlN CMR-S operating at 224 MHz, 634 MHz and 1 GHz (Table 1) were fabricated on the same chip and simultaneously connected to a single multiplexed CMOS oscillator taped-out in the ON Semiconductor 0.5 µm process.

The AlN nano-CMR-S were fabricated with a 3 mask fabrication process analogue to the one reported in [21] while the design of CMOS multiplexed oscillator circuit is described in [17, 26]. Briefly, the CMOS multiplexed oscillator is implemented by means of an inverter amplifier biased in its active region (Figure 2). Transistors *M1* and *M2* form the CMOS inverting amplifier while transistor *M3* acts as a large resistor to provide biasing of *M1* and *M2* in the active region. The single CMOS Pierce-like oscillator circuit can be connected to up to 8 nano-CMR-S by means of an equivalent number of CMOS switches operating in a time multiplexed mode and addressed by a 3 to 8 digital decoder integrated on chip.

Table 1: Resonator Geometrical Dimensions

Resonator	Width	Fingers Number	Length	Surface Area	AlN Thickness
	W (µm)	n	L (µm)	A (µm²)	T (nm)
1	15	3	200	9000	250
2	9	5	200	9000	250
3	3	15	200	9000	250

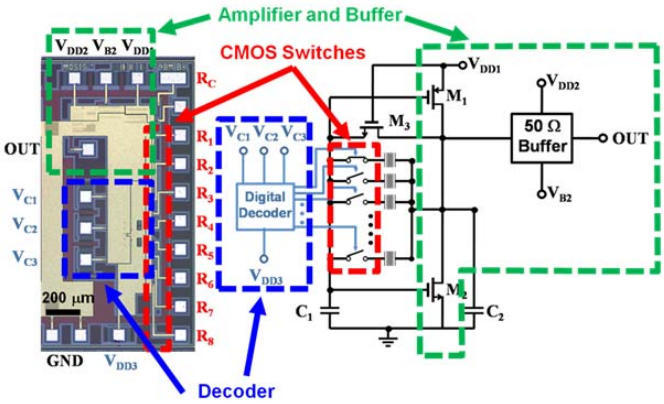

Figure 2: *Micrograph and circuit schematic of the multiplexed CMOS oscillator chip (1.05 mm²).*

The electrical responses of the three fabricated devices were first characterized in open-loop configuration using an RF probe station and the admittance curves were measured by an Agilent® N5230A Network Analyzer after performing a short-open-load (SOL) calibration on a reference substrate. The measured electrical responses of the devices were fitted to the Modified Butterworth van Dyke (MBVD) equivalent electrical circuit [27] and the device performances are reported in Table 2.

In order to characterize the multiplexed oscillator signal for each of the 3 different operating frequencies (corresponding to each of the nano-CMR-S), the 3 combinations of the 2 bit address were provided to the decoder by a Data Acquisition (DAQ) system so as to sequentially turn on each resonator. The Allan Deviation, $\sigma_Y(\tau)$, was measured by a Fluke PM6690 Frequency Counter. The bias of the multiplexed oscillator circuit was adjusted for each of the 3 operating frequencies in order to achieve an output power level, P_{out}, as close as possible to the critical power level, P_{max}, of the corresponding resonator. In order to extract the LOD, each measured value of Allan Deviation was divided by the mass sensitivity value, S, of the corresponding resonator according to Eq. (1). The experimentally extracted LOD values (at the 3 different operating frequencies) are plotted in Figure 3 for different values of measurement time, τ.

TABLE 2: RESONATOR PERFORMANCE: P_{MAX} IS ANALYTICALLY CALCULATED USING THE VALUE OF NON-LINEAR COEFFICIENT, K, EXPERIMENTALLY EXTRACTED IN [25] FOR A 250 NM THICK ALN FILM.

Resonator	Frequency	Q	k_t^2	C_0	R_m	P_{max}
	MHz		%	fF	Ω	dBm
1	224	1109	1.7	554	79	-8
2	634	852	1.67	699	26	-1.1
3	1000	650	1.5	874	13	3.5

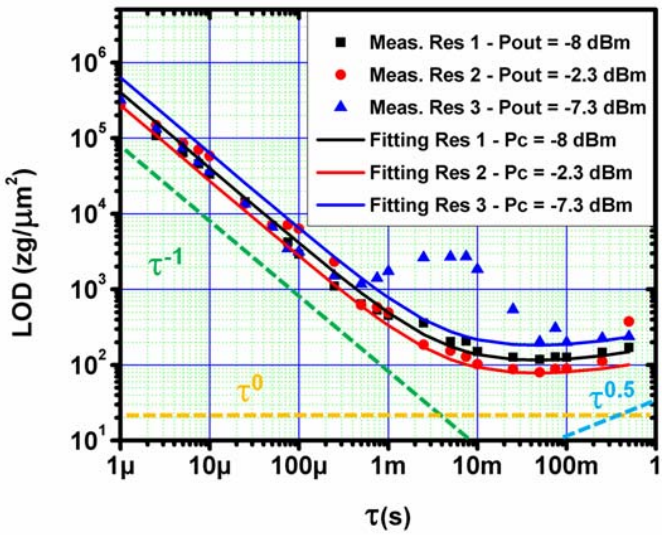

Figure 3: Experimentally extracted LOD values and equivalent analytical model fitting. The experimentally extracted LOD at 1 GHz for measurement time values, τ, comprised between 1 and 20 ms cannot be fitted by the proposed analytical model: this is repeatable, but not yet explained by the authors. It is worth noting that for very fast measurement times, below 1 ms, the relative measurement error of the instrument is larger than 10^{-7}.

The experimentally extracted LOD was fitted by the analytical model discussed in the previous section of this paper and described by Eq. (5) (note that Eq.(5) = Eq. (4) for $P_c = P_{max}$).

$$LOD = \left[\frac{\rho \cdot T}{Q \cdot \sqrt{P_C}}\right] \cdot \left[\alpha_{WP} \cdot \frac{1}{\tau} + \alpha_{WF} \cdot \frac{1}{\sqrt{\tau}} + \alpha_{FF} + \alpha_{RW}\sqrt{\tau}\right] \quad (5)$$

Where: $\alpha_{WP} = 2.2 \cdot 10^{-9}$ [$W^{0.5} \cdot s$]; $\alpha_{WF} = 9.2 \cdot 10^{-11}$ [$W^{0.5} \cdot s^{0.5}$]; $\alpha_{FF} = 4.9 \cdot 10^{-7}$ [$W^{0.5}$]; $\alpha_{RW} = 4.6 \cdot 10^{-7}$ [$W^{0.5}/s^{0.5}$]. The same set of noise coefficient values was used to fit the experimentally derived LOD for all of the 3 different operating frequencies showing the independence of the noise coefficients from the operating frequency, f_0, quality factor, Q, and drive power level of the 3 NEMS resonators employed.

It is important to note that not enough power can be provided by the currently designed circuit to reach the critical power level, P_{max}, at all the operating frequencies. The maximum output power at high operating frequency is limited by the CMOS technology currently employed. This is particularly significant for the 1 GHz case whose output power level (Figure 3) is ~11 dB smaller than the value of maximum power, P_{max} (Table 2), that the corresponding resonator can handle. Consequently the LOD at 1 GHz is higher than the one achieved at lower frequencies. Figure 4 shows a simulated LOD as function of frequency and for a fixed optimum measurement time, τ, of 50 ms. The LOD is simulated employing the same noise coefficients that fit the experimental data, but power levels, P_C, equal to critical power values, P_{max}, at all the operating frequencies. The simulation confirms that the LOD at 1 GHz would be smaller than the one achieved at lower frequencies if the resonator was driven at its critical power, P_{max}.

Therefore, the experiment shows that, as predicted by the design equation, the LOD of an AlN nano-CMR-S connected to a self-sustained oscillator circuit and driven at its critical power level, P_{max}, improves by increasing the operating frequency of the device independently of the quality factor, Q, of the resonator (the device with highest Q shows the worst LOD). A higher Q, though, would still be beneficial to lower the power consumption of the overall circuit, in agreement with the fact that Q is a concept related mainly to energy dissipation rather than noise.

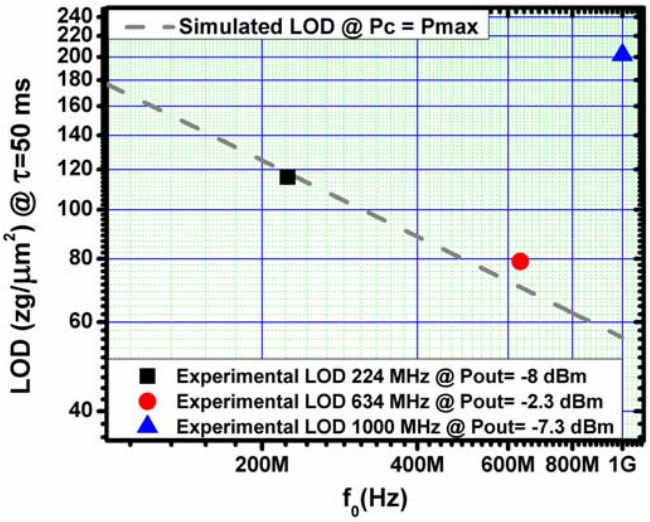

Figure 4: Experimental and simulated LOD as function of frequency and for a fixed measurement time, τ, of 50 ms. The LOD is simulated employing the same noise coefficients that fit the experimental data, but power levels, P_C, equal to critical power values, P_{max}, for each of the operating frequencies.

IV. CONCLUSION

In this paper the analytical modeling and the experimental verification of the effects of volume and frequency scaling on the LOD of AlN Contour-Mode NEMS Resonant Sensors was presented for the first time. An analytical model that relates resonator design parameters, such as resonance frequency and thickness, to the limit of detection of the resonant sensor was developed. In order to experimentally verify the proposed analytical model three nanoscale AlN CMR-S operating at 224 MHz, 634 MHz and 1 GHz were fabricated on the same chip and simultaneously connected to a single multiplexed CMOS oscillator taped-out in the ON Semiconductor 0.5 μm process. The LOD at the three different frequencies was experimentally extracted through Allan Deviation measurements and the

experimental data was fitted by the proposed analytical model. Both the analytical model and the experiments showed that the LOD is improved by scaling the thickness of the AlN plate and by increasing the operating frequency of the device (*i.e.* implementing a high frequency resonant nano-plate). LOD values in the order of *10s of* $zg/\mu m^2$ were experimentally extracted.

***Abstract*—High Tc superconducting materials provide very high Q microwave resonators, which are supposed to make low phase noise oscillators. The expected phase noise has never been observed on operational oscillators. Our goal is to outperform the specifications of acoustic resonators and whispering gallery modes, with 2D resonators operated at 1 GHz: Q > 100,000 low 1/f noise Si transistors, -150 dBc/Hz at 100 Hz from the carrier.**

I. INTRODUCTION

High critical Temperature Superconducting (HTS) materials have been studied, and are commercialized for microwave filtering applications. They provide very selective, very low insertion filters thanks to high quality factor resonators [1-3]. These very high Q resonators are also expected to provide low phase noise oscillator. Nevertheless this has never been clearly demonstrated on operational oscillators. 3D resonators [4] exhibit very high Q > 10^6, but vibration sensitivity creates parasitic lines in the spectrum. 2D resonators [5] provide intermediate Q that decreases versus frequency. The choice of the reference frequency **f** is a very important point for the success of the demonstration.

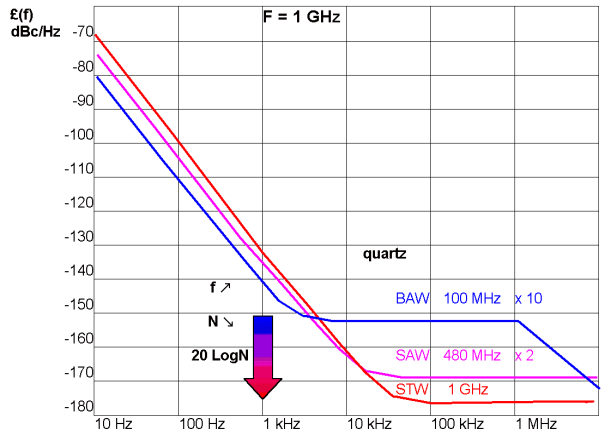

Figure 1. Phase noise £(f) at 1 GHz versus carrier offset frequency: Increasing the reference frequency lowers the multiplication rank and the noise floor level far from the carrier

State of the art reference oscillators are usually made with acoustic wave resonators (Bulk or Surface Acoustic Waves: BAW or SAW) in the megahertz range, and then multiplied by **N** to reach the operating frequency **F** of the system (or **F** is divided by **N** in synthesizers). The floor level is increased by 20 Log **N** (Fig.1). Thus the trend is to increase the reference frequency up to 1000 MHz. The theory of acoustic attenuation [6,7] shows that, for a given material and a given cut, the product of the quality factor times the frequency is a constant. According to the Leeson's theory [8], the phase noise rises from the floor level k_BT (-174 dBm/Hz at 300 K), at the offset frequency **f/2Q**. This results in a shift away from the carrier as the square of the frequency **f**, and in a detrimental increase of the colored noise close to the carrier (Fig.2).

A compromise can be found for many systems, or combining for example a 10 MHz BAW and a 1 GHz SAW can help for more stringent requirements. Nevertheless higher quality factors are highly desirable for improved oscillators, especially for radar applications.

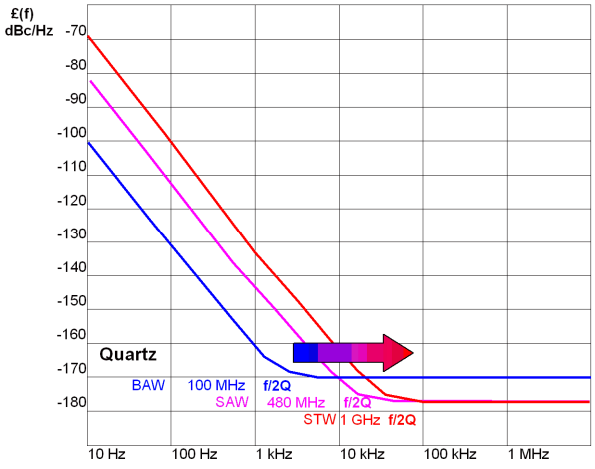

Figure 2. Increasing the reference frequency lowers the quality factor (Q.F is constant), shifts the corner away from the carrier as F^2 and increases the colored noise close to the carrier.

This research is partially funded by DGA REI 06.34.028.

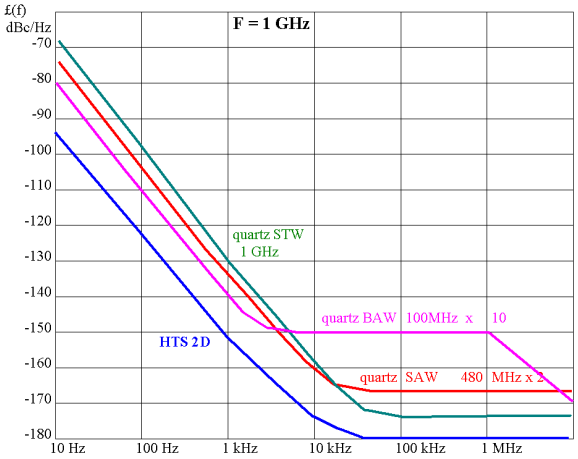

Figure 3. Comparison at 1 GHz between state of the art acoustic wave oscillators and expected phase noise of a HTS oscillator according to Leeson's theory for an unloaded Q of 100,000 and a loaded Q of 50,000 [5].

The goal of the study is to go beyond the performances of acoustic resonators (and whispering gallery modes). We know that 2D HTS resonators can provide a Q higher than 100,000 at 1 GHz (one order of magnitude higher than acoustic resonators), and only 10,000 or less at 10 GHz (a similar law Q.F ~ constant is found for acoustic, dielectric and HTS resonators, through different theoretical approaches). The choice of a 1 GHz 2D HTS resonator seems the most pertinent. Figure 3 confirms the validity of this approach with a phase noise lower than all acoustic wave oscillators for all offset frequencies. Moreover the advantages of 1 GHz are:

- upper frequency range of acoustic oscillators
- lower multiplication rank
- higher Q
- available low flicker noise silicon bipolar transistors
- light cryocooler compatible size (15x15 mm)
- noise floor level –180 dBm/Hz at 70 K

II. SUPERCONDUCTING RESONATOR

A. *Resonator Patterning*

$YBa_2Cu_3O_7$ films are deposited on both sides of a magnesium oxide single crystal substrate by sputtering [9,10].

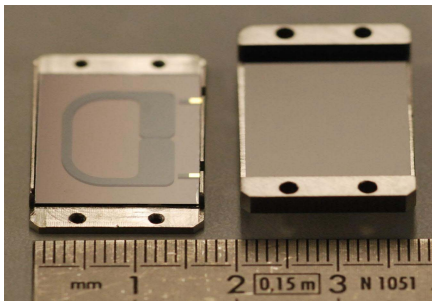

Figure 4. Superconducting resonator: $YBa_2Cu_3O_7$ film (700 nm thick) deposited on a magnesium oxide substrate (500 µm thick)

The surface resistance Rs of the superconducting films is measured at 10 GHz using the dielectric resonator method [10]. The values are between 200 and 300 µΩ at 77 K, two orders of magnitude lower than pure copper. Since the loss of superconductors evolves as the square of the frequency, the Rs at 1 GHz is 2 to 3 µΩ, more than three orders of magnitude lower than normal metals, which vary as the square root of the frequency.

The resonator (Fig. 4) is designed as a folded half wavelength line. Instead of the classical hairpin shape, we optimized the geometry in a nearly closed C in order to: minimize the size (large pads in the capacitive part of the line), improve the power handling capability (large half circle for the inductive part of the line where the current flows), and minimize the radiated energy (very short electric dipole corresponding to the gap).

Both the line and the ground plane are superconducting. The top and the walls of the enclosure are also coated with superconducting wafers in order to minimize eddy current losses.

Accurate integrated input and output couplings modeled with Sonnet e.m. software [12] are patterned simultaneously and overlaid by gold contacts.

B. *Resonator Microwave testing*

The very low surface resistance of $YBa_2Cu_3O_7$ films and the optimized design of the resonator give quality factors much higher than 100,000, typically 150,000 at 77 K (Fig.5). 77 K is often used as a reference temperature since it corresponds to liquid nitrogen, but standard Stirling cryocoolers (utilized for infrared cameras) can easily reach lower temperatures.

It is quite realistic to operate between 60 and 70 K where a Q higher than 200,000 is obtained. Moreover the power handling capability improves by one order of magnitude between 77 and 60 K. This is a most important point since high Q resonators have to carry high reactive power. High Q is not sufficient to get a low phase noise; the reactive power really makes the spectral purity of the oscillators.

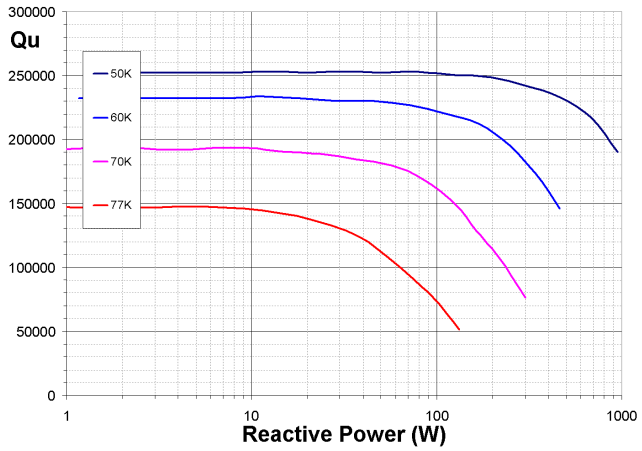

Figure 5. 1 GHz HTS planar resonator unloaded quality factor Q_U versus reactive power and temperature

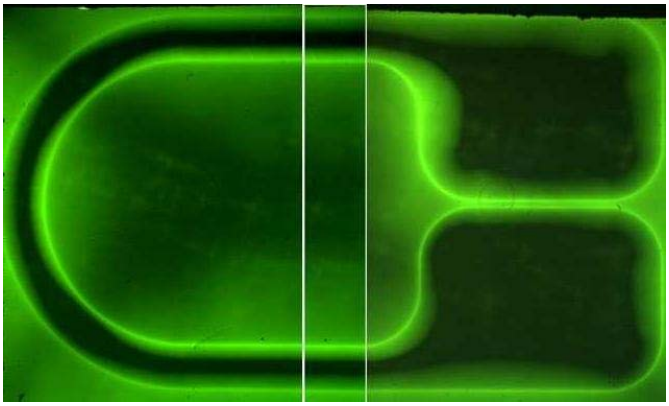

Figure 6. Magneto-optical control of the superconducting properties of the $YBa_2Cu_3O_7$ resonator

The power handling capability of the resonator is very dependent on the quality of the film and of the patterning, which can be controlled by a magneto-optical microscope (Fig.6). A perfect superconductor expels the magnetic field (Meissner effect). By exploiting the Faraday effect in a garnet film, it is possible to visualize the magnetic field map and to control the quality of the superconducting pattern.

III. Oscillator Circuit

The feedback oscillator circuit (Fig. 7) is designed using the AWR-MWO® software [13] for setting the oscillation conditions. This circuit includes:

- NEC-CEL SC 5801 silicon Bipolar Junction Transistor (BJT SPICE model with documented AF and KF flicker noise coefficients).
- Sonnet modeled resonator including integrated input and output couplings to set the gain close to unity
- Sonnet adjusted delay line to set the phase equal to 2π along the closed loop
- Infineon BBY55 Varactor for fine phase trimming
- Bias circuits

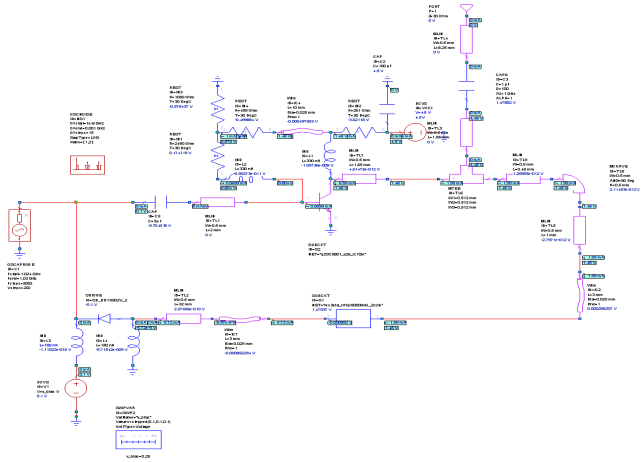

Figure 7. MWO-AWR 1 GHz oscillator modeling including SONNET modeled HTS resonator

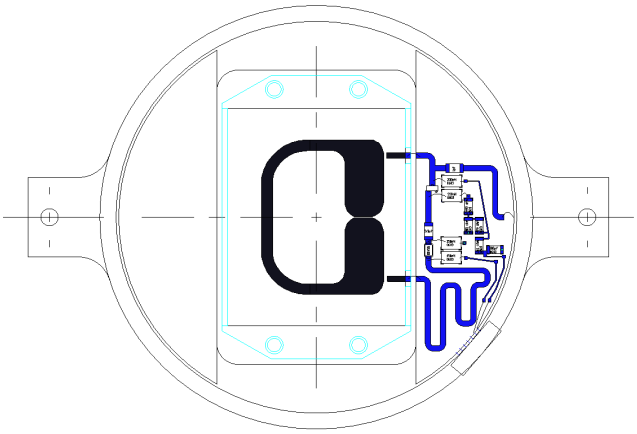

Figure 8. Feedback loop oscillator lay-out with:
60 K cooled 2D HTS resonator (black and light blue, central part),
room temperature low flicker noise Si BJT (deep blue, right part)

It was first intended to use a cooled SiGe transistor, but the flicker noise of SiGe is poorer than that of Si, and increases at low temperature. We chose a Si transistor with a very low flicker noise (1/f corner at 350 Hz), but Si transistors do not operate at 60 K. Thus the active part of the circuit is kept at room temperature (Fig. 8).

The length of the delay line is carefully adjusted in order to get the right phase when closing the loop. The Sonnet modeling takes into account the meander shape of this line and all the connecting lines of the circuit. The permittivity of the alumina substrate is controlled by the split cavity TE_{01n} mode method [14]. And the S parameters are re-injected in AWR-MWO. In spite of all these precautions, a varactor is inserted to provide a fine-tuning for technological dispersion compensation. The setting of the phase strictly equal to 2π is essential for the optimal operation and the purity of the oscillator. It may require an automated control (not utilized here)[15].

IV. Phase Noise

The phase noise of the feedback oscillator circuit is analyzed by the harmonic balance method in AWR-MWO.

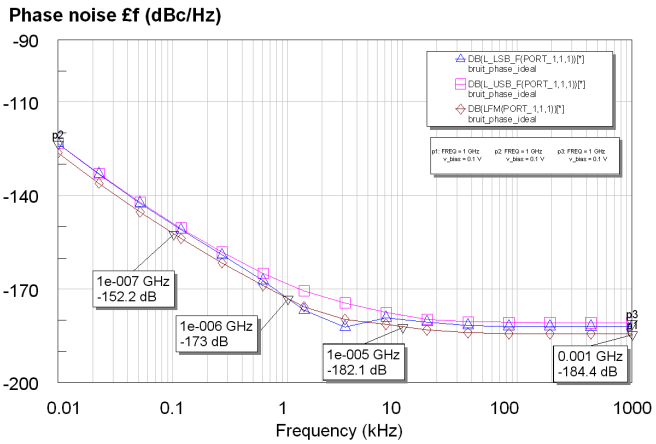

Figure 9. MWO-AWR phase noise modeling £(f_m) = LFM @ 1 GHz with an unloaded quality factor Q_U = 230 000

This modeling gives a theoretical noise, with a floor level at -184 dBc/Hz, which is coherent with a 10 mW output, and a colored noise frequency corner slightly below 10 kHz, which is coherent with a loaded Q_L higher than 50,000. Q_L was set at 50,000 in the open loop configuration, but it cannot be measured when the loop is closed and can only be estimated from the corner frequency.

The slope of the colored noise is -20dB/decade down to 100 Hz and clearly turns up to -30 dB/decade only below 100 Hz, which is better than expected from the transistor flicker noise specifications (1/f corner at 350 Hz).

These results are not incompatible with the straightforward application of the Leeson's theory. Nevertheless, they may appear over-optimistic and make the validity of the software questionable. We decided with the French defense administration DGA to benchmark it versus the Agilent ADS® software [16] (fig. 10).

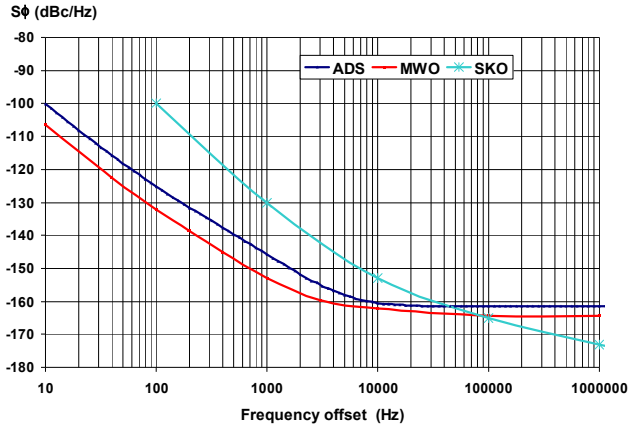

Figure 10. Comparison between phase noise Sϕ = 2 £(f) of multiplied HTS oscillator modeled by MWO-AWR and Agilent ADS, and measured PSI Poseidon® SKO @ 10 GHz

The phase noise Sϕ = 2 £(f) modeled by ADS, and transposed from 1 to 10 GHz for comparison, is about 6 dB higher than AWR-MWO, but remains quite low compared to acoustic oscillators and a SKO sapphire whispering gallery mode oscillator, manufactured by PSI Poseidon [17], which is the X band reference. The floor level is of the sapphire oscillator is lower; but the unloaded Q of a sapphire resonator is typically 200,000 at 10 GHz and 300 K, which gives a frequency corner around 50 kHz. The flicker noise of X band transistors is also higher, and the slope is -30 dB/decade up to 2000 Hz. The colored noise of the 10 GHz 3D oscillator is 10 to 20 dB higher than the multiplied 1 GHz HTS 2D oscillator.

V. CONCLUSION

We designed a superconducting planar resonator and designed a feedback oscillator. The results obtained by modeling with AWR-MWO and Agilent ADS are in good adequacy with the Leeson's theory and deserve the further effort to build a demonstrator. Practical interest of this oscillator lies in the capability of a compact cryogenic integration, which is our actual purpose.

Phase Noise Improvement in Balanced SAW Oscillators

Yao Huang Kao, Jon Hung Lin, and I-Jhih Wu

Department of Communication Engineering, Chung Hua University, Hsinchu Taiwan

Email: yhkao@chu.edu.tw

SAW oscillators as stable clock sources are received a number of applications in information and communication industry. As the frequency is raised up several hundred MHz and GHz range, the output with differential waveform such as LVDS has many advantages for power supply noise rejection and direct match to the preceded stages of mixer and phase detector as in the clock and data recovery applications. However, the configuration of the oscillator normally adopts the Pierce or Colpitts oscillators, which needs a single to differential converter. Here, a balanced SAW oscillator is first presented. The differential outputs possess inherently 180^o out of phase in odd harmonics and in phase in even harmonics. By using these features, the powers of combined signal and noise are raised 6dB and 3dB, respectively. Thus, the phase noise of the combined signal can be improved at least 3dB, which is useful in low phase noise applications.

The balanced oscillator is constructed by using two identical Colpitts oscillators. The functional block is revealed in Fig. 1a. The one-port SAW resonator acts as the tank and is also acted as the phase coupling network between the identical oscillators. Under fundamental vibration mode, the RF current of the opposite plates of the resonator is out of phase, which drives the corresponding outputs of two identical oscillators 180^o out of phase. The balanced SAW oscillator has been fabricated on FR4 substrate and its photograph is shown in Fig.1b. The size of the pc board is 25mm x 25mm for the convenience of measurement. The DC supply voltage is 3.0V. Current consumption is 17mA with each output -2.5dBm. The differential outputs are fed to an output coupling network (0^o or 180^o power combiner) and a push-push oscillator will be available. Output power is increased to +3dBm with 6 dB improvement. Thus, a significant reduction in phase noise was also expected. The measured phase noise is shown in Fig.2. At 100 kHz offset from the carrier, the phase noise is about -158 dBc/Hz for balanced outputs and -164 dBc/Hz for the output combined with 180^o power combiners. Thus, 3dB, at least, improvement in phase noise is verified.

***Abstract*—We report on the generation of millimetre wave signals with frequency instability of a few parts in 10^{16}. Such performance was achieved at 103.750 GHz by multiplying frequencies of two almost identical 12.969 GHz oscillators based on liquid helium cooled sapphire dielectric resonators. The multiplication stages were shown to only add a small amount of noise at averaging times less than 10 seconds, resulting in a minimum of frequency instability of $5x10^{-16}$ at 20 seconds averaging time. Such ultra-stable signal sources operating at frequencies of 100 GHz are very important for many applications including high frequency radio astronomy.**

INTRODUCTION

Precise frequency generation is important for a variety of applications including radar, telecommunications, positioning and navigation, geodesy and time keeping, tests of fundamental physics and radio astronomy [1-8]. So far, signals with the short-term fractional frequency instability of a few parts in 10^{16} have been generated at microwave frequencies only. This was achieved either with classical oscillators based on sapphire loaded cavity resonators cooled to liquid helium temperature, termed as "sapphire clocks" or "cryogenic sapphire oscillators" (CSO) [9-11], or via the use of mode-locked laser technology by extracting high order harmonics of pulse repetition rate from a femtosecond pulse train referenced to an ultra-stable laser [8]. In this letter we demonstrate that the excellent fractional frequency stability of a typical microwave CSO can be transferred to frequencies above 100 GHz by means of direct frequency multiplication.

In the Extremely High Frequency (EHF) band (30-300 GHz) low noise frequency generation at parts in 10^{16} frequency instability below 1000 seconds averaging time has never been achieved. Such precise frequency generation at EHF has application for radio astronomy, high-speed data links, point-to-point high bandwidth communication and space-borne radio communications. In particular the next generation of high frequency VLBI will require a reference oscillator better than the best Hydrogen Masers (which typically have stabilities of parts in 10^{13} to 10^{14} over averaging times of 1 to 30 second) [12].

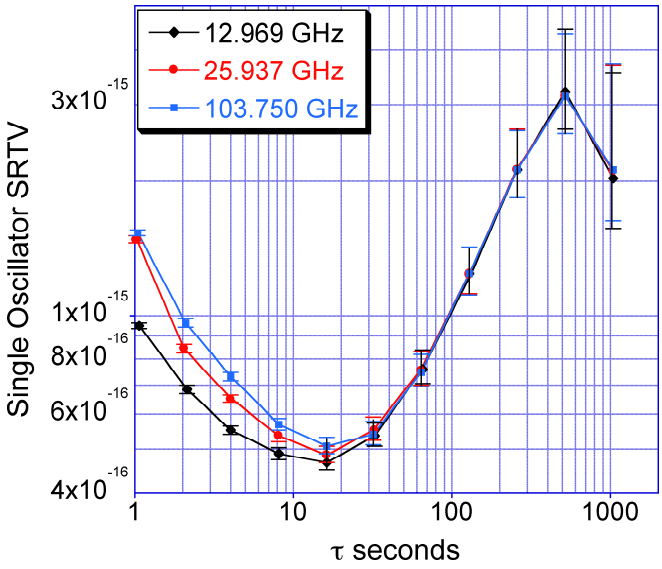

Fig. 2. Frequency instability as measured by the Square Root Triangle Variance with respect to a single oscillator.

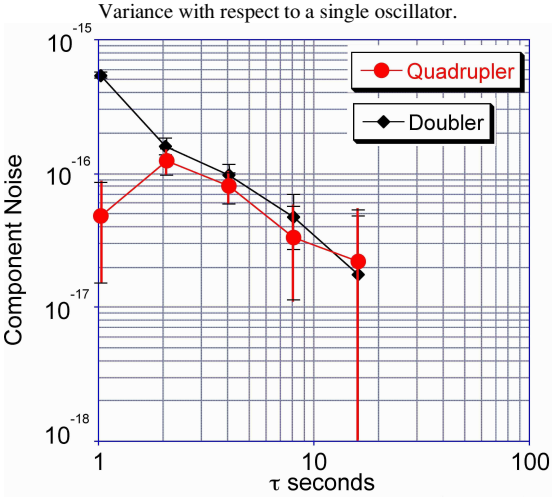

Fig. 3. Frequency instability added by the doubling (bold diamond) and quadrupling (bold circle) stages as calculated by the quadratic difference between the 12.969, 25.937 GHz and 103.750 GHz stages.

CONCLUSION

To our knowledge this is the first time fractional frequency instability below 10^{-15} in the range of integration times 2 to 100 s was demonstrated for mm-wave signals at frequencies above 100 GHz. This was achieved by multiplying frequency of a 12.969 GHz cryogenic sapphire oscillator. The excess noise of frequency multiplication stages was estimated as contributing to oscillator frequency instability at the level of a few parts in 10^{17} for integration times above 4 s. The noise in the multiplication stages was low enough to enable a very low level of frequency instability to be measured at the high frequency of 103.75 GHz. This has important implications for many precision measurement and metrological applications, in particular for the next generation of high frequency precision radio astronomy.

This work was support by the Australian Research Council Grants No. DP0878108, DP0878108 and FL0992016.

Abstract—**We present our recently experimental results on a DFB laser diode pumped Rubidium atomic frequency standard. Our experiment was based on a homemade lamp-pumped Rubidium frequency standard with the discharge lamp assembly removed. In the experiment, we first locked a DFB laser diode to the ^{87}Rb cycling transition ($5S_{1/2}$, F=2→$5P_{3/2}$, F=3) by means of saturation absorption locking technique. After that, we optimized the parameters carefully related to the clock performance, such as temperature of the physical package, amplitude of the modulation signal for the laser locking.**

The preliminary short-term stability of our clock is measured $5.25\times10^{-12}\tau^{-1/2}$ (1s<τ<100s)**.**

I. INTRODUCTION

In a traditional Rubidium frequency standard, a discharge Rb lamp is used as the light source. And after the discharge lamp, an ^{85}Rb filter gas cell is typically employed so that only "b" line light of ^{87}Rb is left to produce the pumping light. However, since the filter process is always imperfect, it results in broadening the microwave resonance line, generally 1-2 kHz and additional light noise. These make the signal contrast of a traditional Rb clock keep below 1% and damp the further improvement in the short-term stability.

To eliminate the problem resulted from the discharge lamp and the filter process, and improve the short-term stability of Rubidium frequency standard remarkably, the narrow linewidth laser diode was proposed to be implemented as the pumping light source. The narrow linewidth laser diode, which can offer excellent control of the light spectra, can greatly improve the pumping rate and avoid the additional light noise. As a result, the short-term stability can be greatly improved in this condition. For the desired improvement, interest and attempts in this field have never diminished, since the preliminary experiment result reported by L. L. Lewis and M. Feldman [2]. On one hand, theoretical analysis and calculation were carried out to make certain of the influence of different noises and shot noise limit of the laser pumped Rb clock [3-9]; on the other hand, experiments were designed to improve the signal-to-noise ratio (SNR) and reduce the light shift effect to advance the performance of laser-pumped Rb clock [10-14]. And during last few years, progress in this field was mainly made on the compact laser-pumped Rb clock [15-16] and the pulsed Rb clock [17-20].

In this paper, we report our recently preliminary experiments on a DFB laser diode pumped Rubidium frequency standard, which is based on a homemade traditional Rb clock with the discharge lamp assembly removed. The similar work was also carried out by C. Affolderbach, *et al*. on a commercial Rb clock [1]. Our paper is organized in the following four sections. Section one introduces the experimental setup. Section two is about the parameter optimizing. The third and fourth sections are respectively the preliminary experimental result and the conclusion.

II. EXPERIMENTAL SETUP

Our experimental setup can be divided into two main parts: the laser head and the clock module. The laser head consists of a DFB laser diode and the frequency stabilization devices. And the clock module is our one homemade traditional Rubidium frequency standard with the discharge lamp removed as shown in Fig. 1.

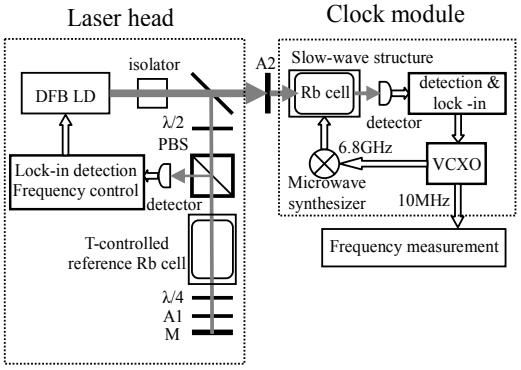

Fig.1. Experimental setup. λ/2 and λ/4, wave plates; A1 and A2, attenuators; M, mirror; PBS, polarizing beam splitter.

In the experiment, we lock the DFB laser diode to the cycling transition ($5S_{1/2}$, F=2→$5P_{3/2}$, F=3) of ^{87}Rb by means of saturated absorption locking technique. In this condition, all the ^{87}Rb atoms on the ground state ($5S_{1/2}$, F=2)

This work is supported by "the Fundamental Research Funds for the Central Universities".

are pumped to the excited state ($5P_{3/2}$, F=3) and fall back to the ground state ($5S_{1/2}$, F=1) through nonradiative transitions. Because of this pumping process, around 33% of all the ^{87}Rb atoms can be utilized for magnetic resonance, with the SNR evidently improved. And to suppress the spectrum drift caused by temperature fluctuation, another temperature controlled reference Rb cell is employed. The energy level structure and saturated absorption spectra for frequency stabilization of ^{87}Rb are presented in Fig. 2.

In the clock module, the microwave resonance signal is generated in the Rb gas cell with the microwave slow-wave structure. The VCXO is locked to the clock transition of ^{87}Rb (F_g=1, m_F=0→F_g=2, m_F=0) and provides 10MHz. signal.

III. PARAMETER OPTIMIZATION

After finishing the basic setup of the clock system, we optimize the parameters carefully related to the clock performance. In this experiment, the environment temperature drift and the light shift effect make great influences on the long-term stability of the clock. The temperature point of the physical package also affects the short-term stability. For the parameters optimizing, we lay emphasis on searching the best temperature point of the physical package, and the amplitude of the modulation signal for laser frequency stabilization.

A. Temperature of the physical package

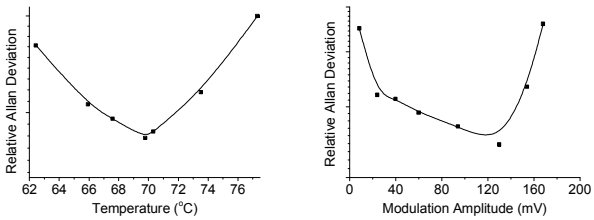
In the Rb gas cell, the temperature factor affects seriously the saturated vapor pressure of Rb atoms. Consequently, the microwave resonance signal intensity will change when altering the physical package temperature, with the laser light intensity unchanged. In this way, the short term stability $\sigma(\tau)$ can be seriously influenced.

On this step, we search for the temperature point where the clock works best. And to find out this key point, we carried out measurement on the temperature dependences of the clock short-term stability (Fig. 3a). As a result, we found that short-term stability appears best when the temperature controlled around 70°C.

B. Amplitude of the modulation signal

The amplitude of the modulation signal for the laser frequency stabilization has a strong influence on the SNR of the error signal. And the error signal affects apparently the frequency stabilization of the laser diode. Since the AM and FM noise from the laser diode greatly limit the short-term stability of the clock, we changed the amplitude of the modulation signal to improve the laser-locking effect and reduce these noises. And the frequency of the modulation signal was maintained at 8 kHz on this step.

To search for the best parameter, we measured the short-term stability of the clock while regulating the amplitude (Fig. 3b). From Fig. 3b, we can read that neither too big nor too small amplitude the clock performs best. The most appropriate amplitude of the modulation signal for laser locking was found to be 130mV in the end.



(a) **(b)**

Fig.3. (a) The relevance between the physical package temperature and the clock short-term stability. (b) The relevance between the modulation signal amplitude and the clock short-term stability.

IV. PRELIMINARY RESULT

After optimizing the parameters above, we measured a preliminary short-term stability of the DFB laser diode pumped Rubidium frequency standard, $5.25\times10^{-12}\tau^{-1/2}$ ($1s<\tau<100s$). And this is 20% better than the lamp-pumped Rubidium clock on the same physical package (Fig. 4).

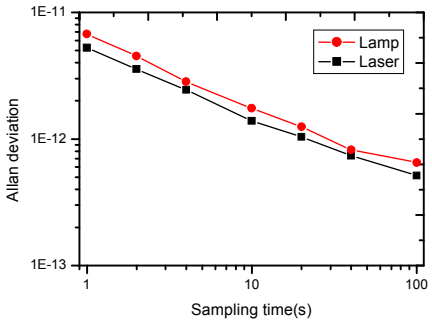


Fig.4. Preliminary short-term frequency stability of DFB laser diode pumped Rubidium frequency standard.

V. CONCLUSION

In this experiment, we built a DFB laser diode pumped Rubidium frequency standard. The laser diode was locked to the cycling transition ($5S_{1/2}$, F=2→$5P_{3/2}$, F=3) of ^{87}Rb. After

relevant parameters optimized, the preliminary measured short-term stability of the clock was $5.25\times10^{-12}\tau^{-1/2}$ ($1s<\tau<100s$). And our recent experiments indicate that the laser noises limit greatly the performance of the clock. When considering the long-term frequency stability, the long term environmental temperature drift and the light shift effects are the major restrictions. We are also trying to improve these factors to get better results for long terms.

***Abstract*— We describe the latest improvements and current status of our cryogenic sapphire oscillator Michelson-Morley experiment that has recently been moved from The University of Western Australia to Humboldt University of Berlin.**

I. Introduction

The original Michelson-Morley experiment [1] used an optical interferometer to search for an orientation dependent change in the speed of light due to the presence of a luminiferous aether. In contrast, this experiment features two orthogonally aligned cryogenic sapphire oscillators that are mounted in the same vacuum space and actively rotated in the laboratory. The beat frequency is recorded and analysed for orientation dependent frequency changes which could be caused by orientation dependent variations in the speed of light. These possible variations are expressed as bounds placed on coefficients in the Standard Model Extension framework [2], [3] and describe violations of Lorentz invariance. Our first cryogenic sapphire oscillator Michelson-Morley experiment ran at The University of Western Australia from 2004 - 2006 [4] and was able to constrain nine photon sector coefficients from the Standard Model [5]. In order to place better bounds on these coefficients we need to improve the frequency stability of the experiment.

II. Cryogenic Sapphire Oscillators

A 5.1 cm diameter cylindrical sapphire crystal is mounted in a silver plated copper cylindrical cavity and excited at 12.968 GHz via SMA antenna probes. This sapphire loaded cavity sustains a standing wave whispering gallery mode ($WGE_{16,0,0}$) with a dominant radial electric field. WGE modes are twice as sensitive to Lorentz Violations compared to WGH modes (dominant crystal axis electric field) which the previous experiment operated in. At cryogenic temperatures the sapphire crystals exhibit quality factors on the order of one billion which is an order of magnitude improvement compared to the previous experiment. These improvements are achievable due to the larger sized diameter of the new crystals. The beat frequency of the two cryogenic sapphire oscillators exhibits a temperature/frequency turning point at 5.5 K (figure 1).

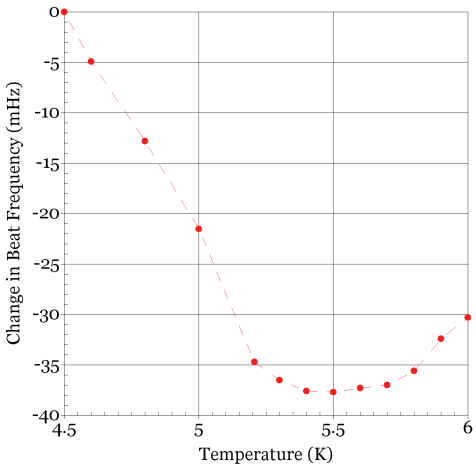

Fig. 1. Beat frequency as a function of sapphire loaded cavity temperature.

Power, frequency and temperature control loops are implemented using voltage controlled attenuators, phase shifters and heaters respectively. These control loops maintain oscillation at the desired mode and increase frequency stability.

III. Experiment Design and Rotation

Two sapphires are mounted orthogonally in the same copper block and are sealed within two vacuum cans to reduce thermal fluctuations. The cans are submerged in a 200 L liquid helium bath that allows for three weeks continuous operation. Three copper heatsinks provide a thermal path to the liquid helium (figure 2). The majority of the control electronics are housed at room temperature above the dewar. Ambient temperature fluctuations in the lab cause phase shifts in the microwave control electronics and may limit the beat frequency stability, the full impact of this effect is currently being analysed. The dewar is rotated with a period of 44 seconds on an air-bearing table that records angular position to within 350 μRads. Power

978-1-61284-110-6/11/$26.00 ©2011 IEEE

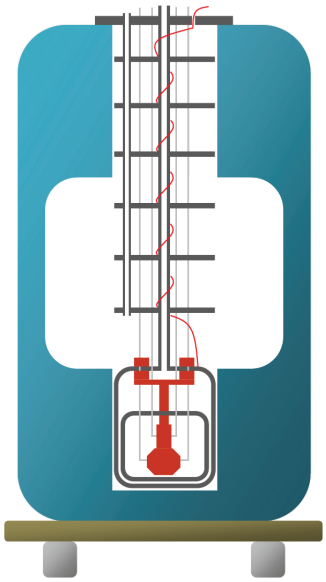

Fig. 2. Cross section of dewar containing liquid helium bath and two sapphire loaded cavities.

and electrical signals enter and leave the table via a rotating connector. A rotating mercury connector is used to bring the 10 MHz reference on to the table for the frequency counter and helium gas returns via a custom made rotating connector.

The table is mounted on three aluminium cylinders which in turn are each mounted on a pressure sensor. These are used to align the centre of mass with the rotation axis. A set of orthogonal tilt sensors are mounted in the middle of the table. Two of the aluminium cylinders are temperature controlled and thus thermally expanded to compensate for long term tilt variations. The experiment tilts up to 6 μRads during one rotation (figure 3) which is believed to be the underlying cause of the dominant systematic as the beat frequency oscillates in a similar manner. Stationary tests have found a beat frequency tilt sensitivity of 17 mHz / Degree which is not enough to limit the frequency stability of the beat. The previous experiment was rotated using a belt and stepper motor system and had no tilt compensation system.

IV. Frequency Stability and Future Work

For short integration times the frequency stability of the beat is limited by rotation induced systematics as can be seen by the hump at twice the rotation frequency in the Allan Deviation plot (figure 4). For longer integration times the frequency stability becomes similar for rotating and stationary results. The frequency stability at half the rotation period is lowered by over an order of magnitude compared to the previous experiment. We are continuing to investigate ways to increase the frequency stability.

The experiment will run for a full year and we anticipate being able to improve our bounds placed on Standard Model Extension coefficients by a factor of 75 compared to our

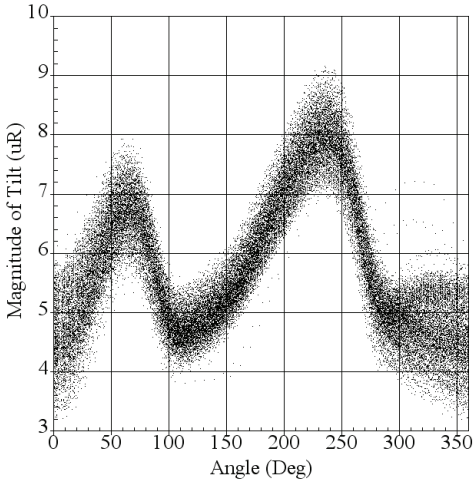

Fig. 3. Magnitude of tilt of experiment as a function of angular position. Data was collected over 1100 rotations.

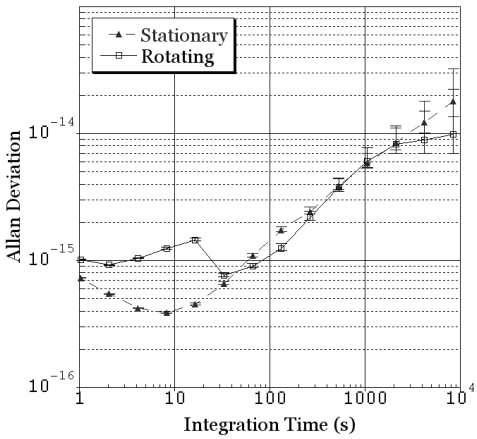

Fig. 4. Beat frequency stabilities with linear drift and $\sqrt{2}$ removed.

previous setup. After this run the cryogenic sapphire oscillators will be combined with a set of optical resonators for a joint experiment that will allow us to place bounds on a wider range of Lorentz violating coefficients [6].

Abstract— **We report on our studies of the light shift in a miniature atomic clock based on Coherent Population Trapping (CPT) in Cesium. There is no data published in the literature on the frequency and intensity-related light shift coefficients for CPT atomic clock on the Cesium D_1 line, only for the D_2 line. With our data we fill this gap and report on the measurements of light shift for the Cs D_1 line in a MEMS buffer-gas cell. The behavior of the light shift due to different laser intensities, laser frequencies and due to different cell temperatures is discussed.**

I. INTRODUCTION

Coherent Population Trapping (CPT) can occur in a Λ system in which the two hyperfine components of the $S_{1/2}$ ground state of an alkali atom are coupled to a common excited state by two laser fields that are nearly resonant with the two atomic transitions [1]. If the frequency difference of the two laser fields is close to the atomic hyperfine splitting of the two ground states, quantum coherence between the two hyperfine components will be effectively generated. This quantum coherence reduces the total absorption and fluorescence and, under certain conditions, atoms can be completely trapped in a so-called coherent dark state, where they do not interact with the light any more. CPT resonances can be very narrow, which makes them good candidates for the realization of atomic clock. For this application however, systematic shifts of the CPT resonance have to be understood and controlled.

In CPT, the presence of two resonant light fields not only couples the two atomic states but may also shift the relative position of the two energy states through the AC Stark effect. This "light-shift" depends on the frequency and intensity of the light and may be expressed as a function of the two coefficients α and β, often referred to as the intensity light-shift coefficient (α) and the frequency light-shift coefficient (β) [2]. In the case of CPT in an ideal three-level system with no decay of the ground-state coherence, significant light-shift suppression is expected. When a single-mode laser, frequency modulated in the GHz range is used to create the CPT signal, each component of its spectrum will contribute to the ground-states shifts. In principle, the two first order sidebands (which are used in this case for coupling the Cs ground states) will create frequency light-shifts of opposite signs and should therefore cancel out. However, second order effects and the shifts due to the carrier and to all the other laser sidebands create additional shifts resulting in non negligible light-shift. In some cases, all these contribution may cancel each other and result in a suppressed light-shift [3]. Here we show that this suppression can also be achieved with carefully selected cell temperature.

II. EXPERIMENTAL SETUP

The experimental scheme is shown in the Figure 1.

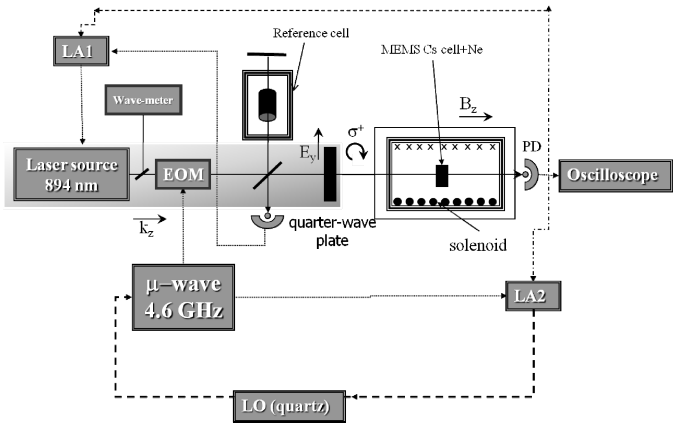

Figure 1. Experimental scheme

A DFB laser at 894.6 nm, resonant with the Cs D1 line is used as a light source [5]. Optical beam is modulated at ν ~4.6GHz by using a fiber-coupled Electro-Optical Modulator (EOM) and two phase-coherent electromagnetic fields, separated by 2ν ~ 9.2 GHz, are generated. In this case the two

This work was funded by EU FP7 (MAC-TFC project, no. 224132) and by the Swiss National Science Foundation (project 200020-118062).

first order sidebands (+ 1 and -1) are used to create the Λ-scheme. A beam splitter is placed directly after the EOM in order to split the laser beam in two different paths. One part of the beam is sent trough an evacuated macroscopic cell and the resulting absorption signal can be used to stabilize the laser frequency using a standard lock-in scheme. The second part of the laser beam is circularly polarized by a quartz-plate before passing through a MEMS Cesium vapor cell placed in the clock's Cs cell package. The Cs MEMS cell contains a Neon buffer gas and its external dimensions are 2.4 x 4 x 6 mm [4]. A photodiode is placed directly after the Cs cell package to detect the CPT signal. This signal can also be used to stabilize the laser frequency in alternative to the separate absorption setup. In this case, the laser is locked to a broadened line (Voigt profile resulting from Doppler and homogeneous broadening due to buffer gas). In the Cs cell package, the MEMS cell is temperature controlled and is surrounded by a solenoid generates a static magnetic field parallel to the light propagation vector to lift the degeneracy of the Zeeman sublevels. The ensemble is surrounded by 2 μ-metal magnetic shields to reduce perturbations from external magnetic fields. The cell temperature can be stabilized in a relatively wide temperature range (45 to 90˚C). A commercial frequency synthesizer (referenced to a Hydrogen Maser or to quartz a VCO – for spectroscopy or closed-loop clock mode, respectively) produces the 4.6 GHz microwave radiation.

III. EXPERIMENTAL RESULTS

We measured the light-shift as a function of the laser power at different MEMS cell temperature and the results are reported in Figure 2. In this case the laser frequency was locked using the buffer-gas MEMS cell and the measurements have been performed for two different situations of laser detuning: coupling the ground states through the F'=4 excited state or coupling through the F'=3 state. These two couplings are achieved by tuning the laser frequency to the optical transition involving the respective excited atomic state. The light-shift coefficient α is extracted as the value of the slopes of the line fits in Figure 2a and 2b.

In the case when the laser is locked to the F'=3 state, for lower temperatures the light shift coefficient α is negative. For higher temperatures, the light shift becomes positive. For cell temperatures around 82˚C, the light shift is significantly suppressed. In the case of F'=4 laser locking, light shift is always positive for any cell temperature and we did not find a temperature with suppressed light shift. Similar results were obtained in the case when the laser is locked to the separate evacuated macroscopic cell.

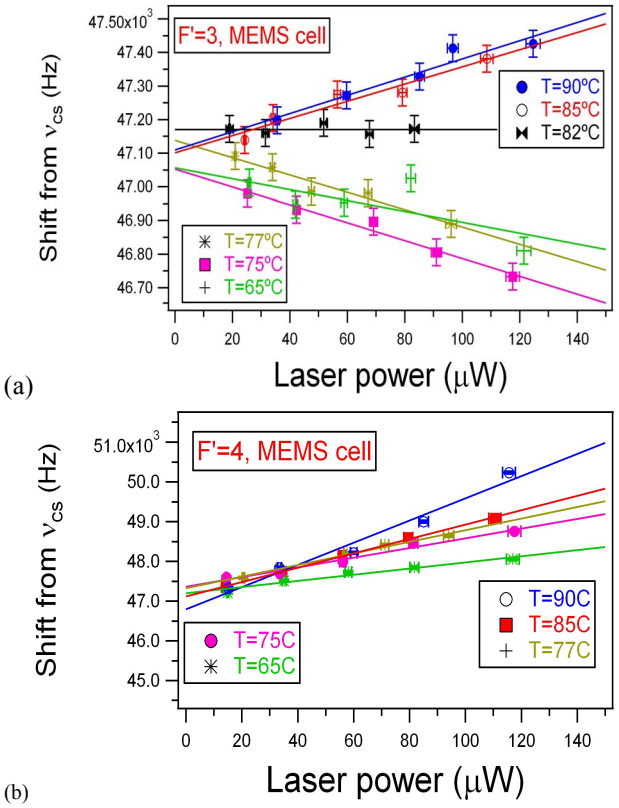

Figure 2. (a): Shift of the CPT line as a function of the laser power for laser frequency tuned to the F'=3 state. The measurements were repeated for different cell temperature (b): Same measurements like in Figure 2 (a) for laser frequency tuned to the F'=4 state.

Our results show that the intensity light-shift changes its sign with changing cell temperature (Fig 2a). With increasing temperature, the first order sidebands will be absorbed more strongly by the Cs atoms, reducing their average light intensity acting on the atoms in the cell. Thus the overall balance between positive and negative light-shift contributions from the different laser sidebands will change, as it is seen on our measurements.

We have demonstrated the impact of the reported light-shift reduction by recording the frequency stability of our clock. At time scales around ~ 1000 s we measured an improvement of clock stability by factor of 10, reaching the 8×10^{-11} level, by choosing the proper temperature of the buffer-gas cell [6].

IV. CONCLUSION

We presented the first experimental results on the light shift in a micro-fabricated cell filled with Cs and pure Ne buffer gas, for CPT spectroscopy on the Cs D1 line (at 894.6 nm). The light-shift is found to change the sign as a function of cell temperatures. A cell temperature was found for which

light shift is significantly suppressed. We previously demonstrated that a mixture of two buffer gases is not needed, because a turnover temperature around 80˚C can also be obtained with pure Ne as buffer gas [7]. This temperature coincides with the one suitable for the low intensity light-shift reported above, in the case when the laser is locked to F'=3 state. Furthermore, this temperature is also in the correct temperature range for operating a miniature atomic clock.

ACKNOWLEGMENTS

We thank our colleagues from LTF-UniNe for their contributions. We also thank V. Giordano and the team from FEMTO-ST CNRS-UFC, Besançon, France for helpful discussions.

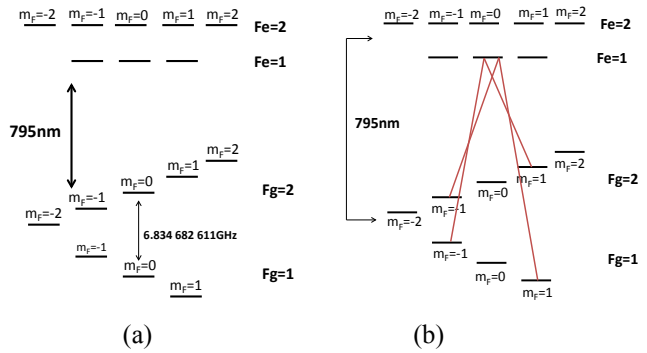
***Abstract*— We report on a comparative study on the light shift in two possible clock schemes for vapor-cell standards, Double Resonance (DR) and Coherent Population Trapping (CPT), by using the same wall coated cell and compact atomic resonator. Our experimental setup allowed us to measure and study the AC Stark shift, resulting from a mono-chromatic or a non monochromatic optical excitation. The light-shift was investigated as function of the laser intensity and the laser frequency.**

I. INTRODUCTION

The light-shift (or AC Stark shift) of the atomic clock transition is often one of the main sources of instability in vapor-cell atomic frequency standards ("Rb clocks"). Here we report on our investigations of the light-shift in two possible clock schemes shown in Fig. 1: Double Resonance (DR) interrogation (Fig. 1a) [1] and Coherent Population Trapping (CPT, Fig. 1b). The CPT resonances are created using the so-called lin//lin scheme [2, 3]. For the DR interrogation, the optical and microwave radiations are applied separately applied to the atoms, but simultaneously and in continuous mode, while for CPT the microwave frequency is imprinted onto the light field by frequency modulation. In both cases, the same laser wavelength was used (Rb D1 transition, 795 nm).



(a) (b)

Figure 1. (a): Double resonance scheme. (b) CPT scheme.

This work was funded by the Swiss National Science Foundation (project 200020-118062) and the European Space Agency (ESA). We also acknowledge the support from the ASRH (Association Suisse pour la Recherche Horlogère).

II. EXPERIMENTAL SETUP

The block diagram of the clock setup is shown in Fig. 2. Light from a compact laser head [4] is frequency-stabilized to the Rb D1 transition (795 nm) and passes through an Electro-Optical Modulator (EOM). Before irradiating the resonance cell, the laser beam is linearly polarized, and has a diameter of 5 mm. The vapor cell is 14 mm long and has 14mm diameter, contains pure 87-Rb, and its inner walls are coated with paraffin. The cell is placed inside a magnetron-type cavity in which the resonant microwave field has a TE011-like geometry, as described in [5]. A solenoid generates a static magnetic field parallel to the light propagation vector and the whole physic package is surrounded by 2 mu-metal magnetic shields. DR (resp. CPT) is obtained by injecting the microwave signal into the magnetron cavity (resp. the EOM).

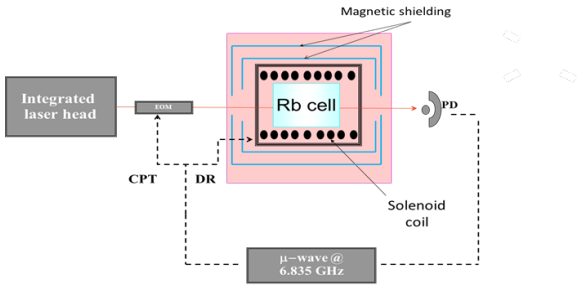


Figure 2. Block diagram of the experimental setup.

III. LIGHT SHIFT MEASUREMENTS

The clock transition may be shifted due to the AC Stark effect [6]. This shift depends on the spectrum of the optical radiation and may be expressed - in first and local approximation - as a function of the two coefficients α and β, often referred to as the intensity light-shift coefficient (α) and the frequency light-shift coefficient (β) [7]. These coefficients and the achievable laser frequency and intensity stabilities ultimately determine the eventual medium and long-term performance of the clock.

A. *Intensity light-shift coefficient (α)*

We measured the intensity light-shift as a function of the laser power at different laser detuning in both the DR and CPT clock schemes and the results are reported in Fig. 3 and 4, respectively. The measurements have been performed when locking the laser frequency to the four available sub-Doppler references (F_{ground} = 1, 2 to $F_{excited}$ = 1, 2). The light-shift coefficient α is given by the slopes of the line fits in Fig. 3 and 4. For instance, when locking the laser to the F_{ground} = 2 to $F_{excited}$ = 1 sub-Doppler transition, and the coefficients are $-7.5 \cdot 10^{-11}$/μW for the DR scheme and $-3.2 \cdot 10^{-11}$/μW for the CPT scheme, respectively.

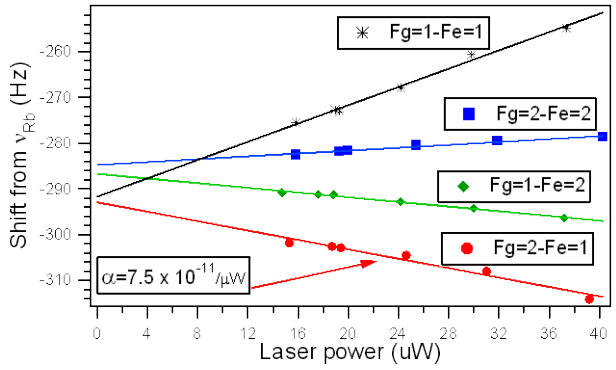

Figure 3. Shift of the DR line as a function of the laser power for laser frequency tuned to the 4 different laser detunings. Shifts are given relative to the unperturbed Rb hyperfine splitting frequency.

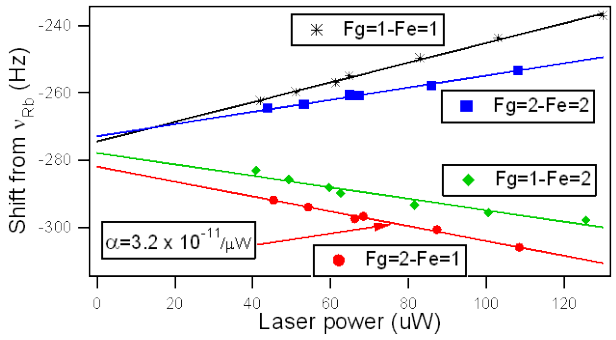

Figure 4. Shift of the CPT resonance as a function of the laser power (similar to the data of Fig. 3 but for the CPT scheme).

B. *Frequency light-shift coefficient (β)*

We also measured the shift of the clock transition as a function of the laser frequency for DR and for CPT. The results are reported on Fig. 5 and 6, respectively. Note that similar measurements were reported in [8], but not over such a large laser frequency scan and only for the case of a buffer gas cell. In Fig. 5, one may observe some differences as compared to the theoretical values presented in [9], in particular concerning the number of laser frequencies which give a zero-value intensity light-shift (we find two such laser frequencies instead of four occurrences given in [9]). Work is in progress in order to understand these differences and to analyze the analogue result for the CPT case.

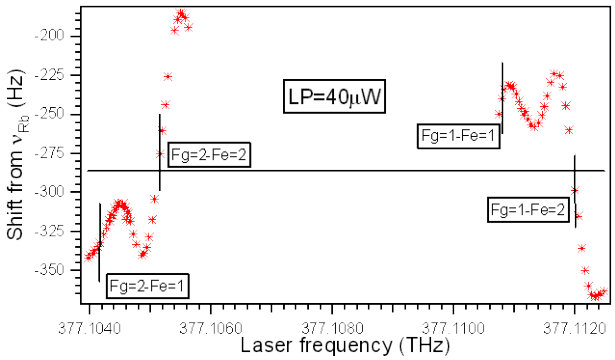

Figure 5. Shift of the DR line as a function of the laser frequency for the constant laser power of 40 μW.

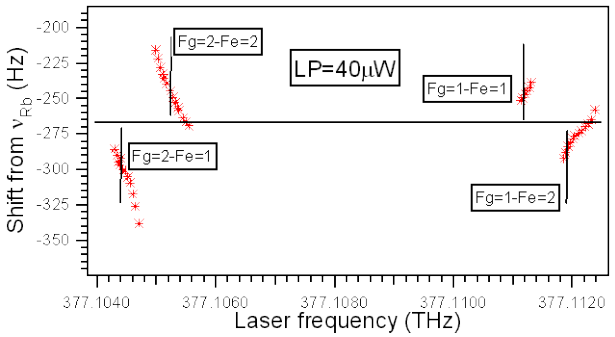

Figure 6. Similar measurements of β for the CPT clock scheme. Shifts are given relative to the unperturbed Rb hyperfine splitting frequency.

From the results shown in Fig. 5 and 6, one may extract the frequency light-shift coefficients (β) for any nominal laser frequency. For instance, when locking the laser to the F_{ground} = 2 to $F_{excited}$ = 1 sub-Doppler transition at an optical power of 40 μW, this coefficient is +310 mHz/MHz for the DR and -93 mHz/MHz for the CPT.

IV. Summary and Conclusions

We present our measurements and study of the intensity and frequency light shift in vapor-cell standards using a wall-coated cell and two clock schemes: DR and CPT. These results will be relevant in order to optimize the performances of a future compact atomic clock and determine its fundamental limits for medium and long-term stability.

Reduction of the Magnetic Sensitivity of an Atomic Clock Against the non-Uniformity and Variations of the C-field

Louis Marmet
Institute for National Measurement Standards

Email: louis.marmet@nrc-cnrc.gc.ca

***Abstract*— The frequency of an atomic clock may be stabilized against C-field variations by applying weak magnetic pulses tuned to the Larmor frequency. The small signal produced by these pulses is a Ramsey spectrum of the Zeeman transitions which, when added to the microwave Ramsey signal, may be adjusted to compensate exactly for the quadratic frequency shift of clock transition at a given value of the C-field. The cancellation is provided by a feed-forward mechanism which modifies the error signal without the need to adjust the C-field. This can be implemented in most atomic clocks by generating the required audio-frequency pulses on wires producing a magnetic field perpendicular to the C-field.**

I. Introduction

In an alkali-atom frequency standard, special care must be taken to produce a uniform C-field, stabilize it over extended periods of time and evaluate the large bias produced by the second-order Zeeman shift. The C-field can change for several different reasons such as variations of the external magnetic field, aging of the shield material, environmental temperature fluctuations, magnetization of the shields or hysteresis, mechanical shocks, and ageing of the electronic circuits. Because the frequency inaccuracy of an atomic clock is strongly dependent on the C-field, some methods have been proposed to reduce the magnetic field sensitivity. These methods can be classified by the type of mitigation used to reduce the magnetic field sensitivity. They fit into four general groups:

i) *Use atomic transitions with a weak dependence on the C-field.* The clock transition is selected to have a quadratic frequency dependence on the magnetic field and a weak magnetic field is used (e.g. the transition labeled 0-0, Fig. 1). A variation on this is to choose a large C-field value where the frequency dependence of the transition becomes null [1] (e.g. the transition between $|3,-1\rangle$ and $|4,-1\rangle$ labeled "$-1,-1$" in Fig. 1). However, this method requires an extremely uniform C-field and has not yet been implemented successfully.

ii) *Generate a very stable and uniform C-field.* Stable electronic circuits, permanent magnets and shielding offer possible methods to stabilize the C-field using passive stabilization or active feedback. A current generating the C-field can be stabilized to a constant value, magnetic shielding can be used to mitigate magnetic field variations, or permanent magnets can be used to generate the C-field. All these methods suffer from a large sensitivity on the temperature.

iii) *Use feedback from a measured value of the C-field.* Several methods have been proposed to measure the C-field and correct its value to keep it constant. One method proposes to use a dual frequency synthesizer [2] to run a clock at a high C-field while simultaneously measuring the C-field. Other methods involving some kind of adjustment to the C-field have been suggested [3]–[6]. However, it is known that such adjustments must be frequently applied because after a C-field change the frequency often relaxes back to almost where it started [7]. Most of the stability problems have been traced to the magnetic shields and their hysteresis effects. Measuring the C-field usually interferes with the operation of the clock, requires a complex system and affects the performance of the microwave system.

iv) *Use a feed-forward mechanism based on the value of the C-field.* For example, the "Multi-Coherent method" [8] uses a combination of many microwave and radio frequencies with optical pumping to achieve multiple measurements simultaneously. However, it only reduces the dependence of the frequency on the C-field by 33% (by using an average of all m_F states) and suffers from problems associated with an increased complexity of the microwave synthesizer which could affect the long-term frequency stability of the clock.

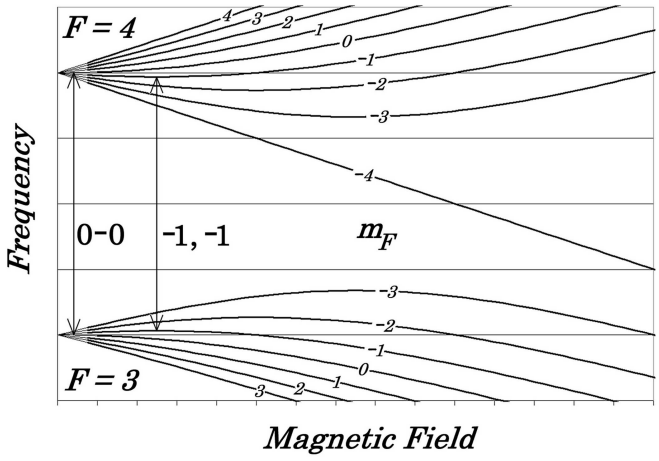

Fig. 1. Diagram of the hyperfine energy levels in a cesium atom. The relative frequency of each level is plotted as a function of the magnetic field.

The stabilization method presented in this paper is a feed-forward mechanism which does not require changing the C-field nor changing the current producing it by more than a very small amount. This keeps the system operating in a linear regime. The feed-forward mechanism is provided by a small asymmetry produced on the microwave Ramsey fringe by coherent transfer of a small amount of population between the Zeeman levels. Two weak rf magnetic pulses are generated at a frequency near the Zeeman splitting of the hyperfine sub-levels and applied to the atoms between the microwave pulses. The magnetic pulses produce rf Ramsey fringes which are dependent on the linear frequency splitting between the hyperfine Zeeman sub-levels. When the C-field changes by a small amount, this rf Ramsey signal causes a frequency pulling on the microwave Ramsey fringes which can be adjusted to compensate exactly the quadratic Zeeman shift. With the proper amplitude adjustment of the rf magnetic pulses, the clock frequency can be made independent of small variations of the C-field. A detailed description is provided below with numerical examples given for the two cases of a beam clock and a fountain clock.

II. Description of the method

Any change in the value of the C-field will affect the frequency of a clock because it is referenced to an atomic transition which has a quadratic frequency dependence on the magnetic field $f_{00} = C_1 \left\langle B^2(z(t)) \right\rangle$, where $\langle\rangle$ denotes the time average, $B(z(t))$ is the value of the C-field at position $z(t)$ along the trajectory between the two microwave Ramsey excitations, and C_1 is a constant determined by atomic properties (in cesium $C_1 = 42.745\text{mHz/nT}^2$). A variation of the C-field away from its nominal value B_0 produces a frequency deviation on the microwave Ramsey fringe $\delta_R = C_1 \left\langle B^2(z(t)) - B_0^2 \right\rangle$. For small variations of the C-field away from its nominal value $B_0 >> B(z(t)) - B_0$ the frequency deviation of the microwave Ramsey fringe is $\delta_R \cong 2B_0C_1 \left\langle B(z(t)) - B_0 \right\rangle$. Therefore, at a given value of the C-field and as long as the deviation is small, the frequency offset of the clock will depend linearly on the C-field deviation from its nominal value.

To compensate this linear dependence of the frequency offset of the clock, one can take advantage of the linear frequency dependence of the Zeeman transitions. Several methods already exist to measure the C-field using the linear frequency shift [9], [10]. However, these measurements interfere with the normal operation of the clock and are only performed during the evaluation phase of the clock. Also, the measurements have to be repeated periodically to monitor the value of the C-field. In the method presented here, only one initial measurement of the C-field is required before running the clock. The feed forward mechanism keeps the frequency of the clock independent of small variations of the C-field.

The feed-forward signal is produced by applying rf magnetic pulses at a frequency f_C tuned near the Zeeman frequency $f_Z = C_2 \left\langle B(z(t)) \right\rangle$, where C_2 is a constant determined by atomic properties (in cesium $C_2 = 3.5$ kHz/μT). The field of the rf magnetic pulses must be aligned perpendicular to the C-field in order produce transitions between the $m_F = \pm 1$ states. The rf magnetic pulses produce Ramsey fringes (see Fig. 2), but in this case the signal is as a function of $f_C - f_Z$. A variation of the C-field away from its nominal value B_0 produces a frequency deviation on the rf Ramsey fringe $\delta_Z = C_2 \left\langle B(z(t)) - B_0 \right\rangle$. Thus, the frequency deviation of the microwave Ramsey fringe can be expressed as a function of the frequency deviation of the rf Ramsey fringe $\delta_R = 2B_0C_1\delta_Z/C_2 = \epsilon\delta_Z$. With weak rf magnetic pulses, the rf Ramsey fringes can be adjusted to produce a "frequency pulling" equal to $-\epsilon\delta_Z$, thus compensating for the quadratic Zeeman shift.

Thus, this technique uses a rf Ramsey interrogation within a microwave Ramsey interrogation. Since the Zeeman frequency shift is much larger than the Ramsey shift ($1/\epsilon \simeq 6800$ for a typical field of $6\mu T$ in a commercial cesium beam clock), the rf-pulses need only to have a small amplitude such that only a small fraction of the population is transferred. Also, since the C-field is sampled by each atom along its individual trajectory, spatial variations of the C-field are canceled as well as temporal variations. Thus, this method stabilizes the frequency of an atomic clock against temporal variations of the C-field and its non-uniformity.

III. Implementation examples

For the examples given below, a commonly used measurement cycle is assumed in the atomic clock. The source of atoms produces atoms distributed between the possible atomic states $|F, m_F\rangle$. A state selector only transmits the atoms in the states $|3, m_F\rangle$ (the cesium atom is used for this description). Ramsey interrogation [11] is used to interrogate the atoms with two microwave $\pi/2$-pulses at a frequency f_{MW} near the hyperfine transition frequency f_{00} between states $|3, 0\rangle$ and $|4, 0\rangle$ (the 0-0 transition or the clock transition). For the detection, a second state selector only transmits the atoms which are in any of the states $|4, m_F\rangle$ before they reach the detector. A typical microwave Ramsey signal measured as a

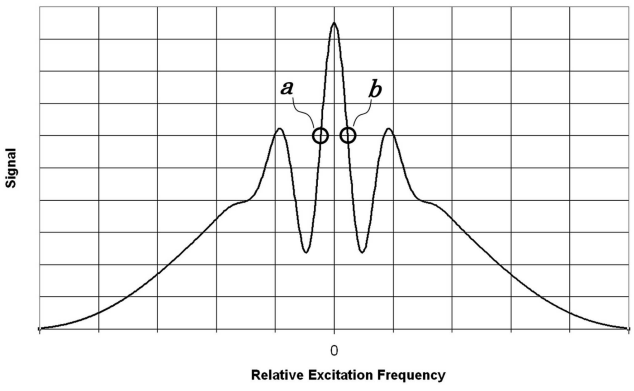

Fig. 2. Ramsey fringes and frequency points used by the locking circuit. The function is referred to as $R(f)$ in the text, with f being either the microwave frequency or the rf-detuning.

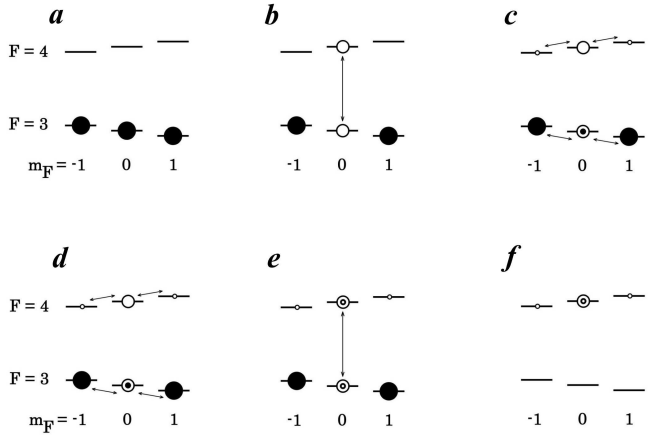

Fig. 3. Populations in a beam clock a) after the first state selector, b) after the first microwave Ramsey pulse, c) after the first rf Ramsey pulse, d) after the second rf Ramsey pulse, e) after the second microwave Ramsey pulse, and f) after the second state selector.

function of $f_{MW} - f_{00}$ is shown in Fig. 2. The local oscillator (clock frequency) is locked to the atomic reference using a frequency modulation scheme at the two frequencies *a* and *b* at $f_{MW} \pm \Delta_f$. The servo control adjusts the frequency of the local oscillator to keep the microwave Ramsey signals measured at points *a* and *b* at the same level. When this condition is met, the local oscillator is locked to the 0-0 transition, that is, f_{MW} is locked to f_{00}.

A. Compensation in a clock without magnetic state selection

This example describes the method as it could be implemented in a typical beam clock or in a fountain clock without state selection. The measurement cycle is assumed to start with all atoms in $F = 3$ states. Two rf magnetic field pulses, timed between the microwave Ramsey pulses, are applied on the atoms.

The states of interest for the microwave Ramsey interrogation are the states $|3, 0\rangle$ and $|4, 0\rangle$ (the notation $|F, m_F\rangle$ is used). Since the rf magnetic pulses have a small amplitude, these two states connect to the states $|3, -1\rangle$, $|3, 1\rangle$, $|4, -1\rangle$ and $|4, 1\rangle$. The contribution from the other states is negligible and not considered in this discussion. The population in each state is $a_{3\pm1}\,|3, \pm1\rangle$, $a_{30}\,|3, 0\rangle$, $a_{4\pm1}\,|4, \pm1\rangle$ and $a_{40}\,|4, 0\rangle$ (the populations are not normalized). Also, $\rho_{3\pm1} = |a_{3\pm1}|^2$, $\rho_{30} = |a_{30}|^2$, $\rho_{4\pm1} = |a_{4\pm1}|^2$, and $\rho_{40} = |a_{40}|^2$. Fig. 3 shows a diagram of the atomic populations, with cesium being used in this example.

a) After the first state selector, only the atoms with populated $|3, m_F\rangle$ states are transmitted. The populations are and $\rho_{3\pm1} = \rho_{30} = 1$ and $\rho_{4\pm1} = \rho_{40} = 0$.
b) The first microwave Ramsey pulse produces a coherent state-superposition between the states $|3, 0\rangle$ and $|4, 0\rangle$, with $\rho_{3\pm1} = 1$, $\rho_{4\pm1} = 0$, and $\rho_{30} = \rho_{40} = 0.5$.
c) The first rf Ramsey pulse produces several coherent state-superposition between the following states: $|3, -1\rangle$ and $|3, 0\rangle$, $|3, 1\rangle$ and $|3, 0\rangle$, $|4, -1\rangle$ and $|4, 0\rangle$, and $|4, 1\rangle$ and $|4, 0\rangle$. The resulting populations are $\rho_{3\pm1} = 1 - 3\epsilon/8$, $\rho_{30} = 0.5 + \epsilon/4$, $\rho_{4\pm1} = \epsilon/8$ and $\rho_{40} = 0.5 - \epsilon/4$. The value of ϵ is related to the amplitude of the rf magnetic field and is kept small (of the order of δ_R/δ_Z).
d) The second rf Ramsey pulse, is phase shifted by $\pi/2$ (that is, the rf frequency tuned to points *a* or *b* on Fig. 2) and produces more population transfers between the states: $|3, -1\rangle$ and $|3, 0\rangle$, $|3, 1\rangle$ and $|3, 0\rangle$, $|4, -1\rangle$ and $|4, 0\rangle$, and $|4, 1\rangle$ and $|4, 0\rangle$. The resulting populations are $\rho_{30} = 0.5 + \epsilon R(f_C - f_Z)$, $\rho_{4\pm1} = \epsilon R(f_C - f_Z)/2$ and $\rho_{40} = 0.5 - \epsilon R(f_C - f_Z)$, where $R(f_C - f_Z)$ is the Ramsey function plotted in Fig. 2.
e) The second microwave Ramsey pulse produces more population transfer between the states $|3, 0\rangle$ and $|4, 0\rangle$, resulting in the populations $\rho_{4\pm1} = \epsilon R(f_C - f_Z)/2$ and $\rho_{40} = R(f_{MW} - f_{00})$.
f) After the second state selector, only the atoms with populated $|4, m_F\rangle$ states are transmitted, resulting in the populations $\rho_{3\pm1} = \rho_{30} = 0$, $\rho_{4\pm1} = \epsilon R(f_C - f_Z)/2$, and $\rho_{40} = R(f_{MW} - f_{00})$.

Finally, the detector measures the total population resulting in a signal:

$$S = \sum_{F,m_F} \rho_{F,m_F} = R(f_{MW} - f_{00}) + \epsilon R(f_C - f_Z). \quad (1)$$

Without rf-pulses (e.g. $\epsilon = 0$), the detected signal would be $S_0 = R(f_{MW} - f_{00})$.

The feedback signal S uses the function $R(f)$ near the two operating points *a* and *b* (Fig. 2). A first order Taylor expansion of $R(f)$ gives the linear relation $R(f) = 1/2 + \beta(\Delta_f \pm f)$, where Δ_f is the offset frequency, the "+" sign is for point *a* and "-" is for point *b*. In order to compensate the frequency shift of the 0-0 transition, the contribution from the rf Ramsey signal is made negative by using a modulation which is out of phase with respect to the microwave modulation (i.e. when the microwave frequency is at point *a*, the rf-frequency is at point *b*, and vice versa.) The signal is then

$$S = \pm\beta[(f_{MW} - f_{00}) - \epsilon(f_C - f_Z)] + (1 + \epsilon)(1/2 + \beta\Delta f).$$

Using $f_{00} = C_1 B_0^2 + \delta_R$ and $f_Z - f_C = C_2 \langle B(z(t))\rangle - C_2 B_0 = \delta_Z = \delta_R C_2/(2B_0C_1)$, the signal is:

$$S = \pm\beta[f_{MW} - \delta_R(1 - \epsilon C_2/(2B_0C_1))] + K,$$

where K is a constant. The servo control modifies f_{MW} in order to keep the error signal S constant. The value of δ_R depends on the C-field, but with the appropriate choice $\epsilon = 2B_0C_1/C_2$, δ_R is multiplied by zero removing the dependence of the signal S on the value of the C-field.

Thus, by selecting the amplitude of the rf-pulses so that $\epsilon = 2B_0C_1/C_2$, the frequency deviation of the rf Ramsey signal will cancel the frequency deviation of the microwave Ramsey signal. The small value of $\epsilon < 0.0002$ needed for this method is to be contrasted to the large population transfer (effectively 100% or $\epsilon = 1$) used in [8] where the $m_F = 0$, ±1, ±2, etc. states are completely mixed by large rf-signals.

With the appropriate selection of the rf-pulses amplitude, the rf Ramsey signal added to the microwave Ramsey fringes

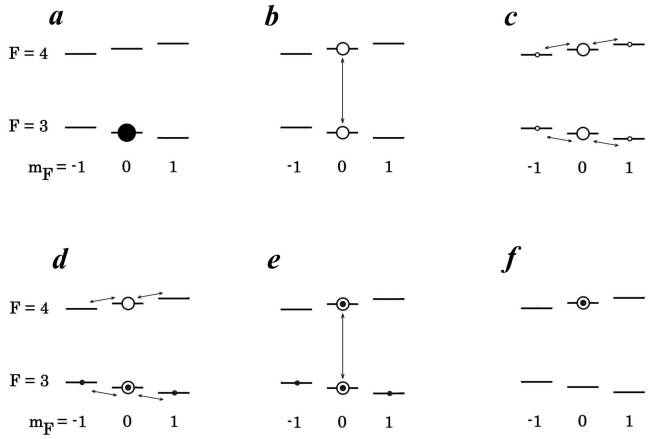

Fig. 4. Diagram of the populations in a fountain clock. The populations in the relevant states are shown by the circles: a) after the first state selector, b) after the first microwave Ramsey pulse, c) after the first rf Ramsey pulse, d) after the second rf Ramsey pulse, e) after the second microwave Ramsey pulse, and f) after the second state selector.

(the error signal steering the frequency of the clock) becomes independent of C-field deviations away from the nominal value determined by the frequency of the rf-oscillations f_C. Since the C-field is sampled by each atom along its individual trajectory (as represented by $\langle B(z(t))\rangle$), spatial variations of the C-field are canceled as well as temporal variations. Thus, this method stabilizes the frequency of an atomic clock against C-field non-uniformity and temporal variations by compensating for the quadratic frequency shift of transitions of the clock. The rf magnetic pulses produce a compensation directly at the level of the frequency servo loop. No feedback based on a measurement of the C-field has to be applied to the C-field dc-current.

Excitation electrodes producing a transversal field over the entire region of the C-field are assumed in this example. However, the excitation electrodes can also produce a longitudinal field over two short sections near the microwave excitation regions.

B. Compensation in a clock with magnetic state election

Some clocks use the initial state $|3,0\rangle$ at the beginning of the cycle, e.g. in some fountain clocks. In this case, the method takes advantage of the small difference between the Zeeman frequency splitting between the $|3,m_F\rangle$ states $f_{Z3} = C_3 \langle B(z(t))\rangle$ and the splitting between the $|4,m_F\rangle$ states $f_{Z4} = C_4 \langle B(z(t))\rangle$, where $C_3 = 3509.8$Hz/μT and $C_4 = 3498.6$Hz/μT in cesium.

a) After the state selector, the populations are $\rho_{30} = 1$, and $\rho_{3\pm1} = \rho_{4\pm1} = \rho_{40} = 0$. Fig. 4.
b) The first microwave Ramsey pulse produces a coherent state-superposition between the states $|3,0\rangle$ and $|4,0\rangle$, giving $\rho_{3\pm1} = \rho_{4\pm1} = 0$ and $\rho_{30} = \rho_{40} = 0.5$.
c) The first rf Ramsey pulse produces the populations $\rho_{3\pm1} = \rho_{30} = \rho_{4\pm1} = \epsilon/8$ and $\rho_{30} = \rho_{40} = 0.5 - \epsilon/4$. The value of ϵ is related to the amplitude of the rf magnetic field and is kept small (of the order of δ_R/δ_Z).

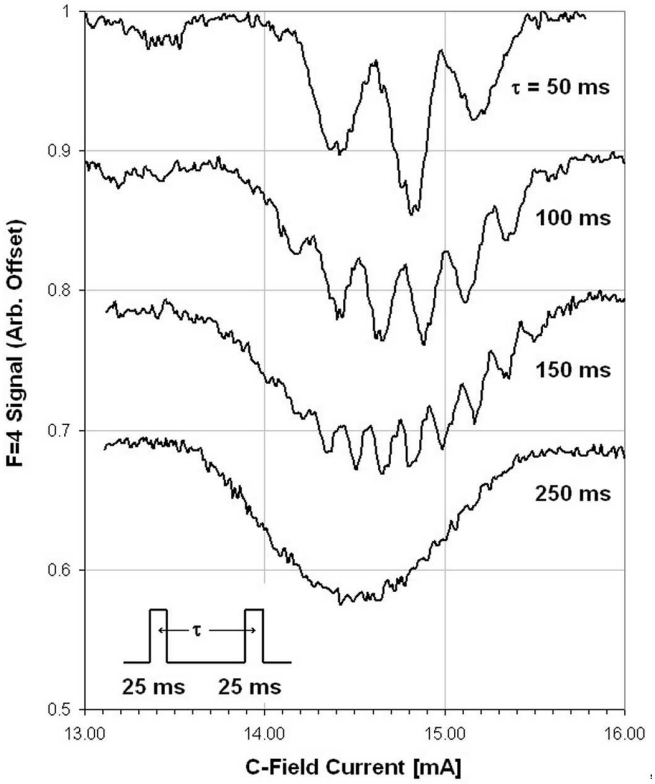

Fig. 5. Ramsey spectra of Zeeman states.

d) The second rf Ramsey pulse, is phase shifted by $\pi/2$ (that is, the rf is tuned to points *a* or *b* on Fig. 2). The resulting populations are $\rho_{30} = 0.5+\epsilon R(f_C - f_{Z3})$, $\rho_{4\pm1} = \epsilon R(f_C - f_{Z4})/2$ and $\rho_{40} = 0.5 - \epsilon R(fC - fZ4)$, where $R(f_C - f_Z F)$ is the Ramsey function plotted in Fig. 2 and f_{ZF} is f_Z calculated with the constants $C_2(F)$.
e) The second microwave Ramsey pulse produces the populations $\rho_{4\pm1} = \epsilon R(f_C - f_{Z4})/2$ and $\rho_{40} = R(f_{MW} - f_{00}) - \epsilon[R(f_C - f_{Z3}) + R(f_C - f_{Z4})]/2$.
f) After the pusher beam, $\rho_{3\pm1} = \rho_{30} = 0$ and only the atoms with populated $|4,m_F\rangle$ states are transmitted.

Finally, the detector measures the total population resulting in a signal $S = \sum_F \sum_{m_F} \rho_{F,m_F} = R(f_{MW} - f_{00}) + \epsilon[R(f_C - f_{Z4}) - R(f_C - f_{Z3})]/2$.

The feedback signal S is used in the same way as the signal of Eq. 1 with the correction term $R(f_C - f_{Z4}) - R(f_C - f_{Z3})$ providing the sensitivity on the C-field to be used as a first-order correction to the second-order Zeeman shift. One has to be careful to select an appropriate launch height/C-field combination for the technique to work.

IV. Measurement of the population transfer in a fountain clock

A measurement of the Ramsey fringes produced by rf magnetic pulses was made to demonstrate the technique. The launch height of the atoms was selected at 15cm above the Ramsey cavity. A pulse duration of 25ms was used with the rf pulse-pairs separated by different time intervals τ. Instead

of tuning the frequency of the rf-pulses, the current in the C-field electrodes was tuned to simulate a change in the value of the C-field. The results are shown in Fig. 5 for different times between the Ramsey pulses. As expected, the fringes become narrower as the time interval is increased. A shift of the central fringe with different time interval τ is the result of some C-field non-uniformity.

The contrast to the fringes decreases to zero when the time interval reached 250ms. This is due to the fact that with a C-field of 1.7mGauss, the Zeeman frequency splitting of the $F = 3$ states is 596.6Hz and the Zeeman frequency splitting of the $F = 4$ states is 594.7Hz. The ~ 2.0Hz difference implies that the states are in phase every 500ms, but are out of phase after 250ms.

V. Conclusion

The method presented in this paper improves the long term stability of a clock without adjustments of the C-field current. The rf magnetic oscillations produce a compensation directly at the level of the frequency servo loop. No feedback based on a measurement of the C-field is required to adjust the C-field dc current. The method also corrects for the spatial non-uniformity of the C-field since each atom individually probes the C-field along their respective trajectories. The method may be implemented in any atomic clock e.g. a fountain clock, a beam clock and in some cases, a hydrogen maser. The implementation is relatively straightforward and inexpensive. The long term stability of the microwave synthesizer is not compromised as this method does not require any modification of the microwave system. The method uses magnetic pulses in the audio frequency range of a few hundred Hertz which can be produced in most existing clocks using already existing coils. The stability of a clock is improved by a factor determined by the amplitude stability of the rf magnetic pulses.

Alternative Variables for Computing Sideband Pulling in Atomic Frequency Standards

Jon H. Shirley
National Institute of Standards and Technology
325 Broadway, Boulder, CO 80305

Abstract—Sideband pulling has long been considered a possible source of frequency bias in atomic frequency standards. We treat a two-level system excited by coherent radiation with amplitude and phase modulation. We create alternative variables to facilitate the second-order solution of the associated time-dependent Schrödinger equation. We extend earlier work to include time-dependent excitation and initial phase dependence.

I. Introduction

Frequency shifts due to the presence of sidebands on the exciting radiation have been of concern from the earliest days of atomic frequency standards [1]. Results valid for sidebands further removed from the carrier than the Rabi width were given long ago [2,3]. In 1978 Audoin et al. published a second-order result for the shift due to a single sideband valid for an arbitrary sideband separation [4]. Although this theory predicted a first-order shift, it was assumed to average to zero for the continuous signals from the atomic beam frequency standards of the time. Their result has been in use ever since to determine sideband intensity limits necessary to avoid a shift larger than other uncertainties.

With the advent of cesium fountains operating in pulsed modes, the possibility of modulation in synchronism with the cycling of the fountain signals was considered [5]. A deliberate application of synchronized phase modulation produced significant shifts in the primary standard NIST-F1 [6]. An accompanying theory agreed with the experimental results.

The purpose of the present paper is to extend the second-order results of Audoin et. al. to include contributions from synchronized pulsed operation and from two sidebands, equally spaced from the carrier, with arbitrary relative amplitudes and phases. Such sidebands may be re-expressed as the simultaneous application of amplitude and phase modulation at the same modulation frequency. We adopt this latter representation since amplitude and phase modulations interact with the dynamics of a two-level system in different manners. The primary focus of our analysis will be the dependence of any shifts on the initial phases of the modulations.

II. Background Theory

We begin with a two-level system excited by an electromagnetic field proportional to

$$B=\left[b+b_a\cos\left(\Omega t+\varphi_a\right)\right]\cos\left[\omega t-\left(b_p/b\right)\sin\left(\Omega t+\varphi_p\right)\right],$$

where $2b$ is the Rabi frequency for the excitation, and b_a and b_p are the corresponding Rabi frequencies for amplitude and phase modulation. These Rabi frequencies may be constant, or have time dependence. For half-sine-wave excitation we have $b(t)=(\pi/2)b_0\sin(\pi t/\tau)$. We assume b_a and b_p have the same time dependence as b. For a single sideband $b_a = b_p$ and $\varphi_a - \varphi_p = 0$ or π. When the rotating wave approximation is made, and the probability amplitudes are redefined by appropriate time-dependent phases to eliminate the rapid ωt time dependence [3,7], the resulting time-dependent Schrödinger equation for the system becomes

$$i\hbar\frac{d}{dt}\begin{pmatrix}\alpha\\ \beta\end{pmatrix}=\hbar\begin{pmatrix}-\Delta & B_{\text{rot}}{}^*\\ B_{\text{rot}} & \Delta\end{pmatrix}\begin{pmatrix}\alpha\\ \beta\end{pmatrix}. \qquad (1)$$

Here $\Delta=\frac{1}{2}(\omega-\omega_0)$ is half the detuning from the atomic resonance ω_0 and * denotes the complex conjugate. The coupling by the field is now represented by the complex quantity

$$B_{\text{rot}}=\left(b+b_a\cos\theta_a\right)\exp\left[-i\left(b_p/b\right)\sin\theta_p\right].$$

We have introduced the abbreviations $\theta_a=\Omega t+\varphi_a$ and $\theta_p=\Omega t+\varphi_p$. We impose on (1) the initial conditions at the beginning of excitation $\alpha(t=0)=1$ and $\beta(t=0)=0$. Then α is the probability amplitude that the system remains in its initial state and β is the probability amplitude that the system changes state. The Rabi transition probability is then $P(t)=|\beta(t)|^2$.

The corresponding Ramsey excitation probability is

$$P_{\mathrm{Ram}} = \left|\beta_{\mathrm{Ram}}\right|^2 = \left|\beta^{(2)}\right|^2 \left|\alpha^{(1)}\right|^2 + \left|\alpha^{(2)}\right|^2 \left|\beta^{(1)}\right|^2 + 2\,\mathrm{Re}\left(\gamma e^{2i\Delta T}\right),$$

where T is the period between the two excitations, and the coefficient γ is defined as

$$\gamma = \alpha^{(2)}\beta^{(2)}\alpha^{(1)}\beta^{(1)}\,*. \qquad (2)$$

The superscripts refer to the first and second excitation regions, respectively. The two excitations are assumed identical, except that the initial phase of both modulations has advanced by $\Phi \equiv \Omega(T+\tau)$ for the second excitation.

The presence of the perturbing modulations causes a frequency shift given by

$$2\Delta_{\mathrm{res}} = \frac{\mathrm{Im}\,\gamma}{T\,\mathrm{Re}\,\gamma},$$

If we expand γ, defined by (2), in powers of the perturbation (subscripts) to second order, we find

$$2\Delta_{\mathrm{res}} = \frac{\mathrm{Im}\,\gamma_1}{T\,\mathrm{Re}\,\gamma_0} + \frac{\mathrm{Im}\,\gamma_2}{T\,\mathrm{Re}\,\gamma_0} - \frac{\mathrm{Im}\,\gamma_1\,\mathrm{Re}\,\gamma_1}{T\left(\mathrm{Re}\,\gamma_0\right)^2}. \qquad (3)$$

The imaginary part of γ_0 was omitted because it is an odd function of Δ and merely makes a small change in the value of T in the denominator (cf. Sec. 3.2 in [7]). Note that the first-order correction to the denominator makes a contribution in the last term. To find the perturbation expansion of γ we need the perturbation expansions of α and β. These are difficult to derive from (1).

III. Alternative Variables

To simplify the derivation of the perturbation expansion we define alternative variables as follows:

$$W(t) = e^{ia(t)}\left[\mathrm{Re}\,\alpha(t) + i\,\mathrm{Im}\,\beta(t)\right]$$
$$\text{and } Z(t) = e^{-ia(t)}\left[\mathrm{Re}\,\beta(t) - i\,\mathrm{Im}\,\alpha(t)\right],$$

where a(t) is defined as the integral of b(t). The variables paired in the definitions are those coupled by the excitation. The exponentials in the definitions incorporate the unperturbed, on-tune evolution of the two level system. These new variables obey the same normalization criterion as α and β:

$$\left|W(t)\right|^2 + \left|Z(t)\right|^2 = 1.$$

In terms of these variables the Rabi transition probability becomes

$$P = \tfrac{1}{2} - \tfrac{1}{2}\left[\mathrm{Re}\left(e^{-2ia}W^2\right) - \mathrm{Re}\left(e^{2ia}Z^2\right)\right].$$

These alternative variables obey the following two differential equations:

$$dW/dt = -i\Delta e^{2ia(t)}Z + ib_a\cos\theta_a(t)W - b_p\sin\theta_p(t)e^{2ia(t)}Z$$

and

$$dZ/dt = -i\Delta e^{-2ia(t)}W - ib_a\cos\theta_a(t)Z + b_p\sin\theta_p(t)e^{-2ia(t)}W$$

where $a(t)$ may be defined by a third simultaneous differential equation,

$$da/dt = b(t).$$

If these differential equations are multiplied by i, they form a Schrödinger-like pair with a two-by-two hermitian Hamiltonian. In the absence of detuning and the perturbation, the right-hand side vanishes. The variables W and Z then remain constant, equal to their initial conditions $W(0)=1$, $Z(0)=0$. Solutions in powers of the perturbation reduce to straightforward integrals.

IV. First-Order Shifts

For small shifts of the Ramsey resonance we may ignore the detuning in the excitation regions. The first-order solution for W is then due only to amplitude modulation,

$$W_1(\tau) = -i\int_0^\tau b_a(t)\cos\theta_a(t)\,dt,$$

and for Z is due only to phase modulation:

$$Z_1(\tau) = \int_0^\tau b_p(t)\sin\theta_p(t)e^{-2ia(t)}dt.$$

Although the expressions for the real and imaginary parts of γ in terms of the alternative variables are complex, their perturbation expansion is simpler, because the zero-order values of W and Z are their initial conditions. Thus we find

$$\mathrm{Im}\,\gamma_1 = -\tfrac{1}{2}\sin 2a\left[\mathrm{Re}\left(Z_1^{(1)}\right) - \mathrm{Re}\left(e^{2ia}Z_1^{(2)}\right)\right],$$

where the argument of a is understood to be the excitation period τ. The real part of γ_0 is $\sin^2 a\cos^2 a$. When we insert the integrals, apply a trigonometric identity, and substitute into (3), we obtain the first-order shift

$$\delta\omega_1 = \frac{-4}{T\sin 2a}\left[I_{CC}\cos a\sin\tfrac{1}{2}\Phi + I_{SS}\sin a\cos\tfrac{1}{2}\Phi\right]\cos\left(\tfrac{1}{2}\Phi + \varphi_p\right). \qquad (4)$$

The integral I_{CC} is given by

$$I_{CC} = \int_0^{\tau} b_p(t)\cos\Omega(t-\tau/2)\cos\left[2a(t)-a(\tau)\right]dt.$$

The integral I_{SS} is the same except that both cosines are replaced with sines. This result is valid for excitations symmetric about their half-way point. For asymmetric excitation additional integrals are required. The integrals can be done analytically for constant excitation to yield the previously published result [6]. They can be easily done numerically for half-sine-wave excitation.

The first-order shift given by (4) has a sinusoidal dependence on the initial phase and a rapid oscillation with the sideband offset due to the phase advance Φ between excitation regions. Figure 1 shows the envelope of this rapid oscillation for both constant and half-sine-wave excitation when the final cosine is replaced by unity.

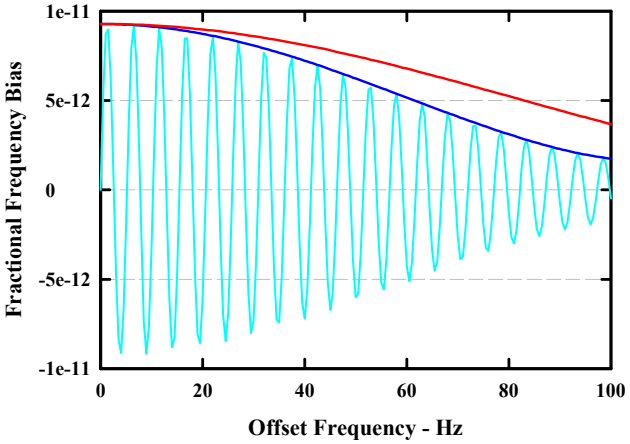

Figure 1. First-order sideband pulling. The light blue curve is for rectangular excitation. The dark blue curve is its upper envelope. The red curve is the envelope for half-sine-wave excitation.

V. Second-Order Shifts

The second-order shift can be found in a similar, if more laborious, fashion. The imaginary part of γ_2 has contributions from the second-order solution for Z and the product of first-order contributions from Z and W. These contributions involve the product of $\cos\theta_a$ and $\sin\theta_p$ at different times. A trigonometric identity allows this product to be written

$$2\cos\theta_a(t)\sin\theta_p(t') = \sin\left(\Omega t + \Omega t' + \varphi_a + \varphi_p\right) - \sin\left(\Omega t - \Omega t' + \varphi_a - \varphi_p\right).$$

Therefore the second-order shift will depend only on the sum and difference of the initial phases and not on their individual values. When the computations are carried out, the shift from the second term in (3) has the form

$$\delta\omega_2 = \frac{b_a b_p}{Tb^2}\left[\begin{array}{l} Q_0\cos\left(\phi_a-\phi_p\right)+\left(Q_C\cos\Phi+Q_S\sin\Phi\right)\cos\Theta \\ +\left(R_C\cos\Phi+R_S\sin\Phi\right)\cos\left(\phi_a-\phi_p\right)+R_0\cos\Theta \end{array}\right],$$

where $\Theta = \Phi + \Omega\tau + \varphi_a + \varphi_p$. This shift is due to the combined action of phase and amplitude modulation. The coefficients are sums of integrals depending on $a(\tau)$ and $\Omega\tau$, but of order unity. The Q coefficients arise from the interactions within each individual excitation region. The R coefficients arise from the interference between the first-order interactions in the two excitation regions. The terms with coefficients Q_C, Q_S, and R_0 do not contribute to the shift when the initial phases are averaged. But the remaining terms survive when φ_a - φ_p is constant. The Q_0, R_C, and R_S coefficients are the ones computed for constant excitation by Audoin et. al. [4]. We have verified their results except that they did not include τ in Φ. The power dependence of their results was discussed in [5]. We note that these terms vanish if $\varphi_a - \varphi_p = \pm\pi/2$, the same condition that makes the two sidebands have equal intensity.

For atomic beam standards the last term in (3) vanishes, since the initial phase dependence in $\mathrm{Re}\gamma_1$ averages to zero. However, if this term is added in, as may be needed for pulsed standards, the Q coefficients are modified, but the R coefficients cancel out. Thus if the shift is then averaged over initial phases, only the Q_0 term survives and there is no Ramsey-like oscillation in the shift. The modified Q_0 term is plotted in figure 2 for both constant and half-sine-wave excitation.

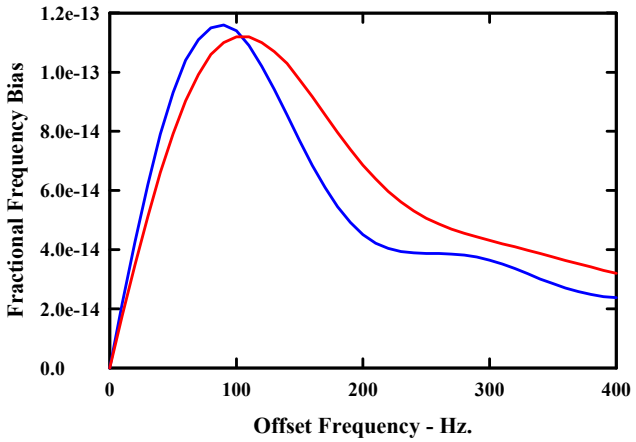

Figure 2. Second-order sideband pulling—initial phase-independent part. The blue curve is for constant excitation. The red curve is for half-sine-wave excitation.

SUMMARY

We have theoretically studied sideband pulling in atomic frequency standards in terms of amplitude and phase modulation. We have introduced alternative variables to simplify a perturbation treatment of the modulation. We find the first-order pulling, generated by phase modulation, for both constant and half-sine-wave excitation. We find the second-order pulling is generated by the combined action of phase and amplitude modulation. We report the initial-phase and Ramsey-time dependence of the second-order shift.

Abstract -- **In this paper, the study advances of a high performance rubidium atomic frequency standard (RAFS) will be reported. The RAFS is a traditional passive rubidium frequency standard. Some important performance test results have been obtained. The RAFS has realized short-term stability of <1.5E-12/1s , and long-term stability of <2E-14/1d**.

I. INTRODUCTION

The investigations of a high performance rubidium atomic frequency standard (RAFS) will be presented. This RAFS is a traditional passive gas-cell rubidium frequency standard. While its physics package employs a novel slotted-tube microwave cavity [1], and uses the separated filter technique (SFT). This kind of physics package features high signal-to-noise ratio, and low light frequency shift [2].

We have made a lot of experiments and tests with the RAFS unit, such as frequency stability, drift, phase noise, harmonics, spurious, magnetic sensitivity, and so on. Some important RAFS specifications have been obtained. The recent test results suggest that RAFS has realized short-term stability of <1.5E-12/1s , long-term stability of <2E-14/1d, and frequency drift of <3E-13/1d.

II. PRINCIPLE AND CHARACTERISTIC

Figure 1 shows a principle block diagram for our rubidium atomic frequency standard. The design of it is a typical gas-cell RAFS schedule. The physics package acts as a very stable frequency discriminator for a frequency around 6.834GHz. By using a frequency synthesizer and two frequency multipliers that are referenced to the 10MHz VCXO, the 10MHz output frequency can be stabilized to the rubidium hyperfine transition frequency.

The novel physics package mainly consists of cavity-cell assembly [3], spectral lamp, C-field and temperature controller, microwave frequency multiplier, and preamplifier. The cavity-cell assembly employs a patented slotted-tube microwave cavity, and utilizes the separated filter technique (SFT) .The slotted-tube microwave cavity has some advantages of higher cavity Q factor, large microwave filling factor, and can obtain a higher signal-to-noise ratio for the physics package.

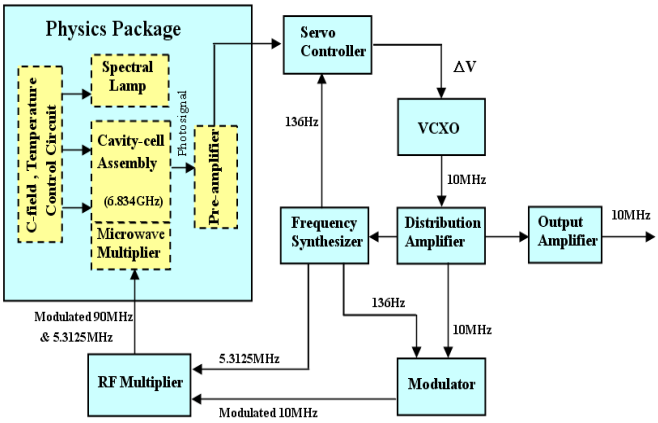

Figure 1. RAFS Principle Block Diagram

Light shift (LS) and temperature coefficient (TC) are the most significant factors that affect the long-term stability of a RAFS. The SFT design of the physics package enables us to deal with the gas parameters of absorption cell and filter cell separately, and buffer gas pressures in both cells can be optimized for the minimum LS and TC.

The spectral lamp is a RF-discharge lamp for optical pumping and detecting, it operates at about 110MHz. The

photosignal is amplified and filtered before being delivered to servo control circuit.

The servo controller is responsible for, synchronously detecting the amplitude and phase of the photosignals at 136Hz and 272Hz, and filtering the error signal to lock the 10MHz VCXO to the rubidium hyperfine transition.

Both the 5.3125MHz signal and the 136Hz phase modulation waveform are generated by the synthesizer. The modulated 10MHz signal is converted to 90MHz signal by RF multiplier. The two signals of 90MHz and 5.3125MHz are input to the microwave multiplier together.

The microwave multiplier is a SRD high-order harmonic frequency multiplier to complete 76th frequency multiplication from 90MHz to 6840MHz, meanwhile it also plays a role of frequency mixer to make frequency subtraction between 6840MHz and 5.3125MHz. Finally it will produce 6834.6875MHz microwave field in the cavity for exciting ^{87}Rb hyperfine transition. The microwave frequency multiplier has no independent resonating cavity, but shares the same slotted-tube cavity with ^{87}Rb atom transition microwave resonator.

III. MAIN PERFORMANCES TEST

After the RAFS unit has been completed, and its operating parameters have been optimized. We conducted some performance tests with RAFS unit.

The short-term frequency stability performance of the RAFS has been reported on the EFTF-IFCS-2009 conference [3]. In this paper, the long-term stability test result will be presented. Figure 2 shows the set-up for RAFS long-term frequency stability measurement.

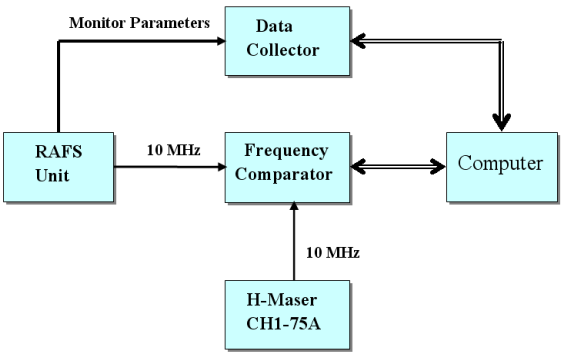

Figure 2. Set-up for RAFS Frequency Stability Test

The reference source used for RAFS test is the KVARZ active hydrogen maser CH1-75A which has an excellent frequency stability of <1E-15/1d. The frequency curve of RAFS is showed in Figure 3, about 78 days test data were collected with a sample period of 10 seconds, from 24 May 2010 to 12 August 2010. The frequency stabilities were calculated with the last 40 days test data in Hadamard deviation. The stability curve of Figure 4 indicates that the RAFS unit has achieved long-term frequency stability of 2.6E-14/10000s and 1.3E-14/1d, while its frequency flicker floor is around of 1.2E-14 level.

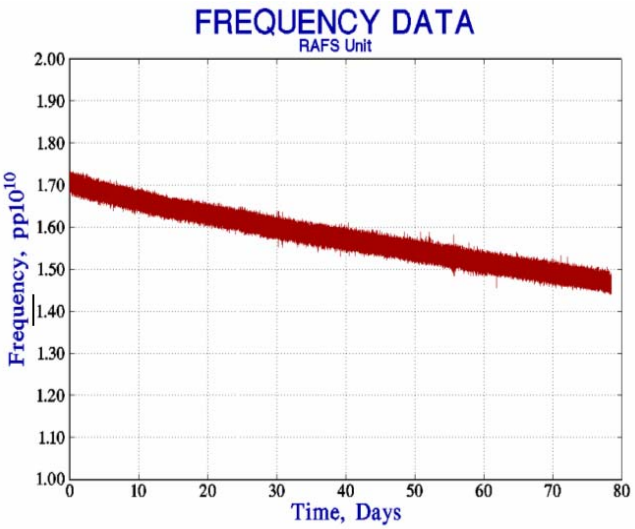

Figure 3. RAFS Frequency Test Curve

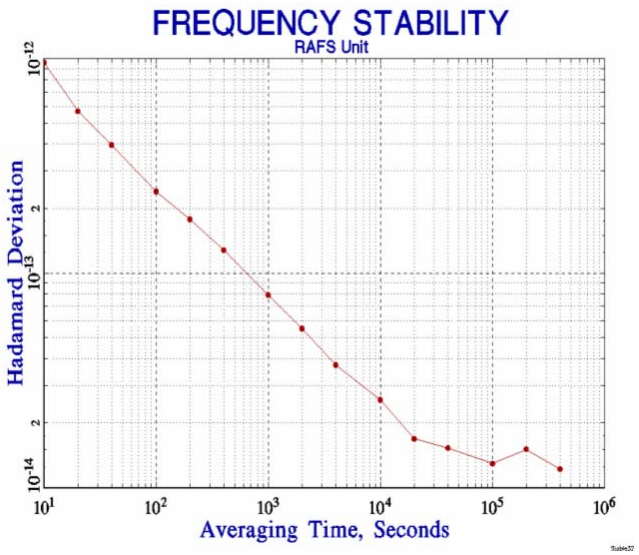

Figure 4. Frequency Stability of RAFS Unit

Based on calculation of the last 20 days data, the frequency drift is 2.5E-13/1d, which still tends to decrease as RAFS unit continue to work. It can be estimated that the drift will finally arrive to 1E-13/1d level or better.

Figure 5 presents phase noise curve of RAFS unit, measured by PN9000 phase noise test system. The measured results suggest that RAFS has a low phase noise, from 1Hz (<-95dBc) to 10kHz (<-147dBc).

The RAFS unit has obtained a low magnetic sensitivity of 1.2E-13/Gauss, benefits from the microwave cavity shielding scheme of three layers mu-metal.

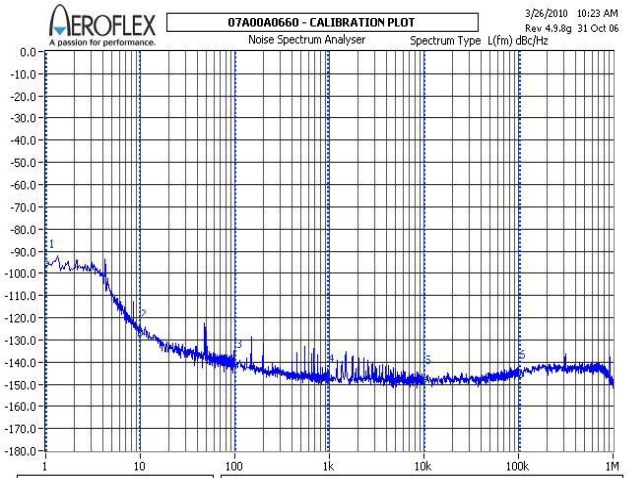

Figure 5. Phase Noise of RAFS Unit

IV. CONCLUSION

We have developed a gas-cell rubidium atomic frequency standard with a novel physics package. The performance test results indicate that the RAFS unit has achieved good frequency stabilities, the short-term stability is of $<1.5E\text{-}12/\tau^{1/2}$ ($1s \leq \tau \leq 1000s$), the long-term stability is of <2.0E-14/1d, and its frequency flicker floor is around of 1.2E-14 level. The RAFS unit also has low phase noise and low magnetic sensitivity.

An Ultra-Miniature Rb Atomic Clock Compatible with OCXO

Yuanhong Cao, Lin Yang, Qifang Li, Haiqing Zhao, Qiaoli Lin, Runchang Du
Spaceon Co. Ltd., Chengdu, China
thomascyh@hotmail.com

Abstract—**This paper shows a traditional Rubidium atomic clock – XHTF1031. The incorporate lamp and ultra-miniature waveguide cavity introduced in the physics package is the main means to downsize the volume of the clock; the electronics consisting of 6.8GHz direct synthesizer and digital servo system is to enhance the automatic functions which ensure massively fabrication available with low costs. At all, the clock has the physical dimensions of a ovenized crystal oscillator (OCXO), measuring 51mmx51mm (2'x2') and standing at a mere 25mm (1'). The Allan deviation of instability is 3E-11/s; the temperature coefficient is 3E-10 in the range of -20~60℃; the frequency aging is below 5E-12/d. The clock has the same dimension and pins' definitions with OCXO used in telecom, but higher performance, and would be popularly used in telecom equipments and base-stations instead of OCXO in future.**

I. INTRODUCTION

Traditional Rubidium atomic clock with a combination of high performance and volume has large engineer value and hearty life until now. Comparing with Hydrogen clock and Cesium clock, compact rubidium atomic clock with merits in aspect of low power, small dimension and excellent precession, is one of the most popular atomic clocks, and bulkily used in Telecom, IP-TV, time-keep system and the Global Navigation Satellite Systems (GNSS), Especially IEEE1588 protocol offering several nanoseconds of web synchronization [1]. In the above area, compact atomic clock will used instead of OCXO partly.

Rubidium clock uses optical pumping by an Rb spectrum lamp to create a population inversion between the ground state hyperfine energy levels F=2 and F=1 in absorption cell [2]. If the atoms of absorption cell are interrogated with microwave radiation, the change in light transmission through the cell can be checked by optical diode, and a discriminating signal in the light is to lock OCXO in the atomic clock. Employing the two naturally-occurring isotopes ^{85} Rb and ^{87}Rb is to enhance the efficiency of the optical pumping by a fortuitous overlap between the two optical absorption lines; and similarly, filling buffer gas (such as N2, NH4) to narrow the line width of the absorption of the clock transition between (F=2, m_F=0) and (F=1, m_F=0). Therefore, the Rb atomic clock has higher Signal-to-Noise ratio and more outstanding short-term ability. There is no vacuum system in Hydrogen clock and Cesium clock, therefore Rb clock has more viable in commercial fields.

When it comes to developing compact rubidium atomic, the most important work is to downsize the dimension of physics package of the clock, including lamp and cavity. In general, the effective means is to pay more attention to the latter than the prior, as for the cavity is the big part in Rb clock. In comparison, the prior can not be indefinitely reduced because of high temperature and exciting RF circuits located in it. Basing On traditional gas cell Rb clock scheme and different cavities, several Rb clocks as a module have been manufactured by Symmetricom, FEI, Spectratime in the world. In China, Xing Hua Time and Frequency (XHTF) joining in Spaceon at present has about forty years history in professional development of Rubidium clock. Until now, Spaceon has an outstanding achievement in miniature Rubidium clock, and designed a smallest gas cell Rb clock XHTF1031 in the world. The XHTF1031 is designed by new physics package and electronics, and has the same typical performances with the above-mentioned clocks. The detailed techniques are presented as below.

II. PHYSICS PACKAGE

A. Lamp

CLAPP oscillator has a high stability, and can be used as the driving circuit of the spectrum lamp [3]. The frequency of the oscillator is decided by L made up of a coil around the bulb, and by C which is in series with the coil. Because of high frequency scaled 100MHz, the distributing parameters will occur while the circuit is placed in the lamp oven. There is the optimal value of the L and C which need to be tuned in an extent. In order to cancel the temperature coefficient of the circuits, a diode is added in parallel with the b-e loop of transistor in the circuit, which would improve fluctuation and aging of Rb clock.

The configuration of assembling the parts to shape the architecture of the spectrum lamp mainly decides the size itself. In general, bulb and exciting circuits are deigned separately as two parts. As is known, the temperature coefficient is added by transistor in the circuits. Taking the

No. 2010XM161, principal technical term, Sichuang, China.

transistor into the case of lamp can be resolved. The spectrum lamp is called incorporate lamp. In the architecture, the bulb of lamp is held into solenoid and together inserts into a bold which is designed by Teflon which ensure the light density stable. All of these are fixed into a case which is designed by aluminum. The PCB is laid into the case simultaneously. In this way, the electromagnetic radicalization can be shielded effectively. Therefore, the power dissipation can be used to heat up the lamp, and the power of the lamp which is capable of reducing at an extent. In a word, the bottleneck in the aspect of the coefficient, the size and the power dissipation has been resolved in the incorporate lamp. The final appearance of the lamp is shown in Fig. 1.

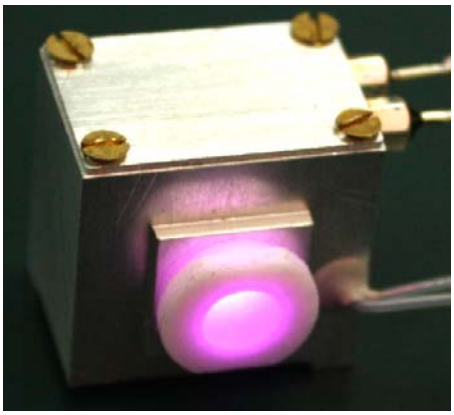

Figure 1. The lamp removed from the clock XHTF1031.

In the process of fabricating lamp, the bulbs are aged with high RF power and high temperature firstly. Secondly, the lamp will be supplied with higher voltage than it being in normal work. All the steps can ensure to fabricate lamp in bulk.

B. cavity

In Rb atomic clock, cavity is a container where absorption cell is located in. Generally, the cavity made of metal, such as copper or aluminum, is resonant with the microwave of atomic transitive frequency from synthesizer which is to interrogate atoms in the absorption cell in order to result in discrimination signal. At this rate, the volume of the resonant cavity is the biggest hamper while developing miniature Rb clock.

To reduce the size of cavity in Rubidium atomic clock, there are several types of cavity as below. The first is cylinder cavity of TE111 model, sometimes filled by Al_2O_3 ceramic [4]. Obviously, this cavity has too small Q quality to bring on poor short-term frequency instability while developing Rb clock by it. The second is magnetron cavity whose mode is similar to TE011, and has high Q quality. The cavity has been used in Hydrogen clock in advantage. But the complex architecture and difficulty in production by machine hamper its expanding to compact Rb clock.

Telecom technology brings digital synthesizer to microwave frequency band, and several synthesizers beyond 7G occur nowadays. The synthesizer has the ability to output the enough power level of 6.8GHz to interrogate atom. So, the cavity has no necessity to be resonant with atomic frequency.

Waveguide port is the avenue for microwave transmitting in a model. One port of the waveguide is enclosed as an emission source, and other port is enclosed excluding a hole laid in the center of bottom as the diaphragm the lamp light goes through. Simultaneously, absorption cell insets into the space in the cavity. In this way, one cavity is shaped in the Rb clock. While designing the cavity, the parameters including diameter and length must be calculated. Due to the boundary abnormity from absorption cell and the hole, the simulation in magnetism is necessary and effective auxiliary tool to calculate the parameters. The simulating is as in Fig. 2.

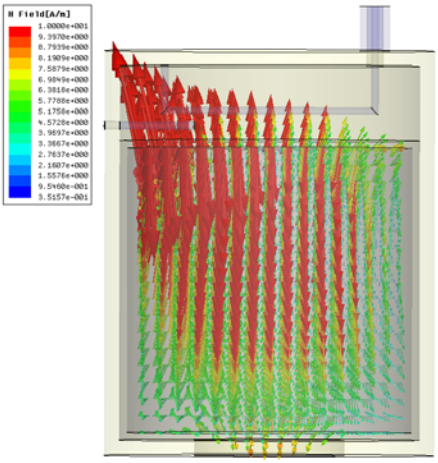

Figure 2. The Cavity of theRb atomic clock XHTF1031.

In Fig. 2, magnetic excitation is from a loop coupling the 6.8GHz microwave. In order to make excitation higher than electricity, there is a special hemicycle soldered with the coupling loop. A bolt made specially is to screw in and out to compensate the boundary abnormity in the cavity after inserting absorption cell. By the design, the tolerance of absorption cell size is bigger than the previous, and the cavity is more available to fabricate in bulk. There is no ceramic in side of the cavity; therefore the lower weight and higher performance in vibration and shock are implemented. In fact, the power level range of -20 to 0 dBm from frequency multiplier is ok to the cavity with screwing the bolt. In addition, the waveguide cavity is made of permalloy metal so as to reduce frequency shift resulted from magnetism.

III. ELECTRONICS

Electronics in Rb clock consists of frequency multiplier which is to multiply 10MHz from OCXO or TCXO to 6.8GHz, and servo which is to synchronously check and output an error to lock VCXO.

A. Frequency Multiplier

Traditional frequency multiplier is designed with step recovery diode (SRD), while SRD has the special property whose capacitance has different quality on the tradition while voltage shifts from positive to negative. 6.8GHz microwave to excite atom is from the high order harmonic wave by SRD. In this way, the resonance cavity must be used as the selective loop to enhance the 6.8GHz microwave, and Rb atoms in the absorption cell laid in the resonance cavity will output the

enough strength of discrimination signal by transmission of light intensity from lamp to lock VCXO. Owning to the configuration of frequency multiplier in Fig. 3, the above-mentioned cavity can be used in Rb atomic clock.

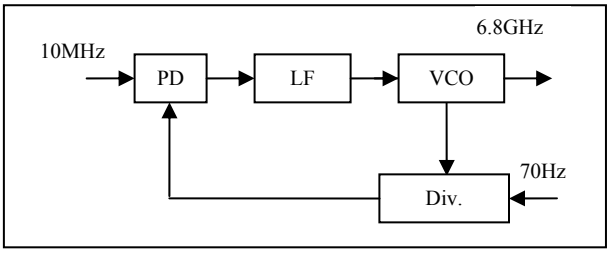

Figure 3. The frequency mitiplier scheme block.

In Fig. 3, the 10MHz from OCXO compares with the similar frequency feeding back from VCO in phase detector (PD), and the error voltage of the phase is filtered by Low Filter (LF). Finally, the 6.8GHz is locked in phase with 10MHz and modulated in frequency by 70Hz.

B. Digital Servo System

This part is embedded in a Micro-programmed Control Unit (MCU). The detailed configuration is as below in Fig. 4.

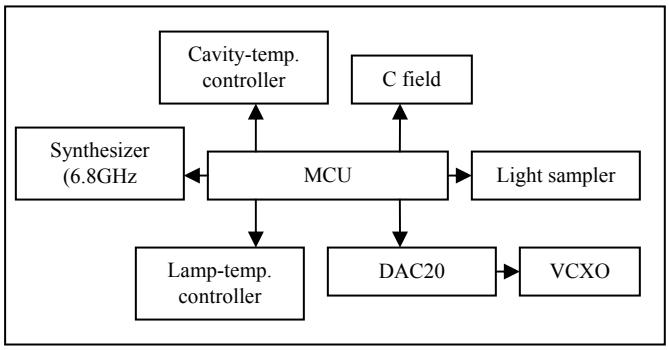

Figure 4. The digial servo system block.

- MCU is the center controller of the electronics in the Rb clock. The first function is to initialize external devices, including synthesizer, DAC20; the second is to sample the light intensity and temperature data and to process digital data to export an error to lock VCXO.
- C field is set by 12 bit DAC which can adjust the accuracy of 10MHz frequency standard signal with high resolution. Therefore, the Rb atomic clock can be disciplined by GNSS via tuning this DAC's transiting data, so the long term stability will up to the level of satellite atomic clock.
- DAC20 consists of two 12 bit DAC and is an equivalent 20 bit DAC, which is to lock the VCXO in normal work and to make the VCXO to be in holdover status in abnormal work.
- Light sampler is to gather intensity of the lamp light which contains work status of the lamp and atomic discrimination signal. The first one could assist to check the lamp's off-on statue to shift the voltage from low to high, and the second is to lock VCXO.
- Synthesizer as a frequency multiplier makes the 10MHz from VCXO to 6.834GHz directly and modulates the microwave with a low frequency 70Hz. The synthesizer is made up of a digital phase comparator, digital divider (Div.) and VCO.
- The cavity-temp. controller and lamp-temp. controller are to control the cavity temperature and lamp temperature respectively according to destination value of temperature automatically.

C. Monitor-control software

The monitor-control software is installed in the PC which communicates with Rb atomic clock with RS232 protocol. Otherwise, the clock's work status including lamp and cavity can be monitored real-timely. Furthermore, the software can also set the parameters including synthesizer's offset and divider coefficient. With the help of the software, the Rb clock can be massively produced at a low cost.

D. Archetechure design

The digital electronics and novel physics package are introduced, and the ultra-miniature Rb atomic clock can be shaped in a low size scale. Because OCXO with 51mmx51mm dimension is popularly used, as is necessary to design the similar Rb clock. Therefore the XHTF1031 has completed on this idea. The clock without case is shown in the. Fig.5. It is clear the synthesizer is enclosed in a metal shield, and the 6.8GHz transmits from the synthesizer to cavity by a microwave line with mini SMB connector.

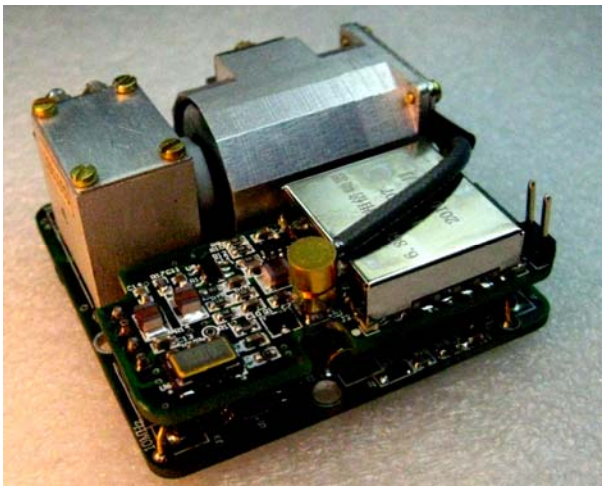

Figure 5. Spaceon Rb atomic clock XHTF1031 with the cover removed.

- The two PCBs are overlapped and fixed by 4 sockets. The frequency multiplier is enclosed in a case and directly soldered on the small PCB which is aligned with the cavity and the lamp.
- The case of Rb atomic clock is made of permalloy metal and is to reduce frequency shift resulted from magnetism again. Therefore the magnetic sensitivity will be reduced at large and finally to achieve the 2E-

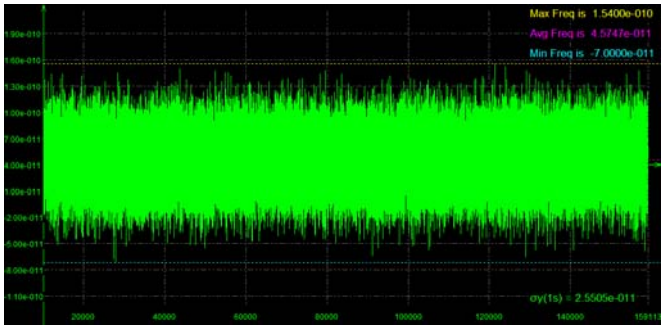
11/G. finally, the dimension is 51mm×51mm×25mm which is compatible with the ordinary OCXO. Especially, the baseplate of the clock has 4 screw hole and can be held safely, which makes the clock‘s frequency specifications tolerable on the condition of shock and vibration.

IV. TEST

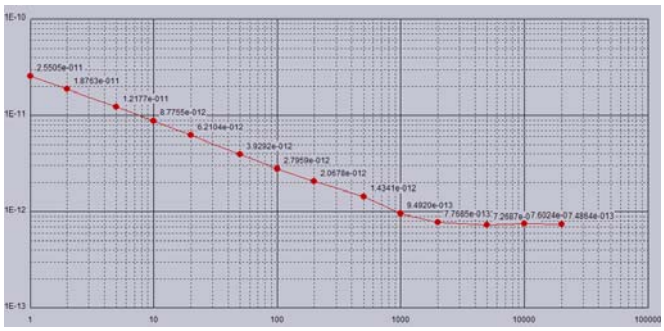
After making the key-technique design, five prototypes of the clock have been fabricated. Firstly, we have tested the five clocks comprehensively. The data and figures of testing are as below.

A. short-term frequency instability

Short-term frequency instability is relative with noise from synthesizer and physics package and the strength of atomic discrimination. In Fig.6, the short-term frequency instability of the clock XHTF1031 is given.



(a)



(b)

Figure 6. XHTF1031 short-term frequency instability. (a) The typical frequency accuracy of the clock. (b) The typical frequency Allan deviation of the clock.

In Fig.6, the short-term frequency instability is showed. The frequency data are sampled per 1 second in two day, therefore the quality of frequency point is enough to calculate the Allan deviation. From the diagram, the short-term frequency instability is about 2.6E-11/s, 9E-12/10s, 2.8E-12/100s, which is satisfied with root tao in Allan deviation, and is laid in the middle level of compact Rb clock.

Obviously, the data is better than ordinary OCXO’s, especially in the term of 10s and the time with big scale.

B. Temperature coefficient

Temperature coefficient is most difficulty in gas cell Rb clock while Doppler shift from hot atoms in absorption cell is appended in resonant frequency [5]. In addition, integrating filer technique in compact Rb clock is popularly used in order to downsize the clock’s volume and brings on bigger coefficient than the scheme of splitting filtering technique. In XHTF1031, the digital electronics is to compensate coefficient by the feeding-back error from the temperature sensor mounted the clock case. In this way, the perfect property of frequency vs. temperature is achieved finally in Fig.7 as below.

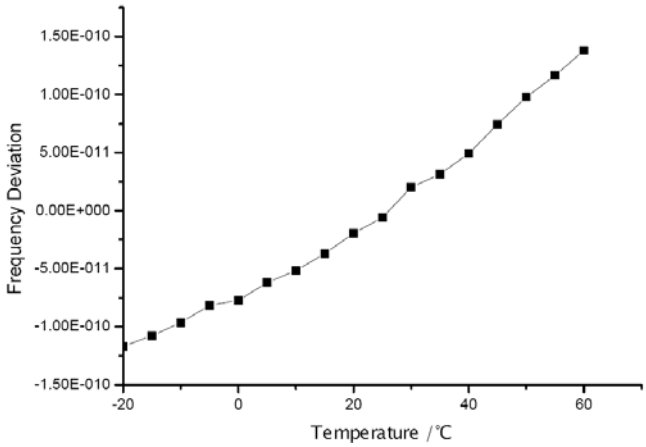


Figure 7. The clock XHTF1031coefficent in the range of -20 to 60 ℃.

The present temperature coefficient in the range of -20 to 60 ℃ is within 3E-10. Next step, the range of work temperature will be expanded to fit defense and avionics environment.

C. Aging

Owning to the bulb and absorption cell are made of a special glass which ingredients is researched by Spaceon, the aging of XHTF 1031 has the outstanding performance.

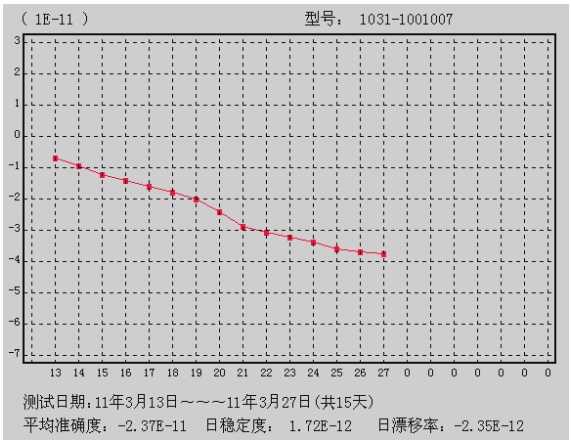

Figure 8. The clock XHTF1031’s Long-term aging test diagram.

In Fig.8, the typical data is below 5E-12/d, and better with two or more order of magnitude than ordinary OCXO's.

V. CONCLUSION

The ultra-miniature Rb atomic clock XHTF1031 basing on traditional gas cell Rb clock scheme is completed now. Furthermore, owning to introduced novel physics package and the digital electronics, the cost, power dissipation and dimension are reduced at large extent. Finally, the shape of the clock is 51mm x 51mm x 25mm (2' x 2' x 1') in the first version of the clock, which is better standing long-term frequency instability than OCXO, but compatible with it. In addition, the clock has better technique maturation than CPT clock occurring several years ago. Consequently, the clock will take on an important application position in future, and will be widely used in aspect of Global Navigation Satellite Systems (GNSS), IEEE1588 web, IP TV, Timing-keep system as frequency standard instead of OCXO with higher frequency performance two or more order of magnitude.

ACKNOWLEDGMENT

We will extremely thank Clive Green and Dr. Cosmo in Quartzlock England for their encouragement and valuable talk while developing the atomic Rb clock. Clive Green tries his best to spread Rb clock for Spaceon in the world also. In addition, some work for designing the Rb clock is done by Junqi Xiang, Xingwen Zhao, Yongjun Liu, Haitao Lin, Miao Liu, Xiaohua Pu, Xuejin Huang.

***Abstract*— Our laboratory has been developing an atomic reference system in which an ensemble of cold atoms of cesium is produced already in the center of a microwave cavity. The timeline of the project is divided in three parts: proof of principle with an antenna, design of a microwave cavity with viewports to produce the magneto-optical trap (MOT) and a movable system with all the parts embedded in a single package. In this work we present the first two parts of the global project with some relevant aspects for the construction of this compact frequency standard.**

I. INTRODUCTION

Compact atomic standards are being developed in many laboratories using different configurations [1][2]. These systems are all intended to have small size and high performance, showing a very promising field in time and frequency that addresses portability. Following this tendency our group is working in a simplified configuration that makes use of cold atoms, trapped in a magneto optical cell.

II. FIRST ESSAYS

The first experiment we did followed ideas from [3], where the ensemble of ^{133}Cs atoms was initially prepared in a magneto optical trap (MOT) and released to expand. During the free fall the clock transition is excited using a microwave field applied with a horn. The main changes in our system were the use of a pyrex cell and a quarter-wave antenna, as illustrated in Fig. 1.

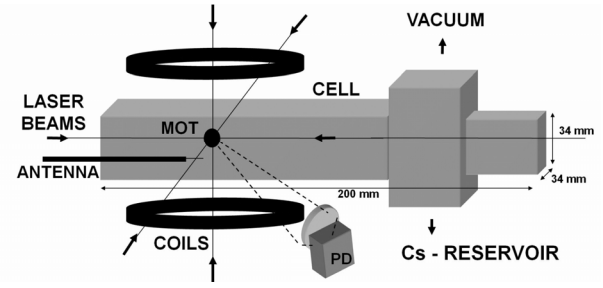

Figure 1. Vaccum cell and antenna used for the first experiment

This research is funded by FAPESP, CNPq and CAPES

Once mounted, the system showed a MOT with about 10^8 atoms that were interrogated with microwave fields in one and two pulses configurations. The detection was done using the same trap laser beams through fluorescence. The results observed for the hyperfine transition using both schemes of pulses are shown in Fig 2. They correspond to durations of 12ms in the single pulse and, in the second case, two 4ms pulses separated by an interval of 8ms.

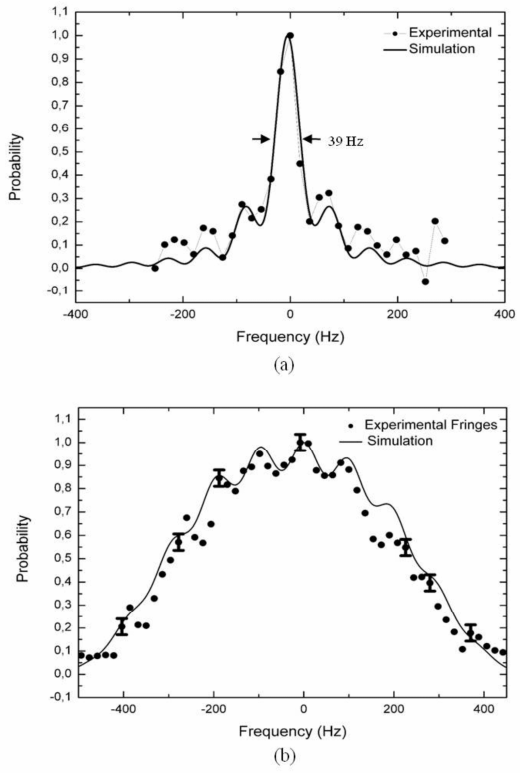

Figure 2. Resonance observed for the clock transition using (a) one and (b) two pulses

The observed results showed to be very promissing, with the linewidth for the single pulse configuration being 39Hz

and an Allan Standard Deviation of $9x10^{-11}\tau^{-1/2}$, when compared with a Cs commercial standard (Agilent 5071A)

The loss of contrast in the double pulse configuration was evaluated and the main contribution found was due to the spatial distribution of the field experimented by the atomic cloud in free expansion [4].

This configuration, despite the distribution of the field, has the very interesting aspect of compactness. Nevertheless, the use in a single pulse mode has shown a linewidth with reasonable contrast. The limitation in stability is atributed to SNR mainly.

III. Microwave Cavity with Cold Atoms

The next step was the evolution of the system for a better behaved microwave field. Since the aim of our experiment is not the use in microgravity, we decided to use the well known cilindrical resonator. Another point to be observed is the six beams configurations of the MOT, giving place to a cavity with at least six viewports. At the end, we finished with a cavity with ten viewports, all them with 10mm of diammeter, since this acts as cutoff waveguides for the used frequency. This number of viewports was necessary to guarantee place for the fluorescence detection, vacuum pump and Cs reservoir and microwave feeding with no adittion of many vacuum adapters. The microwave cavity was sculpted from a single block of 316L stainless steel, forming also the vacuum chamber with no weldings. A photograph of the chamber, with the built covers is shown in Fig. 3.

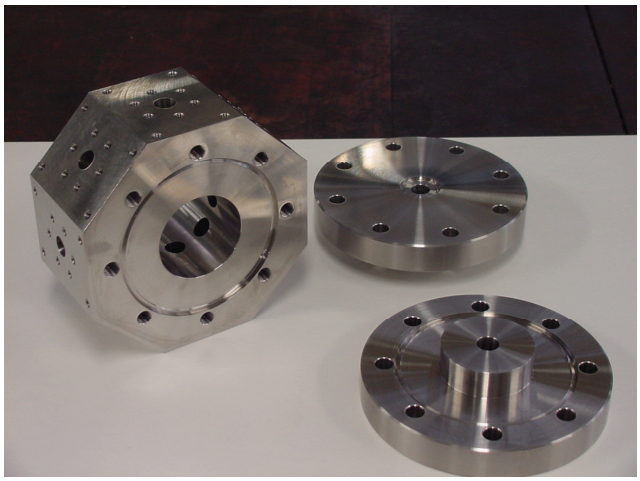

Figure 3. Covers and vacuum chamber body with the resonant cavity sculpted inside.

Because of the deformation of the resonant mode (TE011) due to all viewports, the dimensions of the cavity were first calculated with the use of FEM analysis. The cavity was then caracterized and the obtained quality factor is 1200. The temperature necessary to reach ressonance in the right frequency is 29°C. Considering the conductivity of the SS 316L, the quality factor gave us the confidence of a very good polishing and cleaning obtained in our mechanical workshop.

The MOT was them mounted with 9mm beams and the obtained cloud was measured with 10^9 atoms. The whole temporal sequence used for the experiment is generated using a data acquisition board (PCI-6025E National Instruments), that also performs all the measurements. The sequence include a phase of subdoppler cooling, allowing a cold sample with temperatures below 25μK.

After the subdoppler cooling phase, the cloud is released and submited to a sequence of two microwave pulses. The MOT beams are then turned on again and the fluorescence signal is collected with a PIN photodiode.

IV. Conclusions

The actual stage of our system is still far away the final shape we intent, since it is not optimized for minimum size of all the parts, like laser systems, microwave cavity, vacuum pump and optical bench. The target here was to obtain a vacuum chamber format that shows the feasibility of such system.

This chamber configuration permits also good optical access to the cloud of cold atoms, due to all viewports we were able to obtain, maintaining a reasonable quality factor for the cavity.

We considerate that the fluorescence detection is not the best method to use, since this results in a complete lose of cold atoms and increases the cycle time. One of the improvements we are implementing is the detection by absorption of an independent probe beam.

The actual system has now the objective to be a test bench for different configurations we plan to test, in order to minimize parts and subassemblies. Doing so we are passing to the third phase of our project, that is to design a system to be operated in an embedded configuration.

***Abstract*— The first prototype of an eXtra Small Atomic Resonator (XSAR) was presented by CSEM in 2009. This paper describes the progress realized in 2010 towards the realization of a low-power miniature atomic clock. We present a second prototype as well as the first RF frequency and laser locked loops fully integrated on a chip.**

I. INTRODUCTION

Very accurate local clocks play a fundamental role in modern communication and navigation applications. High precision references enable fast communication data rates, while in navigation they allow longer holdover operation times in absence of synchronization signal, for example from the Global Positioning System (GPS). Even if this high accuracy can be achieved with atomic clocks, only the recent developments in photonics and MEMS processes allowed reaching the low power consumptions and small sizes needed for hand-held devices [1], paving the way to the realization of Miniature Atomic Clocks (MAC). However, reaching the target of overall device volumes < 1 cm^3 and power consumptions < 30 mW [2] requires further miniaturization and improved design of all the system aspects, including the RF control electronics, which has to be low-power without affecting the clock performances. State-of-the-art implementations as in [3] and [4] reached impressive low-power consumption performances, but using discrete electronic components which limit the system miniaturization. This work presents fully integrated RF frequency (RF IC v1.0) and laser (RF IC v2.0) locked loops developed at CSEM and designed for MAC applications, tested in combination with a breadboard level buffered ^{87}Rb cell system [5] based on coherent population trapping (CPT) interrogation.

The CPT interrogation [2] consists in modulating the bias current of a wavelength tuned VCSEL at an RF frequency (ν_{RF}) that is half the ground state hyperfine splitting of ^{87}Rb (ν_{HF} / 2 = 3.417 GHz). Fig. 1 illustrates the principle. Let's consider that a ramp on the laser diode (LD) bias current sweeps the pumping photon energy (E = hν) producing two peaks of absorption corresponding to transitions between each of the two ground states toward the excited states. When amplitude modulation of the LD is added, the absorption spectrum is composed of each individual laser wavelength (carrier plus sidebands). For $\nu_{RF} = \nu_{HF} / 2$, a transmission peak hundreds of Hertz wide (CPT signal) is observed and this resonance provides the high-Q frequency reference (> 10^6) of the MAC. To maintain the system locked around that peak and provide a highly stable clock, the frequencies of both the RF modulating signal and VCSEL must be controlled within feedback loops. In particular, locking of the RF frequency onto the atoms (RF IC v1.0) is obtained introducing frequency modulation of the RF carrier, which allows deriving a signed error signal used to form the RF frequency locked loop.

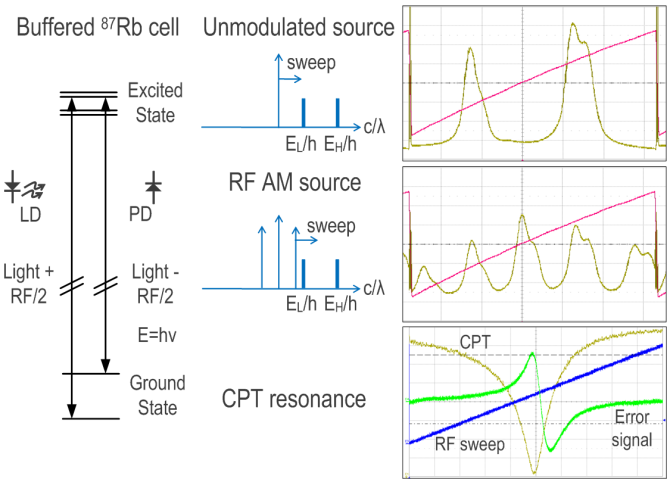

Figure 1. Physical principle of ^{87}Rb CPT interrogation.

II. PROTOTYPE EXTRA SMALL ATOMIC RESONATOR

The first prototype (v1.0) of an eXtra Small Atomic Resonator (XSAR) developed at CSEM had been demonstrated in [5]. It was built around a miniature 5 mm diameter glass cell filled with ^{87}Rb and a mixture of Ar and N_2 buffer gases. The prototype (Fig. 2 left) consisted in an assembly of miniaturized building blocks (the laser and optics

978-1-61284-110-6/11/$26.00 ©2011 IEEE

unit was only 4 mm high – heater and thermistor included) and laboratory-sized sub-systems (the glass atomic vapor cell unit was up to 20 mm long – heaters, thermistors and solenoid included). The performance of the complete clock driven by laboratory electronics and RF synthesizer was in agreement with the expectation: the short term frequency stability reached 5×10^{-11} @ 1 s.

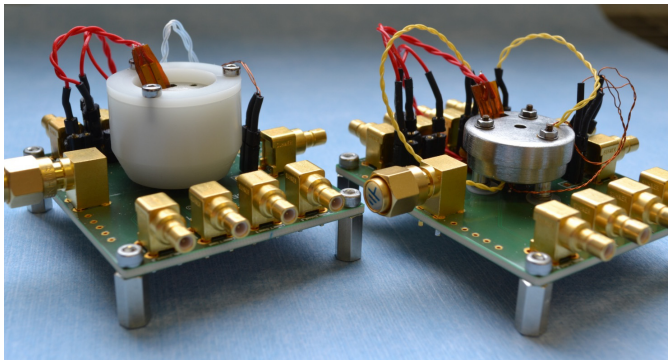

Figure 2. XSAR prototypes v1.0 (left) and 1.1 (right).

A step towards the small size and low-power objective has been tackled by mastering the fabrication of miniature atomic vapor cells using MEMS fabrication techniques (Fig. 3). Filling the cells with natural Rubidium has been realized with different techniques (alkali metal dispenser and alkali metal salt) and included controlled partial pressures of buffer gas mixture. Adding new functionalities to the cell and reducing the cell's external size are ongoing in order to reduce the overall physics package size.

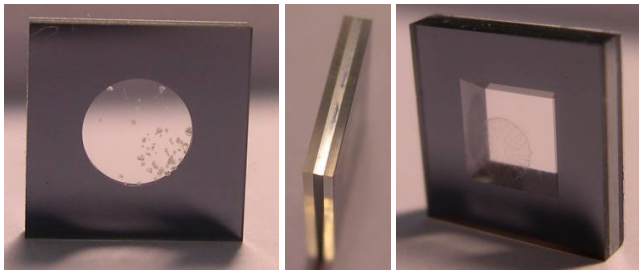

Figure 3. 10 x 10 mm MEMS cells with different filling approaches.

The second prototype (v1.1) of an eXtra Small Atomic Resonator (Fig. 2 right) could be assembled using the miniature MEMS cells. Driving this prototype with laboratory electronics allowed to reach frequency stabilities of the order of 8×10^{-11} @ 1 s. Driving the prototype with the integrated electronics (see below) is still not possible because MEMS cells could not yet be filled with the adequate isotope of Rubidium. The production of MEMS cells, filled with Rb-87, is ongoing. The performance results of the second prototype will trigger the design of the third generation prototype. It should integrate the low-power microwave synthesizer with integrated laser locked loop (see below), an advanced packaging for low power consumption, and a MEMS cell with reduced size and additional functionalities.

III. RF FREQUENCY LOCKED LOOP

Fig. 4 shows the block diagram of the integrated RF frequency locked loop (RF IC v1.0). A transimpedance amplifier (TIA) converts the photocurrent of the PD into a voltage. The signal is then chopped coherently with the FM modulation of the RF carrier before being integrated and low-pass filtered. The resulting voltage drives the frequency tuning port of a 40 MHz voltage controlled crystal oscillator (VCXO). The remainder of the system is equivalent to a direct modulation transmitter featuring a high resolution fractional-N PLL, whose loop bandwidth is chosen to minimize the RF close-in noise that will interact with the atoms. For increased flexibility, the low pass filter was implemented with external components. The standard 40 MHz crystal was chosen for small size (available down to 1.6 x 1.2 mm^2), possibility to derive the traditional 10 MHz reference after integer division and low in-band phase noise plateau thanks to a reduced PLL ratio. An external bias-T is used to couple the RF power and the LD biasing current before driving the VCSEL. The typical RF drive level is from –2 to +2 dBm. Frequency modulation of the RF carrier is performed at a programmable rate and depth with a 2-FSK unfiltered square wave signal. Both are typically in the kHz range with a lock-in amplifier loop bandwidth of 1 Hz. A resolution of the RF carrier frequency of 10^{-12} (ppt) is obtained with a 40-bit 2nd order ΔΣ modulator. The N divider, whose fractional value should be close to 85.425, is implemented with a cascade of dynamic dividers [6] to achieve low power dissipation.

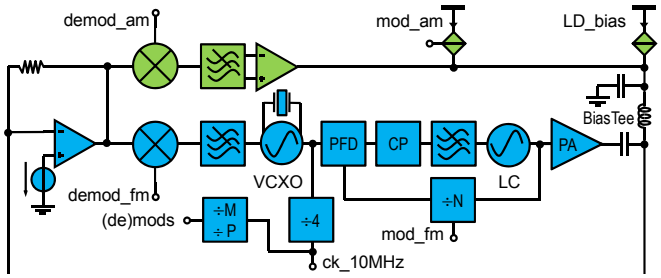

Figure 4. Architecture of the atomic clock RF frequency locked loop IC v1.0 (blue) and laser frequency locked loop IC v2.0 (green).

The photocurrent generated by the PD contains a strong DC component onto which a weak CPT signal, superimposed at the FM rate, has to be amplified. A low noise TIA (Fig. 5) with a band-pass filtering characteristic is implemented with only two transistors, an external capacitor and a current source. The two transistors form a current conveyor that reverse-bias the PD at a constant voltage independent of the photocurrent. At a higher frequency however, the capacitor freezes the gate of the top most transistor that presents at its source a large transimpedance. The latter is maximized with a large overdrive voltage and using a native transistor, resulting in high gain and much reduced noise compared to the PD shot noise. After amplification of the AC square wave signal by the transconductance and current mirror ratios, coherent chopping is performed so that the difference of its two components is integrated on a large external capacitor until the error signal vanishes. The resulting saw tooth voltage is further low-pass filtered with an external RC network before it drives the VCXO differential accumulation varactor. The differential VCXO based on [7], was designed for maximum tuning range (~ 100 ppm). A 7 bits switched capacitor bank with a large on/off ratio is used for coarse frequency tuning down to ppm

level so that ppt stability could be reached on the analog varactor.

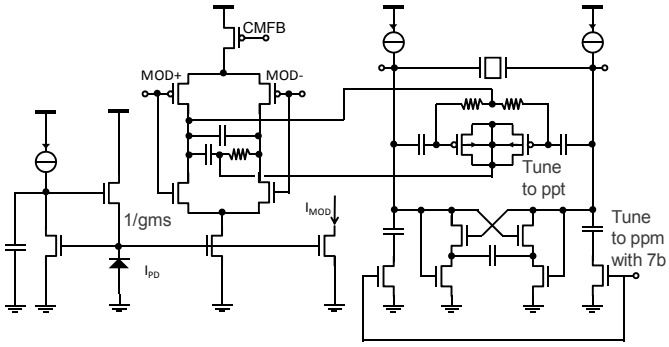

Figure 5. TIA, demodulator, loop filter and VCXO transitor level schematic.

The RF locked loop has been fabricated in a standard digital 0.18 µm CMOS technology. The chip has overall dimensions of 2.1 x 2.3 mm^2 comprised of pads and several test structures, which reduce the active area to about one half. Fig. 6 shows RF IC v1.0 integrated on a dedicated PCB as well as a micrograph with illustrated building blocks.

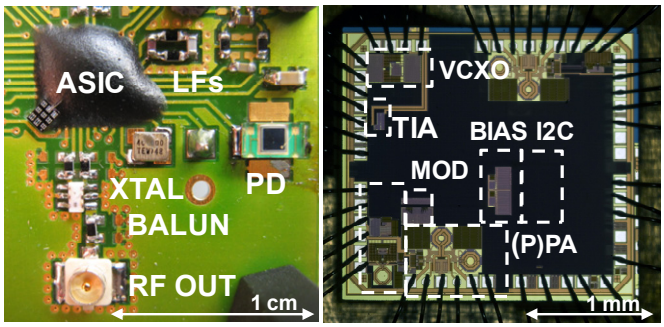

Figure 6. RF IC v1.0 on dedicated PCB (left) and chip micrograph (right).

Fig. 7 shows the measured phase noise of the RF signal (black), corresponding to −85.6 dBc/Hz at 1 kHz offsets from the 3.417 GHz carrier. At the PLL cutoff frequency of 250 kHz, the phase noise is −98 dBc/Hz. The phase noise of the RF signal is compared with what is achievable with typical laboratory equipment. The dark gray curve depicts the noise measured using a bulky oven controlled crystal oscillator (OCXO) in combination with an Agilent N5181A RF analog signal generator. The light gray curve shows the phase noise resulting from the use of the N5181A synthesis together with the integrated 40 MHz VCXO output after division by 4.

Fig. 8 depicts the MAC Allan deviation measured on the 10 MHz clock when locked through the IC RF loop to the physics package (□). The clock exhibits a 1-second intercept point of $\sigma_y(\tau = 1) = 4 \times 10^{-10}$, improving as $\sigma_y(\tau) \propto \tau^{-1/2}$ up to some tens of seconds. Work is ongoing to explain the abnormal drift observed for integration time $\tau > 20$ s also measured when using the IC VCXO in combination with the N5181A synthesizer (∇). The free VCXO frequency stability is also plotted (Δ). The last curve (○) represents the Allan deviation measured when locking the laboratory equipment to the ^{87}Rb cell.

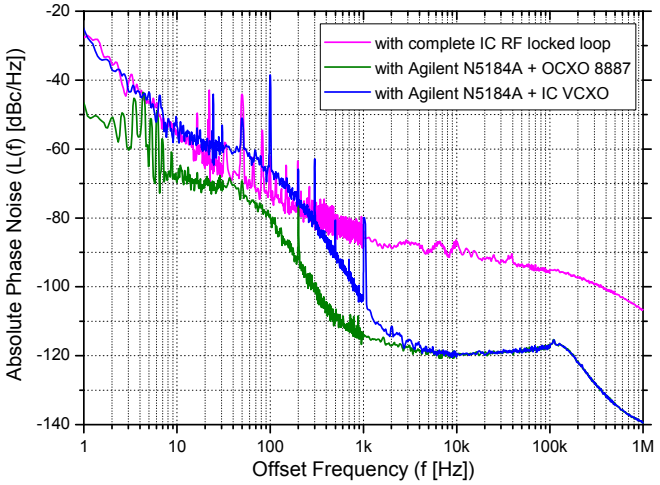

Figure 7. RF frequency locked loop phase noise: RF IC and standard laboratory equipments.

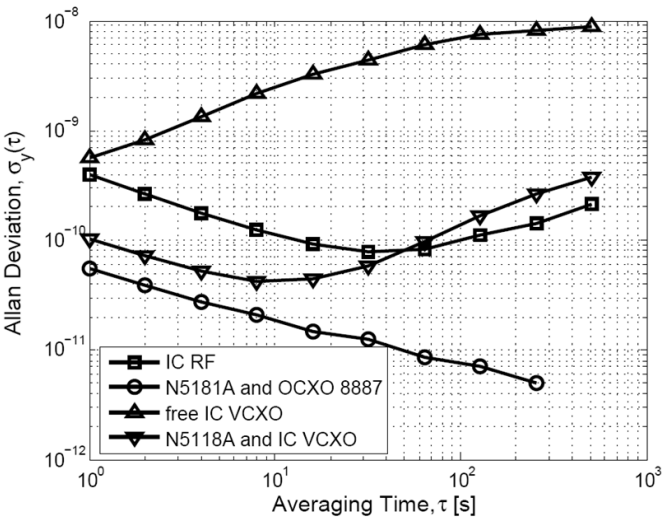

Figure 8. Measured Allan deviation on the implemented 10 MHz clock compared to results obtained with laboratory equipment.

The power consumption of the presented circuit is summarized in Fig. 9, together with a comparison with state-of-the-art RF electronics for MAC. The TIA and VCXO contribute to the overall consumption with only 0.31 mW, while the PLL comprised of the LC VCO consumes 7.89 mW. The overall consumption of 26.35 mW at an output power of 0 dBm suffers from the low efficiency of the power stage, which has been initially designed to reach output power up to 10 dBm. Redesign towards 0 dBm would necessitate the elimination of the power stage, resulting in an overall estimated power consumption of about only 12 mW.

IV. Laser Frequency Locked Loop

Fig. 10 shows the schematic of the integrated laser frequency locked loop added in RF IC v2.0. The laser diode biasing is controlled via an external voltage obtained e.g. from a DAC. The voltage is copied internally and converted into a current across a resistor that is further mirrored towards the laser. A low frequency (10-100 kHz) square-wave modulated tiny current is superimposed to the main biasing current to alter slightly the optical frequency of the laser diode. The interaction with the atoms results in an amplitude modulated current after detection by the photodiode. The resulting signal at the TIA output is fed to a coherent demodulator and integrated on a loop filter whose implementations are similar to that of the frequency locked loop. The resulting tracking voltage is then converted to a current that is fed to the laser for fine optical frequency adjustment, hence closing the laser locked loop. Low frequency laser and RF frequency locked loops output signals are combined on an external bias tee before driving the laser diode.

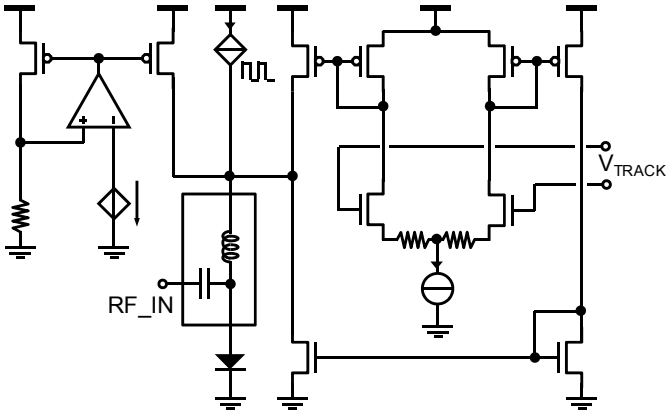

Figure 10. Schematic of the laser frequency locked loop.

The added functionality could be validated experimentally. Driving the laboratory CPT atomic clock described in [5] with RF IC v2.0 integrating the RF frequency locked loop as well as the laser biasing and frequency locked loop (Fig. 11) allowed to reach promising frequency stabilities of 1.5×10^{-10} @ 1s (Fig. 12). This system is to our knowledge the first RF frequency and laser locked loops for Miniature Atomic Clock (MAC) completely integrated on-chip.

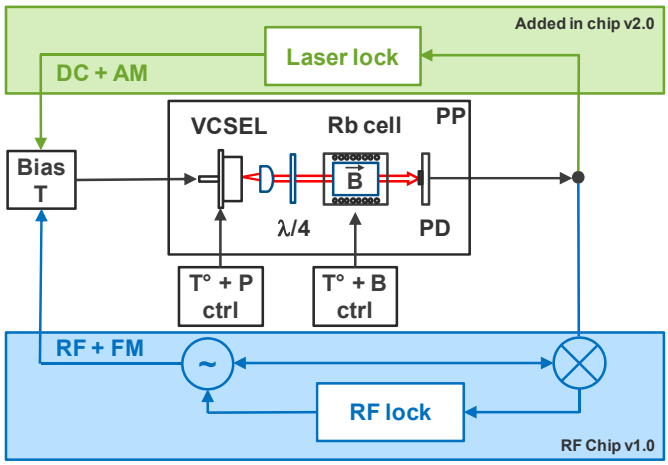

Figure 11. Graphical representation of RF IC v1.0 and v2.0 driving a laboratory CPT atomic clock.

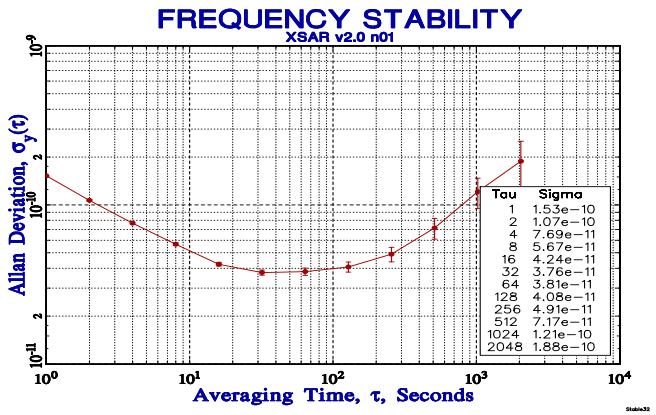

Figure 12. Frequency stability measured on the breadboard CPT atomic clock with the laser fully driven by RF IC v2.0.

Conclusion

The results of the second CSEM XSAR prototype have been presented. The prototype, integrating a MEMS-type atomic vapor cell, showed a frequency stability of 8×10^{-11} $\tau^{-1/2}$. The first version of a low-power integrated RF electronics has been characterized and integrated in a breadboard CPT atomic clock. With an overall chip consumption of 26.35 mW at an output power of 0 dBm, the clock showed a measured frequency stability of 4×10^{-10} $\tau^{-1/2}$. The second version of the RF chip, integrating the RF frequency locked loop as well as the laser biasing and the frequency locked loop, could also be successfully integrated in the clock. The measured preliminary frequency stability reaches a promising 1.5×10^{-10} $\tau^{-1/2}$. The next steps are to fully characterize the second version of the RF electronic unit, to miniaturize the MEMS-type atomic vapor cells adding new functionalities and to update the physics package towards

more integration and better thermal management. The project is ongoing and we expect to report new results soon.

***Abstract*— We report on the measurement of the dependence on temperature of the Cs clock frequency in microfabricated vapor cells filled with a mixture of Ne and Ar through the detection of Coherent Population Trapping (CPT) resonances. The temperature-dependence reduction of the Cs clock frequency is demonstrated in various cells. The inversion temperature at which the Cs clock frequency sensitivity is greatly reduced is found to be only dependent on the partial pressure of buffer gases and is measured to be lower than 80°C as expected with simple theoretical calculations.**

I. Introduction and Basics

The heart of vapor cell standards is an alkali vapor cell. A buffer gas or buffer gas mixture is generally added in the cell to slow the diffusion of the atoms and increase the time for the atoms to collide against the cell inner walls. Narrow linewidths can then be obtained through the Dicke effect [1]. At the same time, collisions between alkali atoms and the buffer gas perturbate hyperfine energy levels of alkali atoms, producing a clock frequency shift. In general, a buffer gas mixture is used. Each of them causes a clock frequency shift in opposite signs. A cancellation of the atomic clock frequency-temperature dependence can then be obtained by adjusting properly the buffer gas mixture composition. This technique is well-known for the development of high-performance compact Rb frequency standards [2]. We study here the Cs collisional frequency shift in vapor microcells filled with a mixture of Ne and Ar.

The frequency ν of the Cs hyperfine transition $|F=3,m_F=0\rangle \rightarrow |F=4,m_F=0\rangle$ can be described by:

$$\nu = \nu_0 + \alpha B^2 + \eta I(\omega) + \Delta\nu_{bg} \quad (1)$$

where ν_0 is the unperturbed Cs atom frequency (9.192 631 770 GHz), α is the second-order magnetic field coefficient (42.7 kHz/(mT)^2), B is the static magnetic field, η is the light shift coefficient and $I(\omega)$ is the intensity of the pumping light. $\Delta\nu_{bg}$ is often commonly called the buffer gas pressure shift and is the major concern of this study.
In a single buffer gas configuration, the pressure shift of the clock frequency $\Delta\nu_{bg} = \nu - \nu_0$ is generally described in a wide temperature range by [3]:

$$\Delta\nu_{bg} = P[(\beta + \delta(T-T_0) + \gamma(T-T_0)^2] \quad (2)$$

where P is the total buffer gas pressure at the reference temperature $T_0 = 273K$, T is the cell temperature, β is the pressure coefficient, δ is the linear temperature coefficient and γ is the quadratic temperature coefficient.
In the case of a buffer gas mixture, we define the ratio a between the pressure of buffer gas 2 and buffer gas 1 such as:

$$a = P_2/P_1 \quad (3)$$

Thus, the expression of the inversion temperature T_i for a given pressure ratio a is obtained by:

$$T_i = -\frac{\delta_1 + a\gamma_2}{2(\gamma_1 + a\gamma_2)} \quad (4)$$

Also, the pressure ratio a required to obtain an inversion temperature at $T = T_i$ is given by:

$$a = -\frac{\delta_1 + 2\gamma_1(T_i - T_0)}{\delta_2 + 2\gamma_2(T_i - T_0)} \quad (5)$$

Fig. 1 shows the estimated frequency shift of the Cs frequency versus the cell temperature for two different Ne-Ar pressure ratio and a total pressure of 6.6 kPa. Coefficients published in [4] are used.

For $a = 0$ (pure Ne cell), the temperature-dependence of the Cs frequency is expected to be cancelled at about 80°C as recently observed experimentally in chip-scale cells [5] and cm-scale glass blown cells [4]. Compared to pure Ne cells, the addition of Ar always shifts the inversion temperature to lower temperatures. The pressure ratio between Ar and Ne determines the inversion temperature.

II. Experimental set-up

Figure 2 shows a compact laboratory-prototype of the Cs CPT clock. It is fully described in [6].

The optical source is a 1.5 MHz-linewidth distributed feedback (DFB) laser diode. An optical isolator is used to prevent optical feedback. Two phase-coherent optical sidebands needed to perform the dark state spectroscopy are generated

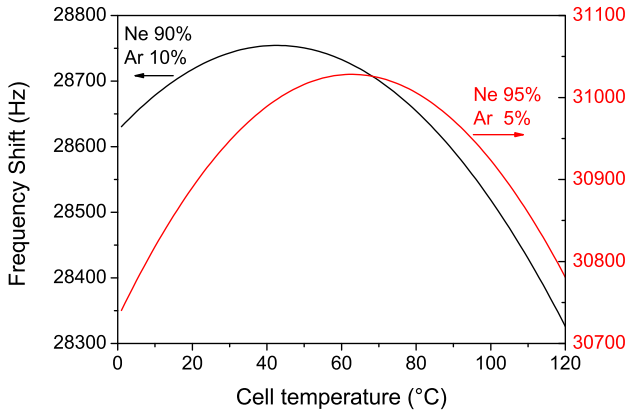

Fig. 1. *Theoretical estimations of the Cs frequency shift versus the cell temperature for cells filled with a Ne-Ar mixture. The total pressure is fixed to be 6.6 kPa. The ratio are Ne-Ar (90%-10%) and (95%-15%) respectively.*

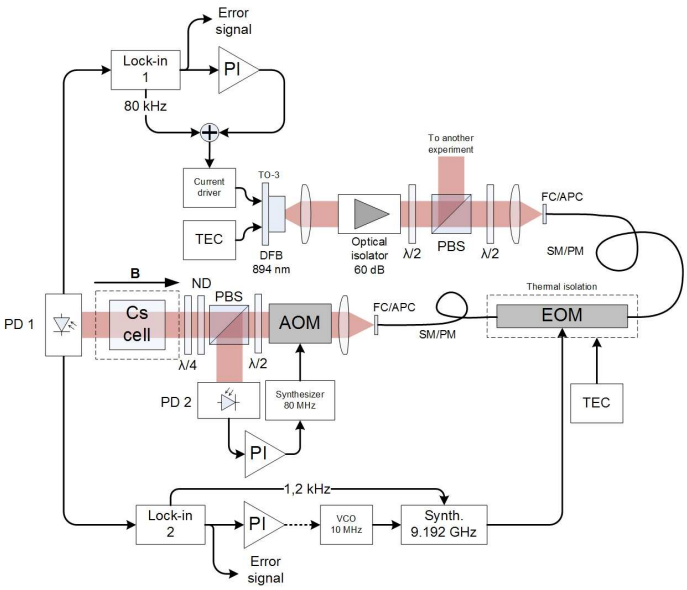

Fig. 2. Schematic of the Cs CPT clock used to test Ne-Ar microcells.

using a pigtailed electro-optic phase modulator. The EOM is driven by a low phase noise 9.192 GHz frequency synthesizer. The laser power is stabilized at the output of the EOM with an acousto-optic modulator (AOM)-based power servo loop. The laser beam is attenuated with a neutral-density filter and circularly polarized before to be sent in a 1.4-mm-long and 2-mm diameter Cs-Ne-Ar microcell shown in Fig. 3.

The cell temperature is stabilized at the mK level using a commercial temperature controller. The cell is surrounded by a solenoid to apply a static magnetic field of 10 μT and raise the Zeeman degeneracy. The ensemble is isolated from spurious magnetic fields using two concentric cylindrical mu-metal magnetic shields. The optical power transmitted through the cell is detected by a low noise Si photodiode PD1. A first servo loop is realized to lock the laser frequency using the

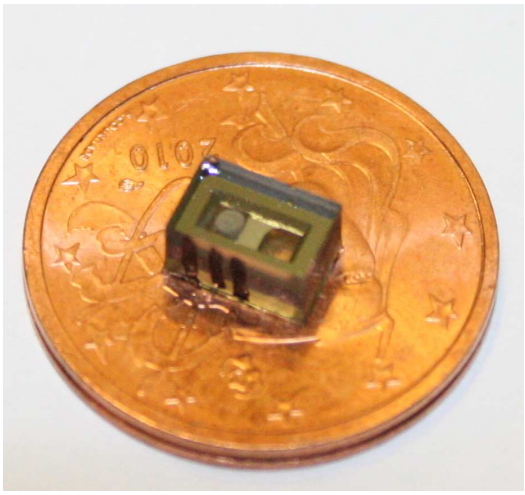

Fig. 3. *Photograph of a Cs-Ne-Ar microcell.*

lockin amplifier 1 while the second loop is used to lock the local oscillator frequency to the clock transition.

III. Experimental results

Several microcells have been realized. All the cells are expected to be filled with 85 % of Ne and 15 % of Ar. Fig. 4 shows a typical CPT resonance observed in a microcell filled with a buffer gas mixture of Ne and Ar.

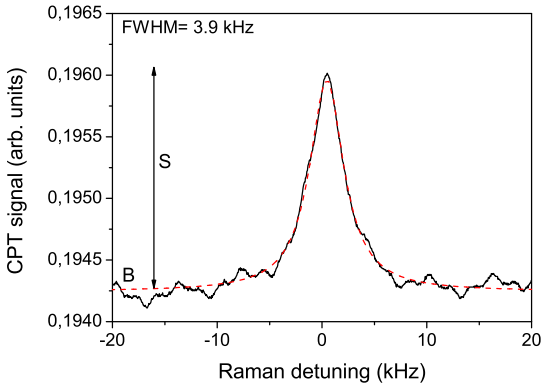

Fig. 4. *CPT resonance in a Cs-Ne/Ar microcell. The solid line is experimental data while the dashed line is a lorentzian fit. The laser power is 20 µW. The cell temperature is 75°C. The total buffer gas pressure is measured to be 8.5 kPa.*

The linewidth of the dark resonance is 3.9 kHz. Fig. 5 and 6 show the frequency shift of the Cs 0-0 hyperfine resonance as a function of the temperature for two different microcells. The buffer gas pressure shift measurement procedure is similar to the one described in [5].

The circles, stars, squares and triangles are the experimental data while solid lines are a second-order polynomial fit to the data. For both cells, the temperature-dependence of the Cs clock frequency is canceled for inversion temperatures lower than 80°C. Data fits are respectively $36170 + 15.39T - 0.14T^2$

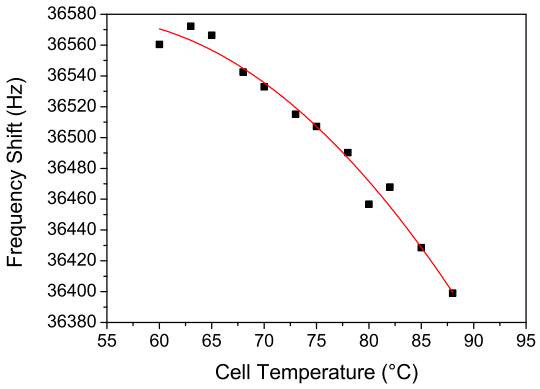

Fig. 5. *Frequency shift of the Cs clock versus the cell temperature in microcells filled with a Ne-Ar mixture. Cell 3.*

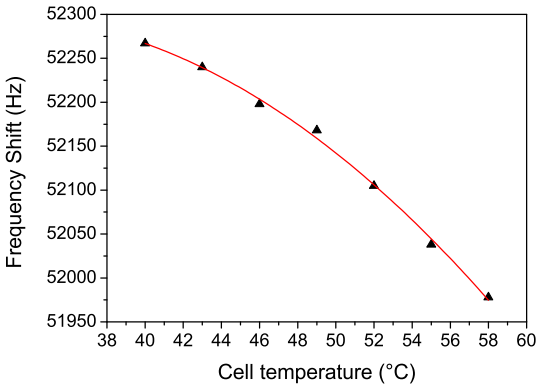

Fig. 6. *Frequency shift of the Cs clock versus the cell temperature in microcells filled with a Ne-Ar mixture. Cell 4.*

and $51823+29.10T-0.47T^2$ for the cells 3 and 4 respectively. The inversion temperature is measured to be 53.0 and 31.7°C for the cell 3 and 4 respectively. From these frequency measurements, we can estimate that the total pressure in the cell is 8.1 kPa and 12.5 kPa for cells 3 and 4 respectively. The Ne proportion is found to be 92.7 % and 87.7 % in cells 3 and 4 respectively. The uncertainty on the Ne proportion and the measured total pressure is typically $\pm$ 3.4 % and $\pm$ 0.9 kPa respectively for each cell.

The linewidth of the CPT resonance tends to be lower for increased buffer gas total pressure. The measured total pressure is found to be about 2-3 times smaller than the expected one. We note also that the measured pressure ratio is not in correct agreement with the expected one. Further tests are in progress to control accurately the actual filling total and partial pressures.

IV. Conclusions

The frequency-temperature dependence of the Cs clock frequency in microcells filled with a mixture of Ne and Ar was studied. A quadratic temperature dependence of the Cs frequency can be obtained with such microcells for inversion temperatures lower than 80°C. The inversion temperature only depends on the Ne-Ar pressure ratio and is shifted to higher temperatures for cells with increasing partial pressure of Ne. The total frequency shift depends on both the total and partial pressures. These results can be useful for the development of vapor cell frequency standards.

***Abstract*—This paper presents a new fabrication method to manufacture alkali reference cells having dimensions larger than standard micromachined cells and smaller than glass-blown ones. This technology fills a gap in cell sizes and already available technologies.**

I. INTRODUCTION

Many efforts are made to miniaturize the overall size of atomic clocks. This miniaturization has many advantages (i.e. reducing the power consumption, the cost and the mass of the physics package of the clock, …) but one drawback is that it degrades the Allan deviation proportionally to the cavity size reduction as shown by Kitching et al. [1]. These chip scale devices are usually manufactured using MEMS (Micro Electro Mechanical Systems) technologies and anodic bonding [2]. For higher precision clocks, glass blown cells are generally used but this technique is limited to cell volumes bigger than few tens of cubic millimeters [3, 4].

Here we present a technology that fills the gap in achievable cell size between the chip-scale MEMS cells and the macroscopic glass-blown cavities. For applications where a cavity size with a critical dimension of few millimeters is required, the glass-blown technique does not allow good control of cell geometry or flat window surfaces, and standard MEMS technology based on DRIE (Deep Reactive Ion Etching) or KOH etching of silicon is not applicable due to the required etching depth.

II. TECHNOLOGY COMPARISON

This chapter will show the advantages and disadvantages of the possible cell fabrication techniques, depending on the application or the requirements. Some arguments are summarized in Table I.

A. Glass blowing technique

The glass blowing technique, discovered about 50 B.C. [5], is still used today. It consists of creating an object by gathering molten glass on the end of a hollow blowing pipe and inflating it like a bubble. It can be blown into a hollow mold to form it with good precision or freely shaped with simple tools.

Modern variants of this technique are used as state-of-the-art technology for the fabrication of macroscopic alkali cells used in the commercially available products. It is possible to obtain cells exempt of impurities and their long lifetime were already proven. The inconvenience of this technology appears when reducing drastically the size of the cell down to a couple of millimeters. The blowing induces rounded edges and does not allow obtaining a flat window surface quality. If the surface is not perfectly flat, light losses are observed. The minimal achievable reasonable cell size is of around 6-10 mm total length or diameter.

B. Microfabrication technology

MEMS technology development started a couple of decades ago, at first mainly for the microelectronics industry processes. Inventions like DRIE allowed creating structures in bulk substrates, mainly on silicon. The advances in bonding techniques allowed creating more and more complex and ever smaller structures in three dimensions.

TABLE I. COMPARISON BETWEEN THE TWO PRESENTED TECHNOLOGIES

Technology	Advantages	Issues
Standard glass-blowing	Well-know and clean technology	Relatively poor window quality for small cavity size
	Long cell lifetime proven	Minimum achievable size of around 10 millimeters
Microfabrication technology	Perfectly flat window	Expensive technology
	Wafer-level fabrication	Alkali dispensing method difficult to implement
	Freedom concerning the shape of the cell	Long term aging not yet fully studied

This work was supported by the Swiss National Science Foundation (Sinergia grant CRSI20-122693/1).

One of the major advantages of this technology is the possibility to process several samples in parallel at wafer level and the freedom in the shapes that can be given to structures as it is defined by a photolithographic mask. Furthermore, for fabrication of alkali cells by bonding several of these wafers together to form a cavity, the obtained sidewalls have a very low roughness and it is possible to obtain perfectly polished window surfaces. On the other hand, this technology requires heavy and expensive equipment. Several alkali filling methods were already reported [6, 7] but the precise amount of alkali is difficult to control. Working microfabricated cells were presented during the last years and accelerated thermal aging tests were already performed [8] but yet the long term behavior is not fully studied.

III. VAPOR CELL DESIGN

The designed chip is represented in Fig. 1. Its dimensions are the followings:

- Internal diameter: 4 mm
- Internal height: 4.05 mm
- Outer footprint: 6x6 mm
- Outer height: 5.05 mm.

It is composed of a 3 mm thick drilled core made out of glass and bonded to two rims of silicon on each side, creating a 4.05 mm long cylindrical cavity. This cavity is closed with glass lids on both sides.

IV. FABRICATION PROCESS

A schematic view of the process is shown in Fig. 2. After cleaning the required substrates (Fig. 2 A), our approach is to start with a thick glass wafer in which through holes are drilled. This glass wafer is anodically bonded to a first silicon wafer patterned by DRIE (Fig. 2 C). The result obtained is bonded to a glass wafer to create the bottom windows of the cavities. This stack of three wafers is again bonded to a silicon wafer patterned by DRIE on the other side of the thick glass substrate (Fig. 2 E). These bonding steps are performed in a Süss bonding machine at 400°C and up to 1000 V.

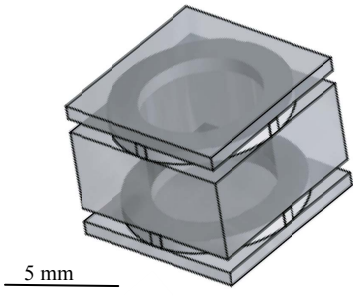

Figure 1. CAD image of the vapor cell.

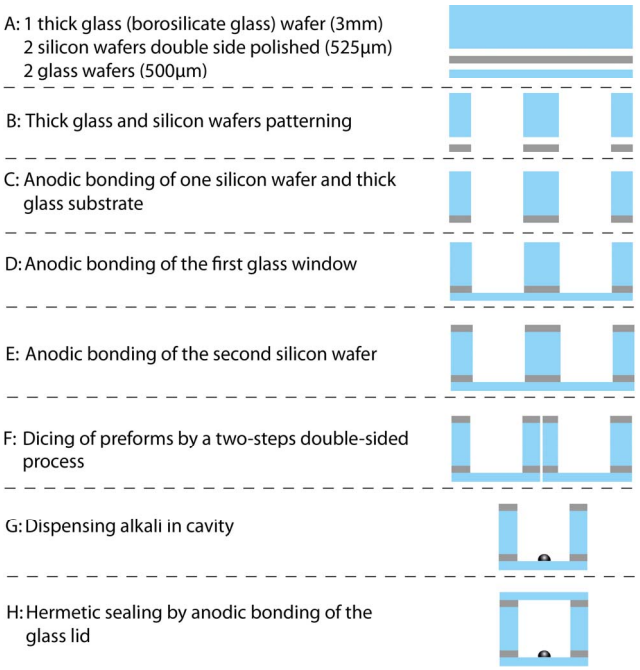

Figure 2. Fabrication process flow.

The obtained stack is then diced using a double-sided dicing process. The dicing is performed on both sides due to the large thickness of the structures (4550 µm). The alignment of the blade is performed on dicing marks patterned on both silicon wafers.

The diced pre-forms are then filled with a droplet of alkali and a glass lid is anodically bonded on top. The dispensing technology was previously presented by Pétremand et al [9]. The method is based on the condensation of alkali vapor produced by a commercially available dispenser from SAES Getters.

V. FABRICATION AND SPECTROSCOPY RESULTS

The cell fabricated according to the described process is depicted in Fig. 3. The left picture shows a top view of the cell. A small metallic spot of alkali is visible in the center of the cavity. The right picture shows an isometric view of the device. It can be seen that the outer dimensions are almost

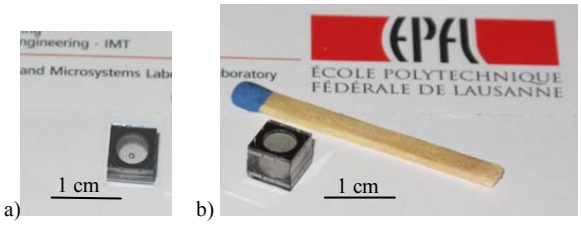

Figure 3. Pictures of the obtained cell. a) Top view. A small spot of alkali metal can be seen in the cavity. b) Isometric view.

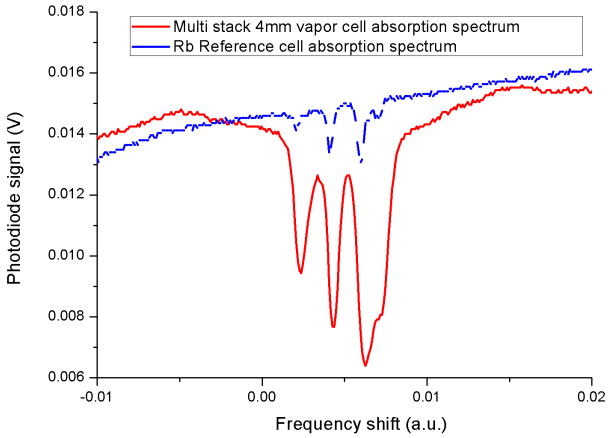

Figure 4. Absorption spectrum measured through the 4 mm thick Rubidium cell.

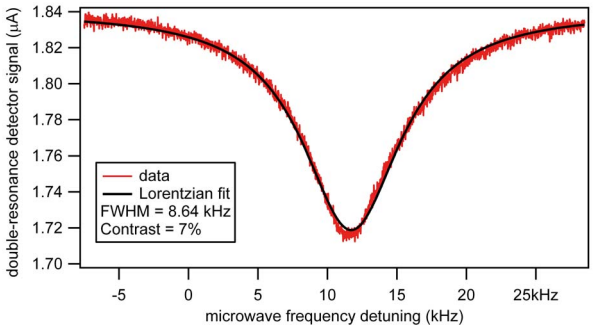

Figure 5. Double-resonance signal of the clock transition observed in the 4mm thick cell.

cubic. Preliminary test showed the expected Rb absorption spectrum (Fig. 4) for a cell heated to about 100°C (here, absorption lines are broadened due to the buffer-gas filled into the cell).

Double resonance measurements were performed with the alkali cell as shown in Fig. 5. The initial tests gave estimated clock short term stability of $7 \times 10^{-11}\ \tau^{-1/2}$. These results were obtained without optimization of the parameters and will be improved in a near future.

VI. Conclusion

A new type of middle-sized cells fabricated using microfabrication technology is shown. Spectroscopy measurements were performed and double resonance signal was measured. Initial measurements show a clock signal compatible with a clock stability of at least $7 \times 10^{-11}\ \tau^{-1/2}$.

The presented technology opens the perspective for massively parallel production of Rb vapor cells of few millimeters dimensions by using MEMS / microfabrication technologies. These cells are of interest for use in compact conventional Rb atomic clocks using small vapor cells.

***Abstract* — In this article we present our development of a high performance laser-pumped Rubidium gas-cell atomic frequency standard based on the continuous microwave-optical double resonance interrogation. A larger resonance cell is employed and no laser noise cancellation is required to reach a short-term frequency stability below $4\times10^{-13}/\sqrt{\tau}$ for $40 < \tau < 1000$ s.**

I. Introduction

Since last few decades the development of laser-pumped rubidium standards has become the subject of interest in view of improving the stability, mainly by replacing the lamp with a laser for optical pumping [1]. The initial experiments using lasers already proved to be improving the signal-to-noise and shot-noise limits attainable in contrast to that of lamps [2]. Since then, the constantly improving technology of compact laser sources and their availability has made the subject more reliable. For instance, the recently available Distributed-Feedback (DFB) laser sources are compact and robust. A compact, laser-pumped clock using an Extended Cavity Diode Laser (ECDL) had been already demonstrated with a short-term stability of $3\times10^{-12}\,\tau^{-1/2}$ [3]. And we note our recent work with improved performance of $<4\times10^{-13}/\sqrt{\tau}$ and reaching 1×10^{-14} at 10^4 s [4].

Our motivation is to achieve the stability of $<1\times10^{-12}/\sqrt{\tau}$ between 1 to 1000 s (short- and medium-term) and $<1\times10^{-14}$ (drift removed) up to one day. To achieve such a goal, the design requirements of our clock include; (i) the physics package (PP), that is able to give a DR linewidth of <1 kHz, and a discriminator slope of the clock signal > 1 nA/Hz. The detection noise due to the laser after passing through PP should be <5 pA/√Hz. The optimized buffer-gas mixture on the clock cell should give a temperature coefficient of $<1\times10^{-11}$ /°C, this parameter is essential in reaching medium and long-term stabilities of $< 10^{-14}$ level. Magnetic shields are required around the Rb cell to have $<10^{-13}$/G sensitivity. (ii) A stabilized laser source, with 780 nm wavelength and power output of few tens of microwatts in order to optically pump the atoms in D2 transition of ^{87}Rb to one of the hyperfine ground states. The linewidth of the laser should be of few MHz range to resolve all the sub-Doppler transitions, which is useful for laser locking and stabilization to an auxiliary, evacuated Rb cell. The Relative Intensity Noise (RIN) and FM noise should be $<10^{-11}$ Hz^{-1} and <10 kHz/√Hz, respectively. The power stability of the laser needs to be <0.1 %/day, at fixed environmental conditions. And (iii) microwave Local Oscillator (LO) synthesizer that can generate a stable 6.835 GHz and a power output of few dBm is required. A tuning range of 2 MHz with steps of <1 Hz resolution is essential. Most importantly, the phase noise in the clock frequency modulation, f_m range, when referred to a 10 MHz source should be ≤ -137 dBrad^2/Hz.

The flow of this paper highlights the important steps, tests and results in building the clock to achieve the goal envisaged by our motivation.

II. Experimental Setup

In Fig. 1 we show the block diagram of the laser-pumped Rb atomic frequency standard. We briefly describe below its three main components: the physics package, the laser head and the electronic control system.

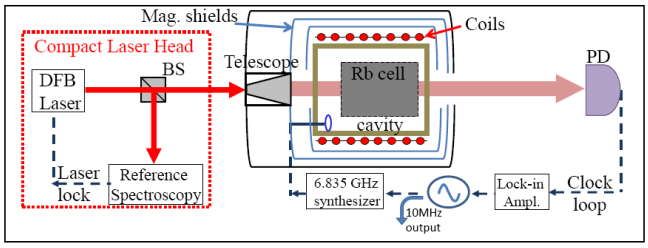

Fig.1. Schematic of the Double-Resonance clock setup.

A. Physics Package (PP)

As presented in [5], the atomic resonator is made of a 25mm-diameter glass-cell filled with rubidium and a mixture of Argon and Nitrogen as buffer gases. This clock cell is placed in a newly developed magnetron-type microwave cavity resonant around 6.8 GHz and surrounded by a C-field coil and two magnetic shields. The overall volume of the Physics Package (PP) is below one liter.

This work was supported by the Swiss National Science Foundation, the European Space Agency, and the Swiss State Secretariat for Education and Research – Space Affairs Division.

B. *Laser head*

Following our previous realization of a compact extended-cavity laser head, which includes a saturated-absorption reference cell [6], we have developed an improved version based on a DFB laser source [7] and its variant that comprises also an Acousto-Optical Modulator (AOM) that allows a fine tuning of the laser frequency towards a "magic" zero intensity light-shift point [5]. For the study presented here, we have used the version without AOM and operating around 780 nm. The overall volume of the laser head is below one liter. Fig. 2 shows the Allan deviation of the beat frequency of two identical compact non-AOM laser heads. The stability after 100 s is degraded by the external thermal fluctuations in the room, though during the clock operation we had better control over the thermal isolation of the laser head.

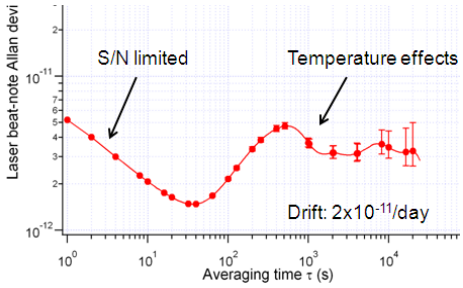

Fig. 2. Stability of two identical 780nm compact laser head units.

C. *Electronics control system*

For this work we used home-made laboratory electronics modules consisting digital temperature controllers for the PP, the Laser Head and a low-noise current source with the lock-in for the DFB laser source. The microwave source (or Local Oscillator, LO) and the computer-controlled lock-in were realized in INRIM and are described in [5, 8, 9, 14].

III. SPECTROSCOPIC STUDIES AND CLOCK STABILITY

A. *Double resonance signal and signal-to-noise limit*

Fig. 3 shows a typical double resonance signal, which corresponds to a shot-noise limited frequency stability of $1.4\times10^{-13}/\sqrt{\tau}$. Presently, the laser AM and FM noise and a residual contribution of the LO phase noise prevent us from reaching this performance and set a signal-to-noise limit of $2.9\times10^{-13}/\sqrt{\tau}$.

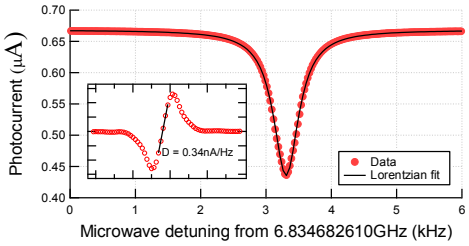

Fig. 3. Double-Resonance signal and the clock signal discriminator slope in the inset is also shown.

B. *Light-shift*

One of the main limits for the medium-term and long-term frequency stability of laser-pumped Rb clocks results from the AC Stark effect, through the laser intensity (α-coefficient) and frequency (β-coefficient) light-shift phenomena. Fig. 4 and 5 depict these two effects in our experiment when locking the laser source to the different possible sub-Doppler spectroscopy lines and at different optical pumping intensities. The influence of light-shift proves negligible in the short-term (below 1×10^{-14} for $1s < \tau < 100s$) while limiting the stability to around 2×10^{-14} for $\tau = 10'000$ s.

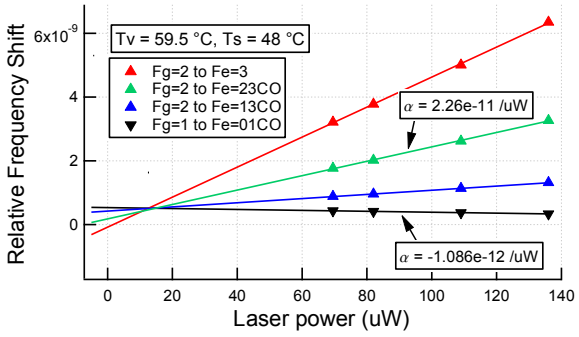

Fig. 4. Intensity light-shift (α) for different laser locking transitions of D2 line. Locking to the Fg = 1 to Fe = 01CO results in a minimum α-coefficient.

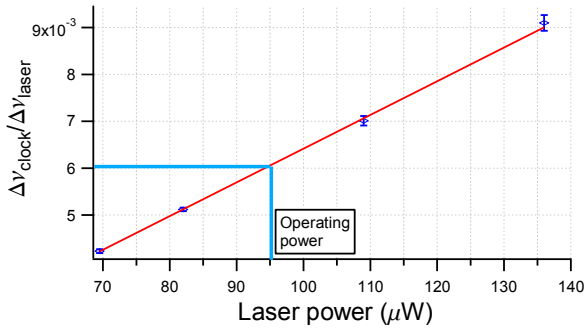

Fig. 5. Frequency light-shift coefficient (β) as a function of interrogating laser power.

C. *Temperature coefficient and other effects*

The relatively large total frequency shift in gas cell frequency standards is due to collisions with the buffer gas. Using an in-house cell filling system, we have filled the clock cell with a mixture of Argon and Nitrogen that prevents the Rubidium atoms from colliding with the cell's inner walls (buffer gas effect) and strongly suppresses their fluorescence (by quenching) that would otherwise reduce the optical pumping efficiency. The pressure of the mixture gives rise to a constant shift, which we have used in reducing the intensity light-shift for Fg = 1 to Fe = 01CO transition, whereas the ratio of this mixture allows fine tuning of the temperature coefficient inversion point, as shown on Fig. 6. When the cell is operated at a temperature close to 59°C, an overall temperature stability of the resonant cell within a few mK is sufficient to reduce the resulting fractional clock instabilities to below 10^{-14}.

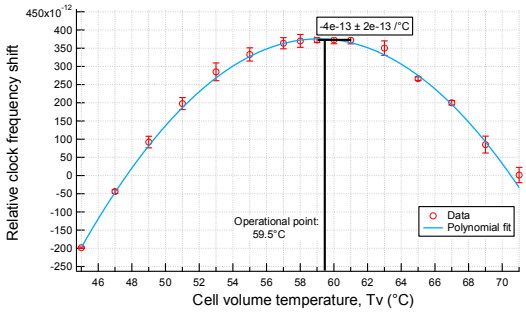

Fig. 6. Temperature coefficient of the clock cell. Ratio of the buffer gases determines the inversion point.

The other sources of clock instability, such as the unavoidable thermal gradients, the spin-exchange effect and the microwave power coefficient are presently under study.

D. Clock stability

Fig. 7 displays our present clock frequency stability results of $4\times10^{-13}/\sqrt{\tau}$ for 40 s < τ < 10000 s. The inset of the graph shows the raw frequency data measured. The signal-to-noise limit (red-line) $2.9\times10^{-13}/\sqrt{\tau}$, the shot-noise limit (green-line) $1.4\times10^{-13}/\sqrt{\tau}$ and the measured stability (black-line) $4\times10^{-13}/\sqrt{\tau}$ are shown. Our measurement system has a limit with $1/\tau$ dependence, which is shown in the blue-dotted-line. We suspect that the bump around 20 s is due to noise in the measurement system loop.

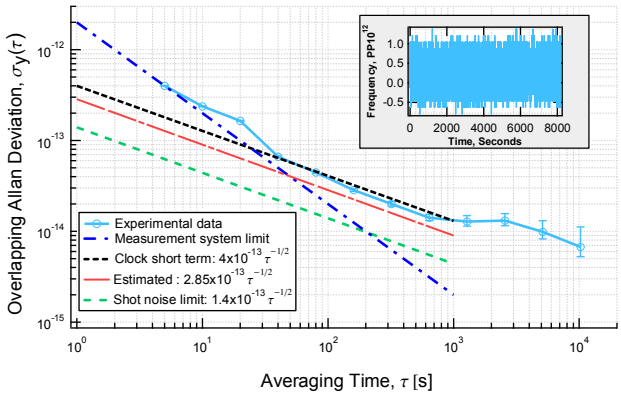

Fig. 7. Allan deviation of the clock and the inset shows the measured frequency data. Linear drift of 2.5×10^{-13}/day is removed [4].

IV. CONCLUSION

In this paper, we presented an improved Rb standard and its important parameters: the light-shift effect and temperature coefficient which are well-controlled to reach the stability around 10^{-14} over a period of 1day. The compact DFB laser-heads' beat-note stability was also presented. The clock Allan-deviation reaching the estimated goals of $<1\times10^{-12}/\sqrt{\tau}$ between 1 to 1000 s (short- and medium-term) and $<1\times10^{-14}$ (drift removed) up to one day was shown along with the estimated limits.

In comparison to the previous realization of the continuous wave (CW) operation using laser [3], we have shown an improved standard. Our clock has a smaller volume in comparison to vapor-cell clocks in pulsed operation [9], passive hydrogen maser (PHM) [10], HORACE [11], space optical clock [12] and Cs-beam clock [13], and gives the stability that is still sufficient for the next generation clocks for navigation systems, such as GALILEO and future telecommunication applications.

ACKNOWLEDGMENT

We thank M. Pellaton for fabrication of the cells and the other members of LTF, in particular P. Scherler and M. Durrenberger who have contributed in realizing this clock.

Abstract—**The abstract presents a fully functional Ramsey-CPT atomic clock, which has the characteristics of compact structure, small volume, low cost, strong adaptability, high stability, convenient for adjustment, unique design, and easy-to-commercialization. The Ramsey-CPT atomic clock combines the method of separated oscillatory fields and the phenomenon of coherent population trapping, so as to obtain narrower line width and better signal-to-noise ratio of the resonance signal for improving the frequency stability. It not only keeps the advantages of miniaturization and low power of the CPT atomic clock, but also can obtain higher frequency stability than CPT atomic clock about one order of magnitude.**

I. INTRODUCTION

Coherent population trapping (CPT) phenomenon is a quantum interference generated by atoms interacting with coherent light [1]. A new chip-scale passive atomic clock implement is currently a frontier technology in the field of atomic clocks. However, the CPT atomic clock is, at present, theoretically the only one that can be realized as a chip-scale atomic clock, by making use of good coherent properties of laser to prepare atomic "CPT state".

The scope of application of subminiature, even chip-scale atomic clock can be greatly expanded, especially used in measuring instruments, the portable communication and the navigation equipments.

In this system to be described, two coherent optical radiation fields are applied to a low-cost natural Rubidium (Rb) atoms ensemble. The fields are in resonance with the D_1 transitions [2] between the two hyperfine levels of the ground state and one of the hyperfine levels of the excited state, forming a so-called Λ system.

This paper aims to do some further research on Ramsey-CPT phenomenon and to promote the study of device level and producibility of Ramsey-CPT atomic clock. The Ramsey-CPT atomic clock combines the method of separated oscillatory fields [3] and the phenomenon of coherent population trapping, so as to obtain narrower line width and better signal-to-noise ratio of the resonance signal for improving the frequency stability. Using vertical-cavity surface-emitting laser (VCSEL) [4] as optical source, we propose an appropriate physics package and design a comprehensive servo system, forming a fully functional Ramsey-CPT atomic clock for the purpose of developing high-performance and commercialization of Ramsey-CPT atomic clock.

II. THEORETICAL ANALYSIS

A. Operating Principle

Fig. 1 shows the schematic illustration of the practical realization system of the Ramsey-CPT atomic clock. The frequency conversion circuit and the digital step attenuator are controlled by the microcontroller to generate the required microwave signal. With the digital step attenuator generating any form of microwave pulse signal, we can achieve more superior discriminator curve. Through the Bias-Tee, the signal couples with the drive current of the VCSEL to achieve two coherent lights, which phase difference is constant and the frequency difference is equal to the frequency of the microwave signal.

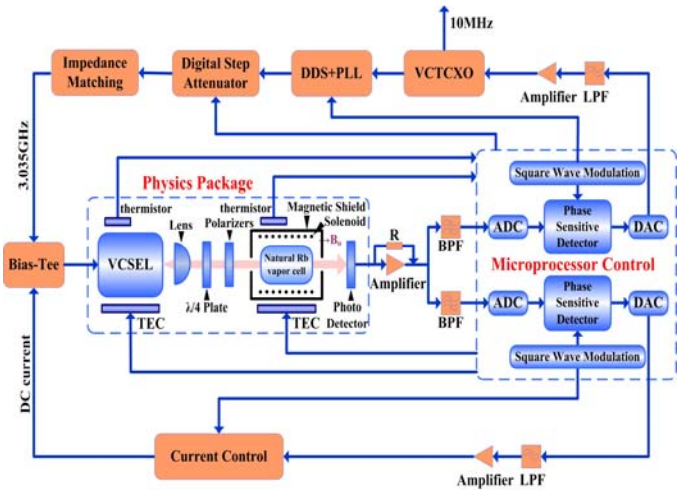

Figure 1. Schematic illustration of the practical Ramsey-CPT atomic clock. The bias-tee is used to couple the VCSEL injection current and the microwave modulation frequency. The λ/4 plate provides circular polarization required in the excitation process by transition selection rules. B_o is the applied small magnetic induction providing an axis of quantization for the atomic ensemble.

The form of the CPT system consists of two parts: the physics package and the servo circuit system. The physics package forms the optical path of laser beam from the VCSEL emitter to the photo receiver, and it consists of the laser used to generate the coherent light, the alkali metal atoms cell, the photodetector used to receive the radiation, and so on. The servo circuit system includes two locking loop: (1) laser frequency locking loop; and (2) microwave frequency locking loop. The first loop is to lock the laser wavelength to the atomic D1 transition line for ensuring the stability of CPT incentive. The second loop is to lock the modulated microwave frequency to the CPT hyperfine resonance frequency for providing a high-performance frequency signal.

B. Comprehensive Analysis

Based on the related data and previous studies [2], we can obtain the relationship between characteristics of Ramsey-CPT system and influencing factors as shown in Fig. 2, which can be used as an important theoretical guide for future design and optimization of the system.

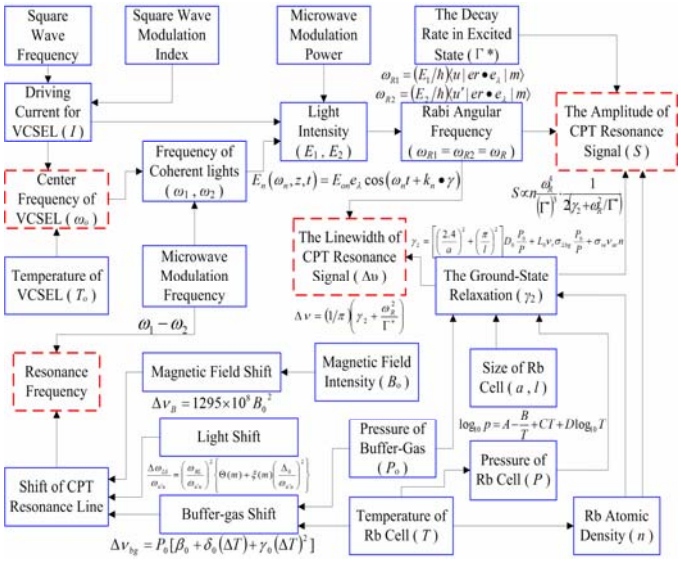

Figure 2. Block scheme of comprehensive analysis of the system.

As is clearly seen in this block scheme, the influencing factors are complex with each other. The shift of CPT resonance line consists of light shift, buffer-gas shift, and magnetic field shift. The line width and the amplitude of CPT resonance signal are the main object of comprehensive analysis of the Ramsey-CPT system.

The factors to be considered are mainly in: (1) the operating temperature of VCSEL and Rb vapor cell, (2) the modulating frequency of microwave, (3) the transmitted light intensity, (4) the weak magnetic field, and (5) the driving current of VCSEL.

Therefore, in practice, we need overall consideration to develop a high-performance Ramsey-CPT atomic clock.

III. IMPLEMENTATION METHOD

A. Physics Package

Depending on the size and volume limited and considering the organic combination with servo circuit system, we realize a physics package required by the system in which the laser beam can be collimated and adjustable, both temperature and magnetic field can be digital quantization, and the light intensity can be stepping adjustments.

Fig. 3 shows the photograph of the physics package which consists of three parts. The first part includes VCSEL, lens, and λ/4 plate. We can control the diameter of the light spot by adjusting the distance from lens to VCSEL. The second part consists of two polarizers which can quantitatively change the light intensity by rolling the bearing with 32-divided scale on it. The third part includes magnetic shield, Rb vapor cell, solenoid, magnetic sensor, and photodetector. The magnetic sensor is used to monitor the weak magnetic field. The magnetic shield, which is produced to a cavity using permalloy, can reduce the effects brought by stray magnetic field and earth's magnetic field.

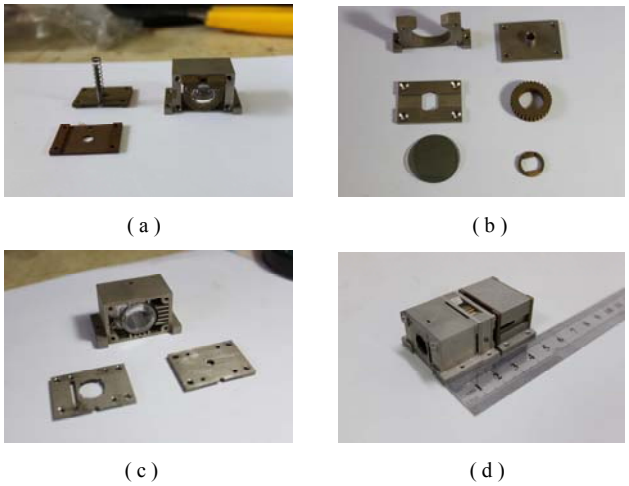

Figure 3. Photograph of the physics package. (a) The first part; (b) The second part; (c) The third part; and (d) the whole physics package.

The beam divergence of VCSEL is about 10 ° – 25 °, so we need to collimate the beam via a collimating lens. A plano-convex lens with 10mm focal length is used here. The beam, after passing through the lens, becomes approximate parallel beam. Then, the laser beam is circularly polarized and attenuated. Finally, the photodetector is required to detect the laser beam which has interacted with Rb atoms.

In short, the physics package designing is the key for obtaining a subminiature, adjustable and measurable system. It can be further development.

B. Comprehensive Servo System

Using comprehensive design method of microwave and high precision circuit and the technology of high density printed circuit board (PCB) designing, we design and implement comprehensive servo system of Ramsey-CPT atomic clock as shown in Fig. 4.

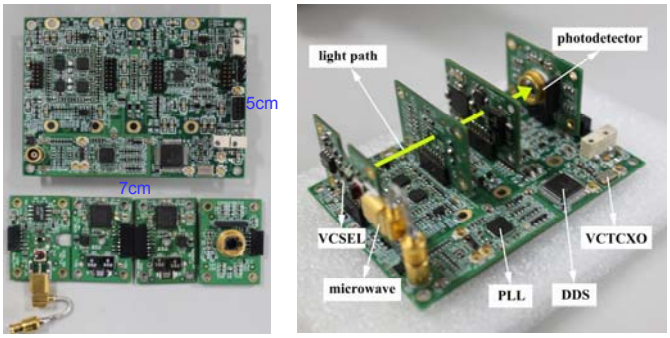

Figure 4. Photograph of the comprehensive servo system.

The servo circuit system consists of five printed circuit boards, which are VCSEL driving circuit, temperature control circuit for VCAEL, temperature control circuit for Rb cell, photo detector and magnetic field monitor circuit, and motherboard circuit. They are connected by the four connectors on the top of the motherboard.

The small and digital servo system has been designed for realizing automatic scan and locking control, monitoring the temperature and magnetic field, and so on.

The detection signal outputted from the physics package is amplified to an appropriate range, sampled by ADC, and then sent to the microprocessor to make the phase sensitive demodulation. At this point, we can obtain the differential curve of the absorption spectrum which is regarded as correction curve for locking the laser frequency. Finally, the feedback loop can be closed and locked. Based on the same approach, the microwave laser modulation frequency can be identified and then locked to the maximum of the CPT resonance transmission line.

C. *The Integral System*

Make the physics package connect to the servo system, and then we can obtain the overall architecture of the fully functional Ramsey-CPT atomic clock system. Its photograph can be seen in Fig. 5. This CPT atomic clock system has a volume about 60cm^3, and is convenient to adjust and measure.

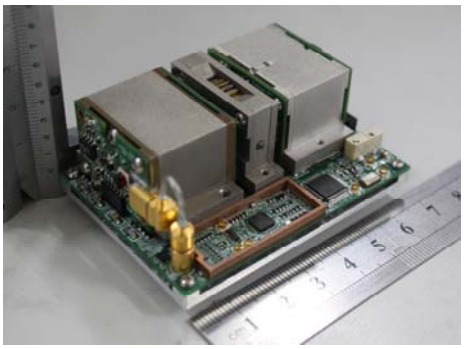

Figure 5. Photograph of the integral system.

In additional, based on the integral system, the chip-scale atomic clock can be developed through simplifying the structure of the physics package and the digital servo circuit, especially the physics package, because they have enough space for improvement.

IV. CONCLUSION

In conclusion, we describe the operating principle and the comprehensive analysis of the Ramsey-CPT system. Based on these theories, we have outlined the practical realization and well characteristics of the fully functional system. The whole system has the characteristics of compact structure, small volume, low cost, strong adaptability, high stability, convenient for adjustment, unique design, and easy-to-commercialization. It is believed that these characteristics of the Ramsey-CPT system can be improved in future developments.

Abstract

The transverse relaxation time of the laser pumping of ^{133}Cs atomic vaporing. Even if the temperature rises, the extension of the energy distribution of the electron is suppressed the effect of a thermal extension by the quantization and can lower the oscillation threshold to the quantum-dot structure of the VCSEL without causing the decrease in the gain to the utmost limit. The design of the system that measures the brain magnetism at 100fT level. The cause brain magnetic field from 10^{-13}T to 10^{-14}T or more can be detected.

1. INTRODUCTION

The first step of Table1 shows various magnetic fields in the natural world, and an artificial magnetic field and the third step show the range of motion of the magnetic field weighing device in the second step. If the effect of Hanle of happening when the pumping magnetometer on electron does the diffusion conduction while shining and doing the precession movement is used, the sensitivity of 10^{-16}T can be obtained. Figure 1 and Figure 2 show the principle of transverse optical pumping. [1] Only slight element H_0 (Permanent magnet) of the direction of z remains about 0 when sweeping it so that the magnetic field element of the direction of x may pass 0 when a horizontal pumping to enter the circularly polarized light from the semiconductor of luminescence on the side laser into direct-current magnetic field H_0 vertically is done and the transverse magnetization is detected. In this paper, the optical pumping magnetometer researches the practical use of the diagnosis of the bodily function of the brain magnetism.

2. ^{133}Cs brain magnetometer

Figure 3 shows the magnetometer of ^{133}Cs developed brain. ^{133}Cs gas absorption cell that is the sensor of this brain magnetometer is put in a permanent magnet.

There is a transverse pumping to make the pumping light a circularly polarized light as a method of greatly improving the sensitivity of the optical pumping magnetometer and to enter into the direct-current magnetic field vertically. As for the magnetometer of the brain, the one that operates at the same temperature as the temperature of the living body is desirable. 10ms or more is necessary to monitor the neuron activity the transverse relaxation time of the laser pumping of ^{133}Cs atomic vaporing. The design of the system that measures the brain magnetism at 100fT level is as follows.

Figure 4 heats the operating temperature of the gas absorption cell of which the easing gas is neon to the Cs atom to 28℃-46℃, passes the gas absorption cell the VCSEL (Vertical Cavity Surface Emitting Laser) light of 852.1 nm in luminescence wave length modulated in the gas

978-1-61284-110-6/11/$26.00 ©2011 IEEE

absorption cell by the Raman transition frequency, and shows the relation between the sealing pressure and the easing time of the neon when Laser pumping is done. The easing time becomes the lowest at the time of a temperature it near 28.4℃ in melting point of the ^{133}Cs atom 28℃.

Figure 5 is a luminescence spectrum of VCSEL. Even if the temperature rises, the extension of the energy distribution of the electron is suppressed the effect of a thermal extension by the quantization and can lower the oscillation threshold to the quantum-dot structure of the VCSEL without causing the decrease in the gain to the utmost limit. [2]

The photocount distribution that was wider than the Poisson distribution becomes a subPoisson distribution with only the half in the state of coherence by the negative feedback of the semiconductor laser before putting the negative feedback on the semiconductor laser. [3] Figure 6 puts the negative feedback on the semiconductor laser and is a result of having precisely measured the noise level of photocurrent directly after the detecting phase as for the output light. A usual excitation method is asymptotic in the standard quantum limit of the coherent state. If the pump swing is suppressed with negative feedback loop, the standard quantum limit can be exceeded as shown in Figure 7.

Figure 8 is two step type A-D converter of the pipelined architecture that processes the lamor frequency signal. The A-D conversion of high speed and high resolution is achieved. It is sampled by track/holding (T/H) circuit, and the input signal is maintained as pipeline T/H, and controlled as an analog signal voltage value in the timing control part. After the voltage value is converted into a digital value of m bit with the pre. A-D converter, A-D is converted into the analogue signal again with the D-A converter. The difference with the analogue signal that delays the analogue voltage value maintained in this analogue signal and track/hold circuit by an analog delay line is requested. The rest error amplifier converts the voltage of this difference into a digital value of m bit with the main A-D converter. The output of these two A-D converters is matched and the A-D conversion value of the m+n bit is obtained. The signal from ADA and main A-D enters the error correction machine. The signal from the error correction machine becomes a digital output. An analog DeLay line is necessary so that it may make amends for the operation delay time of the D-A converter following pre A-D converter and it.

Figure 9 is an analog lowpass filter that passes DC-40Hz of the lamor frequency signal. The analogue signal is processed with the low pass filter by the FIR method of the sampling frequency 80Hz. In this low pass filter, the signal of the frequency 43Hz or more has been suppressed to 60dB or more. As for the signal that passed this low pass filter, the image is processed as image brain magnetic wave signal of the A-D conversion.

Figure 10 shows the measured brain wave. A horizontal axis is an alpha wave, a beta wave, and the ordinate is strength of the magnetic field of the brain. The brain wave shows the effect of the ionization current that happens by the dendritic process of about 50,000 neurons in the synaptic transmission.

3. Magnetic shaking

Figure 11 shows magnetic shaking mechanism. [4] Magnetic shaking Magnetic shaking is to put a big exchange magnetic field more than to some

degree on the magnetic substance because it always keeps the magnetic wall of the magnetic substance showing in Figure 11 in vibrating state of the movement. It explains the mechanism of this magnetic shaking by using the relation between a distance and magnetic energy of the magnetic wall. As for energy e of the magnetic wall, the resilience that the magnetic wall receives by the function of distance s of the magnetic wall is shown with de/ds. Does the magnetic wall move very greatly and the size of the most important permeability in the magnetic shielding is decided to pressure for each unit magnetic field that joins the magnetic wall. For instance, the magnetic wall turns regularly in the abcd loop in the state that only the shaking magnetic field hangs when the resilience of the magnetic wall is shown typical by the harmony of the sine function and the linear function like figure. Under such a condition, the loop moves easily by several cycles and changes into the state of efgh if magnetic field ΔH of a small amplitude whose frequency is lower than the shaking magnetic field that corresponds to small pressure Δp (= 2IsΔH and Is are the saturation magnetizations) at the difference level of f point and b point is put further. This increases and is shaking under magnetic shaking rapid the incremental permeability to a minute magnetic field.

4. Simulation with thermic fluid

Figure 12 shows the outline of two nonstationary dimensional analyses process where two or more work-sheets were made to correspond to the time series. When the work-sheet group until prescribed time completes once, all the calculations are automatically executed only by changing the value of the parameter that calculates.

Conclusions

In a magnetic shaking container where the vibration magnetic field where a part of the brain magnetic field measurement part by an optical pumping had been liberated was impressed, this developed bodily function diagnosis device measures the magnetic field distribution of a primary change according to the nervous activity of brain neurons. The cause brain magnetic field from 10^{-13}T to 10^{-14}T or more can be detected.

Abstract— **Mass sensitivity of thin aluminum nitride (AlN) film S0 plate wave resonators is theoretically and experimentally studied. Here, two-port 888MHz synchronous thin film plate acoustic resonators (FPAR) are micromachined and subsequently coated with plasma-polymerized hexamethyldisiloxane (pp-HMDSO) thin films of various thicknesses. Systematic data on frequency shift and insertion loss versus film thickness are presented in a comparative manner. Measurements in gas phase environment are further presented in a comparative manner.**

I. INTRODUCTION

During the past 20 years, micro-acoustic gas sensors utilizing various types of surface acoustic waves (SAW) have demonstrated improved performance [1]. As the wave field of SAW is confined to the vicinity of the substrate surface, their propagation characteristics become sensitive to any kind of surface perturbation and more specifically to mass loading. The detection is performed in either delay-line or resonator-stabilized oscillation, the latter being preferred in gas sensing due to the higher Q and lower device loss resulting in substantial noise reduction and resolution improvement. At present, these sensors are well known and have already entered the stage of commercial interest [2]. Quartz-based SAW gas sensors exploiting Rayleigh SAW (RSAW) and SH-SAW (Love, STW) have been extensively studied [3]. The results indicate sensor resolutions in the ppb range due to high sensitivity and very low noise levels [4,5].

Contemporary thin film electroacoustic technology brought a new dimension to the acoustic wave sensors development. Thin film bulk acoustic resonators (FBAR) operating in the lower GHz range, employed in silicon-integrated miniaturized gas sensors, have demonstrated high mass sensitivity [6, 7].

This work is supported by the Swedish Research Council (VR) and the National Scientific Fund of Bulgaria under contract VU-F-203/2006.

In this paper we study the mass sensitivity and the applicability of thin film plate acoustic resonators (FPAR) in gas sensing applications.

FPARs represent a class of thin film acoustic devices utilizing the lowest order symmetric Lamb wave (S0) propagating in thin aluminum nitride (AlN) membranes [8,9]. The S0 mode is known for its low dispersion, high velocity (10000 m/s) and moderate electromechanical coupling [10] which makes it a high velocity alternative to the conventional SAW. Further, the FPARs topology, while similar to that of the SAW-based devices (see Fig. 1), is micro machined on AlN membranes on a silicon (Si) substrate [9] thus making it compatible with integrated circuits.

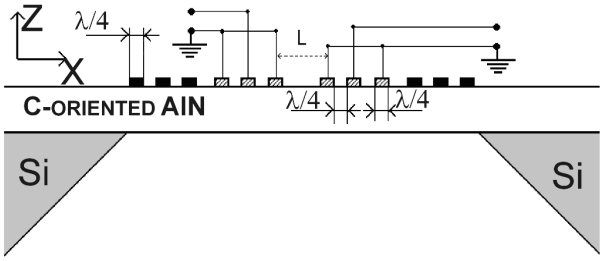

Figure 1. 2 Port FPAR Schematic

Two-port FPARs have demonstrated insertion losses of around 5dB and an unloaded Q of 3000 at a frequency of 0.9GHz [10]. Also, 0.9GHz FPAR-based oscillators have exhibited low phase noise [11]. These results, along with the expected high mass sensitivity of the S0 Lamb mode in acoustically thin plates, motivated us for the present study. Here the mass sensitivity of the FPAR is theoretically and experimentally studied in view of combining high sensitivity

with low losses. The results are further supported by measurements in gas phase environment.

II. THEORETICAL CONSIDERATIONS

The mass sensitivity of the S0-Lamb wave in an acoustically thin plate loaded by a sensitive layer is described by using the equations of motion complemented by a full set of boundary conditions for a waveguided solution with polarization in the XZ-plane. Details are omitted here for brevity, since they have been thoroughly discussed elsewhere [12]. Mass sensitivity is assessed through the fractional change of the acoustic velocity as a function of the sensitive layer thickness. It is revealing to calculate and compare theoretically the mass sensitivity of the S0 Lamb wave to those of the RSAW and Love wave propagating on layer coated AT-cut quartz. The RSAW calculation can readily be done using the algorithm described in [13], while the Love wave calculation employs the layer boundary conditions derived in [14].

In this specific case an AlN acoustic plate with thickness-to-wavelength ratio d/λ=0.167 as well as an AT-cut quartz substrate, both loaded with the glassy polymer pp-HMDSO are theoretically considered [15]. We found that that the S0 mode demonstrates a considerably higher mass sensitivity as compared to the RSAW and Love waves. However, increased sensitivity must not necessarily be the best choice for a practical system. Generally, improved mass sensitivity should correlate with improved damping especially at thicker layers [16]. This aspect is further theoretically studied for the S0 Lamb mode in comparison to RSAW and Love waves on AT-cut quartz. The S0 mode attenuation is found comparable to that of the RSAW and Love waves for relatively thin layers h/λ < 1%. At larger layer thicknesses the S0 attenuation is significantly higher than the attenuation of the RSAW mode. The latter determines the frame where the use of S0 Lamb wave can be beneficial. The use of relatively thin sensing films seems to be preferable, similarly to the case of surface transverse waves (STW) [16].

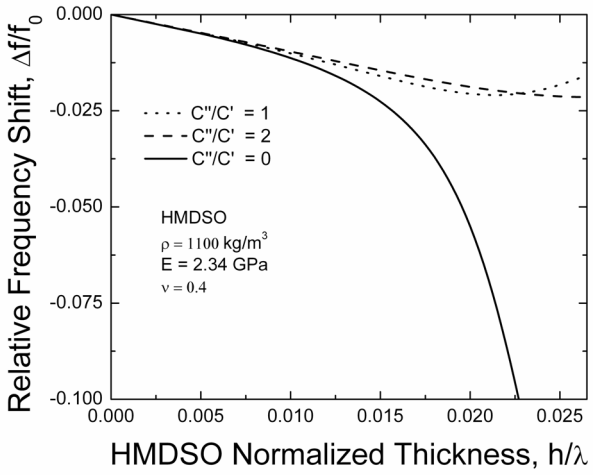

Figure 2. Theoretical mass sensitivity as function of layer viscosity.

Further, the layer viscosity itself influences the S0 mass sensitivity especially for pp-HMDSO layers with relative thicknesses h/λ > 1% (see Fig. 2). In this range the sensitivity deteriorates significantly compared to the case of a lossless layer. This effect is explained by the field distribution of the dominant longitudinal component within the composite plate as calculated by the algorithm proposed in this work. It shows that the viscosity tends to decrease the energy trapping to the low impedance layer, which in turn reduces significantly the sensitivity at thicker layers. Quite a similar effect has been discussed for polymer coated SH-SAWs [13] although its nature has not been discussed so far.

III. FPAR EXPERIMENTAL LOADING BY PP-HMDSO

In this section we compare the theoretical relative frequency shifts of the S0-mode with experimental values. The experiments were performed with a 2-port FPAR with acoustic wavelength λ=12μm (grating pitch 6μm). The FPAR device was micromachined on a freestanding AlN membrane with a thickness d=2μm resulting in a d/λ value of 0.1667. Then the FPAR has been coated with pp-HMDSO thin films of various thicknesses. The actual thickness of the sensing films has been measured during the deposition. After each deposition step the frequency shift as well as the insertion loss were recorded with a Vector Network Analyzer. In Fig. 3 the experimental frequency shift is compared to the theoretically determined one presuming a lossless pp-HMDSO film. For layer thicknesses h/λ < 1% the agreement between the lossless theory and experiment is excellent, while for thicker layers a progressive discrepancy is observed. This point comes to support the loss of sensitivity mechanism discussed in the previous section. The experimental data is seen to be in excellent agreement with the lossy theoretical predictions for $C''/C' \approx 1$ (ratio between imaginary and real part of elasticity).

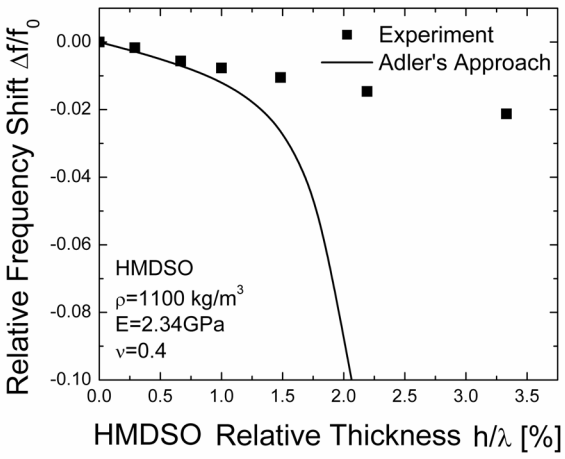

Figure 3. Theoretical lossless vs experimental mass sensitivity

In Fig. 4 the recorded changes in FPAR insertion loss as a function of the pp-HMDSO thickness are shown. Relative losses of up to 2dB are observed for layer thicknesses h/λ<1%. In Fig. 5 the close-to-resonance frequency response of a 2-port synchronous FPAR is shown prior the deposition of an

acoustically thin pp-HMDSO layer with h/λ=0.6%. The FPAR demonstrates around 4 MHz (4600ppm) frequency downshift at the expense of only 0.6 dB loss increase due to the HMDSO loading. The coated FPAR demonstrates an insertion loss of around 7dB and a loaded Q of 700. Note that an FPAR with such a performance was readily employed in a low noise frequency generator, which is a prerequisite for achieving high measurement resolution.

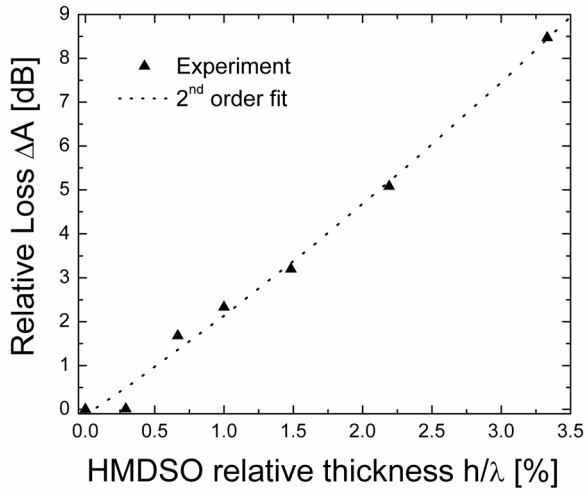

Figure 4. Change in insertion loss of a pp-HMDSO coated FPAR

IV. GAS SENSITIVITY EXPERIMENTS

Here we further considered a comparison of the FPAR gas sensitivity to that reported for other HMDSO-coated resonant devices using different types of acoustic modes. In [4] HMDSO-coated STW resonators at 700 MHz and SAW resonators at 430 MHz have been tested for their reaction against a number of gases including xylene. That study was aimed at achieving optimum HMDSO-layer thickness promoting maximum sensitivity. At the optimum thickness the wave energy is concentrated at the surface area of the film and strongly interacts with the sorbed gas [4]. Optimum values of HMDSO thickness were 100 nm (h/λ=1.4%) for the STW case and 280 nm (h/λ=3.9%) for SAW. The resulting sensitivities for xylene have been 6.4 Hz/ppm and 3.1 Hz/ppm, respectively. The conclusion drawn has been that STW-resonators have higher gas sensitivities at the same wavelength – a result that is in direct agreement with the theoretical comparison here, although Love waves are chosen as a representative of the SH-SAW family. To check this comparison experimentally, an FPAR device with an HMDSO layer as thick as 380 nm (h/λ=3%) was tested. The frequency downshift due to the layer deposition was 27 MHz (30 000 ppm). The HMDSO layer has not been optimized with respect to gas sensitivity and represents a relative thickness (h/λ) somewhere in between optimum values for STW and SAW, respectively. The device was gas probed with xylene vapors. The non-flow experimental method of applying the gas that we used for xylene probing has been described in detail in [17]. The changes of the resonant frequency and insertion loss have been recorded by a scalar network analyzer. The experimental sensitivity of the 380 nm HMDSO coated FPAR device to xylene concentration is shown in Fig. 6.

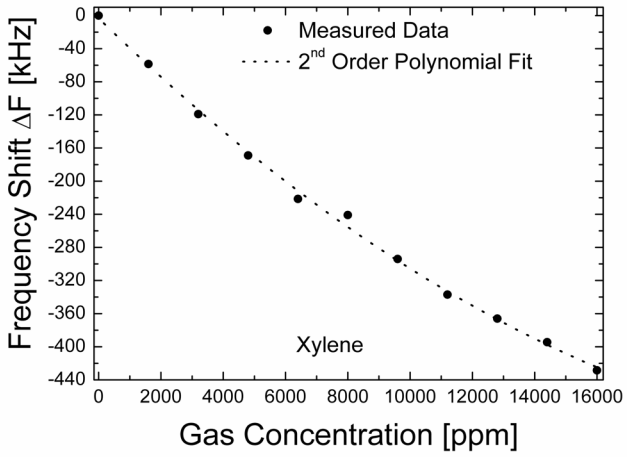

Figure 6. Sensitivity versus xylene for the FPAR with 380 nm HDMSO

The sensitivity curve is nearly linear with a 33 Hz/ppm slope, which is about 5 times higher than the sensitivity of the STW resonator from [4], operating at about the same frequency. At the same time the FPAR loss varied within 1 dB over the whole concentration range, which has a negligible effect on the sensor oscillator performance.

Further, the relative sensitivity to xylene defined as the ratio of the absolute sensitivity [in Hz/ppm] to the unloaded resonance frequency was calculated for FPAR, STW and SAW. These sensitivities were found to be in relation 5.0/1.3/1.0 for FPAR vs. STW vs. SAW, respectively, which is in a good agreement with the theoretical expectations.

It is further to note that HMDSO selectivity has also been assessed within this study. HMDSO coated FPARs have shown sensitivities towards ethanol, acetone and formalin in the range of about 1Hz/ppm which is more than one order of magnitude lower than the sensitivity to xylene. The latter results seem reasonable if one bears in mind that HMDSO has

been known as highly hydrophobic. Xylene molecules, also hydrophobic, should be adsorbed on the polymer surface at much larger quantities than the polar molecules of ethanol, acetone and formalin. Similar results have independently been observed in [18], where pp-HMDSO has demonstrated much higher sensitivity to the hydrophobic (non polar) toluene and diethyl ether as compared to the sensitivity to the polar acetone and ammonia. The above explanation is further supported through gas probing experiments with acetic acid vapors (see Fig. 7).

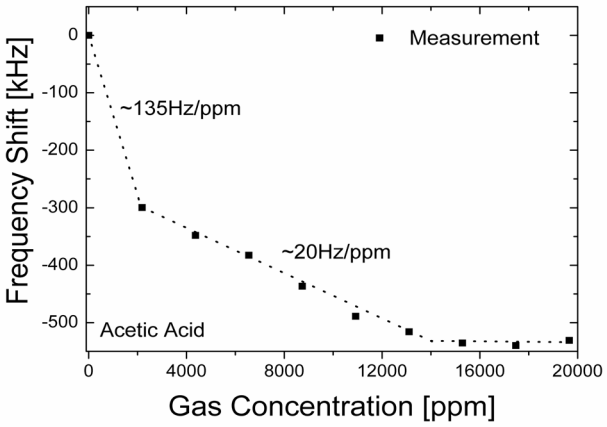

Figure 7. Sensitivity versus acetic acid vapors

The HMSDO-coated FPAR has shown very high sensitivity of 135 Hz/ppm exhibited at low concentrations, up to 2500 ppm, followed by a linear part with slope of 20 Hz/ppm that extends to about 20000 ppm gas concentration, where frequency reached the saturated downshift of – 550 kHz. These features are also noticeable in the behavior of the loss whose increase again does not exceed the 1 dB range. A high reaction of HMDSO towards the acetic acid has been already established by QCM assisted experiments [18] but the effect has not been clarified. To look for a possible explanation, we repeated the check of the FPAR against xylene. The reference equilibrium frequency has been shifted downward by approximately 200 kHz and the gas sensitivity has decreased for higher gas concentrations (see figure 8). The most plausible reason for this kind of behavior is that the covalent surface bonding produced by the acetic acid chemisorption possibly leads to the formation of polar functional groups of silanol and acetic ester types that irreversibly add extra material to the surface. These groups seem also to contribute to adsorption of additional quantities of acetic acid by physisorption saturation mechanism. The covalent bonding ultimately results in a decreased specific adsorption area for xylene molecules in the repeated experiment. This may not be significantly manifested during the first stage of the adsorption (small gas concentrations) but definitely limits the adsorption capacity as observed at higher concentrations.

Further research is needed to explore in details the effects of membrane scaling on the sensor performance.

Note that the weak dispersion of the S0 Lamb mode allows to improve the sensitivity of the FPAR without any change of the resonant frequency, i.e. decreasing the membrane thickness.

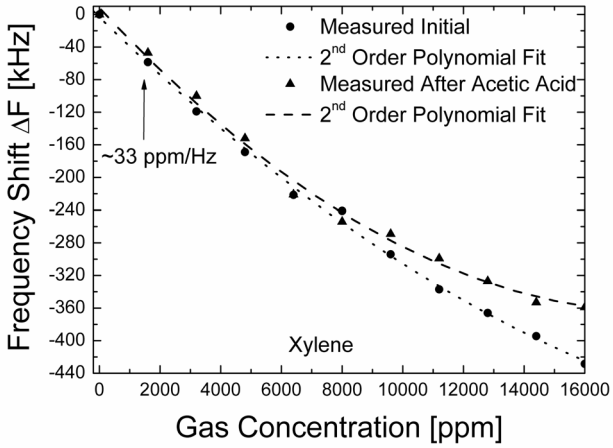

Figure 8. Sensitivity versus xylene before and after acetic acid

This unique opportunity has also been discussed in contour-mode resonant configurations employing the same mode [19]. More generally, the improvement in sensitivity is expected to be combined with reduced affinity to the viscous losses in the sensitive layer, which in turn imposes stronger limitations on the gas sensitive coating thickness. The latter applies also to frequency scaling where the used membranes are thinner and the layer losses larger. In other words, the optimum FPAR sensor design is application specific, i.e. requires a trade off between FPAR mass sensitivity and layer losses in order to achieve maximum resolution.

V. CONCLUSIONS

These initial results from the gas sensing experiments clearly support the theoretical predictions for high mass-sensitivity of the studied resonator type. The considerable sensitivity improvement over one of the most efficient acoustic wave mode gas sensors– the STW, for the same types of polymer film and probing gas, and at comparable frequencies and losses, reveals the great potential of the S0 mode for sensor applications. Another issue of practical importance is the fact that this high sensitivity is accompanied by a weak effect on the resonator loss even at high concentrations of aggressive gas phase compounds interacting with the polymer-coated surface. The authors believe that these features may be attractive for integrated circuit compatible FPAR sensor systems in the near future.

Calibration of Non-contact Temperature-compensated SAW Resonant Torque Sensors

V. Kalinin

***Abstract*—A new calibration method has been proposed for passive wireless torque sensors based on SAW resonators. It requires individual calibration of the sensors at the production stage only at room temperature and individual measurement of the difference frequency drift at zero torque over the operating temperature range. This approach greatly simplifies calibration and reduces its cost in the case of high volume manufacturing. Analysis of calibration statistics for the torque transducers has shown that the total measurement errors achieved in this case are very close to those obtained in the case of the individual sensor calibration in several temperature points over the entire operating temperature range.**

I. Introduction

Passive wireless or contactless sensors based on SAW resonators have been developed and found industrial application for temperature [1, 2], pressure [3] and torque measurement [4, 5, 6]. Recently, contactless resonant SAW torque sensors have been developed for various automotive applications such as electrical power assisted steering [7] and powertrain [8, 9]. Due to technological tolerances of the SAW die manufacturing and packaging processes, the SAW sensors usually require individual calibration of each unit in order to achieve a good accuracy around 1% full scale (FS). It is especially applicable to torque sensors due to additional contribution to the spread of sensor characteristics made by a glue interface between the SAW die and the part where shire strain is measured.

Automotive torque sensors are very demanding from the point of view of calibration since they need to produce a temperature compensated torque reading within a wide range from -40°C to +125°C and sometimes even at higher temperatures. This means that calibration of each torque transducer (application of a known torque) has to be performed at a number of temperature points more or less uniformly distributed within the operating temperature range. In the case of SAW temperature and pressure sensors, a large number of them can be placed into an oven and calibrated simultaneously because of their small size. The size of the SAW torque transducers can on the contrary be quite large so that only very few of them can be placed into the oven and calibrated simultaneously (see Fig. 1 showing torque calibration rig just for one flexplate transducer used to measure the output engine torque [8]). Large thermal mass of the rig including mechanical components required for torque application can increase time needed to reach a steady state temperature at each calibration point up to 2-3 hours so that the whole calibration process can take from 15 to 30 hours. As a result the calibration significantly increases the sensor manufacturing cost making it unacceptable for high volume automotive applications.

One of the solutions of the calibration problem has been recently proposed in [10]. The idea of the method is to reduce the number of the temperature calibration points from five-nine to just two. This approach gives extra calibration errors below ±1% FS for the flexplate transducers if the two-point individual calibration data are combined with the generic characteristics of the SAW sensors. It reduces calibration time at least by a factor of five. Nevertheless it still requires application of torque to a transducer at one elevated temperature, e.g. +80°C. This significantly complicates design of a calibration rig and increases the calibration time in comparison with calibration only at room temperature.

Figure 1. Calibration rig for the SAW flexplate torque transducer

The aim of this paper is to propose an alternative method of calibration when torque is applied to each individual SAW sensor only at room temperature. This method also relies on previously measured generic temperature characteristics of a particular type of the senor. It has been developed for torque sensors used in kinetic energy recovery system (KERS) of Formula 1 vehicles.

The structure of the paper is as follows. Design of the SAW KERS torque sensor and its generic characteristics are described in Section II. The next section presents a gradual development of the calibration method from a trivial approach to a more refined one. The method in its fully developed form is discussed in Section IV where it is applied to a number of the KERS SAW torque sensors. Section V presents some conclusions.

II. SAW KERS Torque Sensor

The sensor has been developed for F1 vehicles to monitor the amount of torque transmitted trough a short shaft from an electric motor to an engine [9]. The main features of this application are: (a) a very high rotation speed up to 18000 rpm, (b) very strong and fast torsional vibrations, (c) the temperature range from +20°C to +160°C, and (d) a limited space available for the sensor installation. These features dictated the sensor design based on two diametrically opposite SAW sensing elements, the 4x6 mm^2 SAW die being directly bonded to the KERS shaft as shown in Fig 2, and the cylindrical co-axial RF rotary coupler.

One of the sensing elements, HFSAW, contains three one-port resonators on Y+34° cut quartz. Two of them, with resonant frequencies $f_1 \approx 437$ MHz and $f_2 \approx 435$ MHz, are at ±45° to the X axis of the substrate and the shaft axis so that $F_{m1} = f_1 - f_2$ linearly depends on the applied torque M. The third resonator, with the frequency $f_3 \approx 433$ MHz, is used for temperature compensation since $F_t = f_2 - f_3$ depends on temperature T differently compared to F_{m1} allowing an independent measurement of T [5].

The second sensing element, LFSAW, contains only two SAW resonators with frequencies $f_4 \approx 431$ MHz and $f_5 \approx 429$ MHz positioned at ±45° to the shaft axis so that $F_{m2} = f_4 - f_5$ also linearly depends on M. Orientation of LFSAW relative to the HFSAW is such that $F_m = (F_{m1} + F_{m2})/2$ is sensitive to torque and insensitive to the bending force applied in both planes.

Each resonant frequency is measured by the interrogation unit wirelessly by means of launching 2 µs RF interrogation pulse through the RF rotary coupler and picking up free oscillations of the resonator after the pulse is over [7, 8]. The resonator excitation, the response sampling and the spectral analysis take 155 µs. The torque values are updated every 310 µs. The standard deviation of the measured difference frequency F_m is approximately 300 Hz.

Typical calibration characteristics of the KERS sensor measured at five temperature points within the torque range ±50 Nm (FS = 100 Nm) are shown in Figs. 3 and 4. The mathematical model of the sensor is as follows:

$$M = \begin{cases} C_p(T)\left(F_m - F_{m0}(T)\right)/(10^3 \times 2^{18}), & F_m \geq F_{m0}(T) \\ C_n(T)\left(F_m - F_{m0}(T)\right)/(10^3 \times 2^{18}), & F_m < F_{m0}(T) \end{cases} \quad (1)$$

$$F_t = 100a_1 - a_2T - 10a_3M/64 + a_4T^2/1600 + a_5T^3/102400 \quad (2)$$

where $C_{p,n}$, the reciprocal sensitivities of F_m to positive and negative torque respectively, the offset $F_{m0} = F_m$ at $M = 0$ and the coefficients $a_{1\text{-}5}$ are found from the measured data by means of LMS method. The numerical coefficients in (1) and (2) are selected in such a way that all the calibration parameters can be represented by two-byte integers in the interrogator's DSP memory. $C_{p,n}$ and F_0 as functions of temperature are stored in the form of lookup tables. Torque and temperature are found from the measured values of $F_{m,t}$ by means of an iterative solution of (1), (2).

The parameters of the model (1), (2) vary from one unit to another one. The degree of variation was investigated in

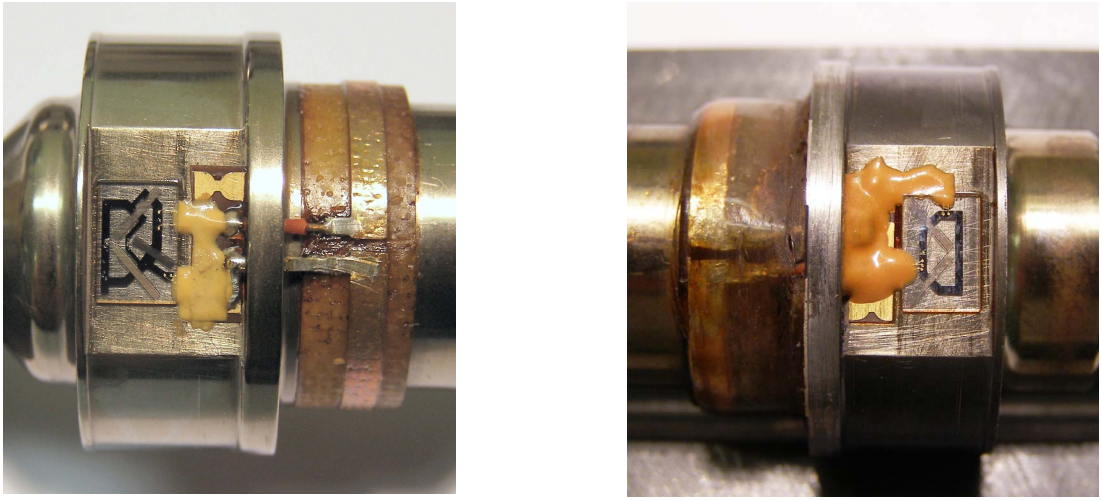

Figure 2. SAW sensing elements, HFSAW (left) and LFSAW (right), bonded to the two opposite sides of the KERS shaft

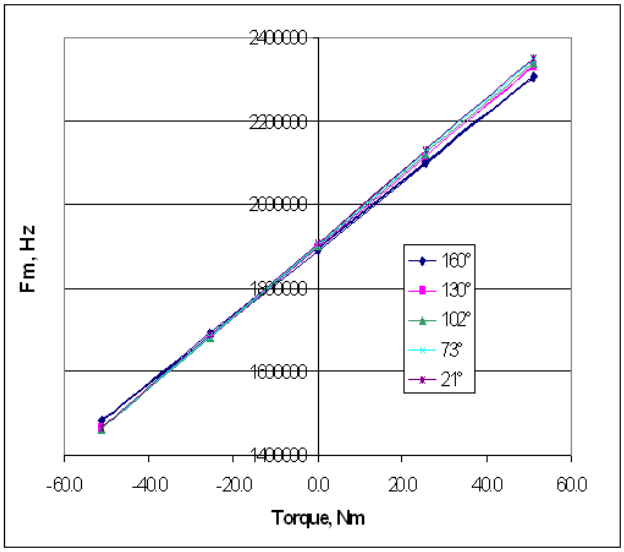

Figire 3. Variation of F_m with torque at different temperatures

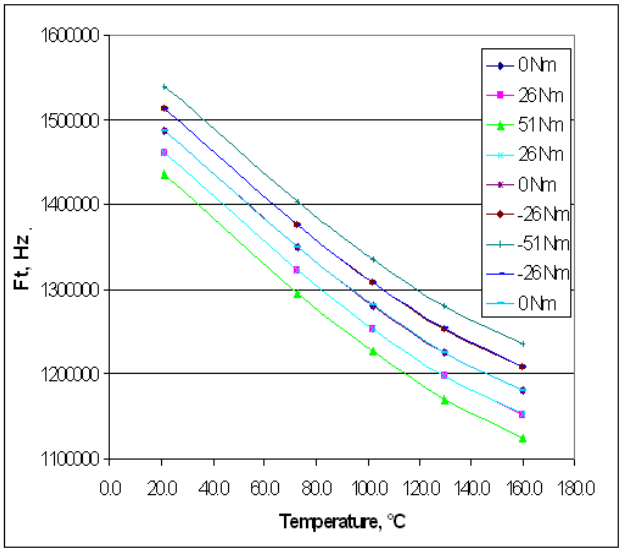

Figure 4. Variation of F_t with temperature at different torque values

[10] for the flexplate transducer and a similar variation has been observed for the KERS sensor. By averaging the values of $a_{1\text{-}5}$ and $C_{p,n}(T)$ for a certain number of units one can find generic calibration parameters for a particular type of a sensor. Tables 1 and 2 show generic calibration parameters for the KERS sensor $a'_{1\text{-}5}$ and $C'_{p,n}(T)$ obtained by averaging the characteristics of 45 units. One can notice that the torque sensitivity of F_m decreases with temperature due to reduction of the stiffness of the glue bond between the SAW die and the shaft.

III. Various Approaches to Calibration

Let us consider several possible approaches to calibration in the order of increasing complexity and investigate torque measurement errors associated with them.

A. Full Individual Calibration

In this case each unit is calibrated at five temperature points. After calibration, one can find the total measurement errors ΔM characterizing deviation of the sensor model (1), (2) from the real characteristics (calibration errors), hysteresis, non-repeatability, noise (it is greatly suppressed by averaging 400 measurement results) and errors in setting M and T. Fig. 5 shows the total torque errors measured for the sensor No. 46 that does not belong to the group of units used for finding the generic calibration parameters. Different curves in Fig. 5 correspond to different torque values from $-M_{max} = -50$ Nm to $M_{max} = 50$ Nm.

TABLE I. Generic Coefficients for F_t

a'_1	a'_2	a'_3	a'_4	a'_5
15400.56	2843.84	5900.64	-4023.09	3027.67

TABLE II. Generic Reciprocal Sensitivities

T	20	50	70	90	120	150	180
C'_p	29993	30042	30108	30221	30533	31482	33462
C'_n	30019	30060	30115	30215	30508	31413	33283

At $T < 100$°C the errors are dominated by non-linearity, non-repeatability and noise. At $T > 100$°C the errors start increasing mainly due to increased visco-elastic hysteresis in the glue bond. As a result, the maximum torque error is around 1% FS at the highest temperature and 0.1% FS at the lowest temperature.

B. Calibration Only at Room Temperature

In this case the sensor is only calibrated at $T_0 = 20$°C so only $F_{m,t}(M, T_0)$ are known. The complete set of calibration parameters is obtained in the following way. It is assumed that the offset $F_{m0}(T) = F_{m0}(T_0) = const$ and $C_{p,n}(T) = C_{p,n}(T_0) = const$ and $a_{2,4,5}$ equal generic values from Table 1, $a'_{2,4,5}$.

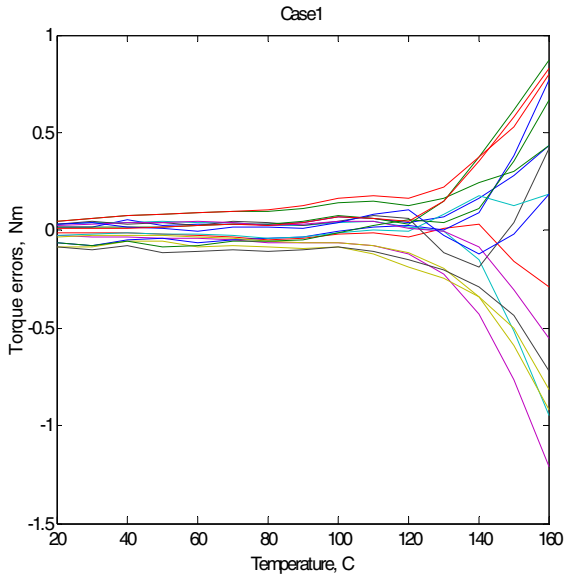

Figure 5. Torque measurement errors in the case A.

The rest of the coefficients are found as follows:

$$a_3 = -3.2[F_t(M_{max}, T_0) - F_t(-M_{max}, T_0)]/ M_{max}, \quad (3)$$

$$a_1 = [F_t(T_0,0) + a'_2 T_0 - \frac{a'_4 T_0^2}{1600} - \frac{a'_5 T_0^3}{102400}]/100. \quad (4)$$

In other words, the thermal variation of F_m is totally ignored and the thermal variation of F_t is assumed to be the same as the generic one. One should bear in mind that there is no point in using a generic variation of the offset F_{m0} with temperature. The spread of the characteristics $F_{m0}(T)$ is so large due to unpredictable modification of the SAW temperature characteristics by the glue bond [10] that this will not improve the accuracy of the calibration model.

The torque measurement errors obtained for the sensor No. 46 in this case are presented in Fig. 6. Clearly, they acquire a large systematic component that increases almost linearly from 20°C to 125°C up to -1.8 Nm. This happens mainly due uncompensated variation of the offset F_{m0} with temperature. Variation of the torque errors with torque at 160° is ±3.8 Nm – both due to the hysteresis and due to the fact that the torque sensitivity variation with temperature is not taken into account and temperature compensation is inaccurate because of using generic coefficients $a'_{2,4,5}$. The total errors are up to 6.5% FS at the highest temperature that is unacceptable for the application under consideration.

C. *Accounting for the Thermal variation of the Offset F_{m0}*

The next step in refining of the calibration method is to take into account the actual characteristic $F_{m0}(T)$ as well as more accurately find the coefficients $a_{1\text{-}5}$. It can only be achieved if the measurement of F_m and F_t is performed for each individual sensor at zero torque in a number of temperature points in addition to calibration at T_0. When doing this, a large batch of transducers can be simultaneously heated and cooled thus reducing the calibration time and cost.

The complete set of calibration parameters is found in this case in the following way. First, it is still assumed that $C_{p,n}(T) = C_{p,n}(T_0) = const$. Second, the complete matrices of raw calibration data

$$F_m(M, T) = F_m(0, T) + 10^3 \times 64 \times 4096 M/C_{p,n}, \quad (5)$$

$$F_t(M, T) = F_t(0, T) - 10 a_3 M/64 \quad (6)$$

are calculated at a number of torque and temperature points, while a_3 is defined by (3). After that, all the calibration parameters are found in a usual way by LMS method.

The torque measurement errors for the sensor No. 46 in this case are shown in Fig. 7. There is no a systematic component of the error varying with temperature any more. This is because variation of the offset F_{m0} with temperature is correctly taken into account and the temperature compensation of torque readings is performed correctly due to using the correct coefficients $a_{1\text{-}5}$ found from $F_t(0, T)$. However, the torque errors grow faster from ±0.1% FS at room temperature to ±1% FS at 125°C compared to the Case A because variation of the torque sensitivity with temperature is ignored. The errors increase up to ±4% FS at 160°C that is still unacceptable for the KERS application.

D. *Accounting for the Thermal Variation of the Sensitivity*

We do not have data for determining the torque sensitivity variation with temperature for each individual unit but we can use the generic thermal characteristic of the sensitivity instead. The question is whether the spread of the thermal variation of the torque sensitivity is small enough to achieve significant error reduction.

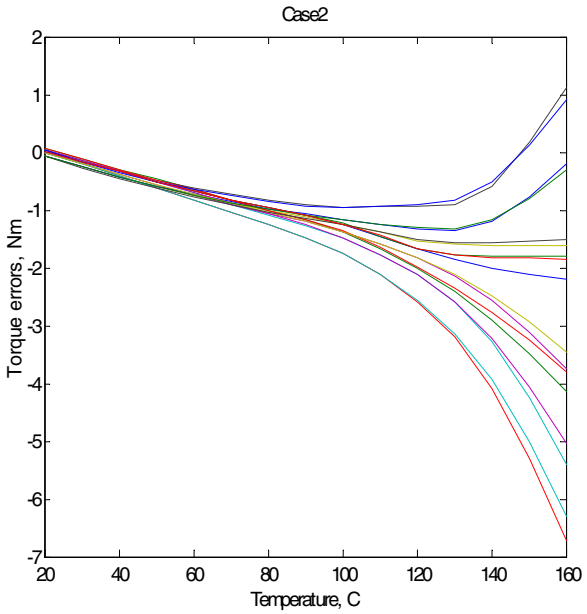

Figure 6. Torque measurement errors in the case B.

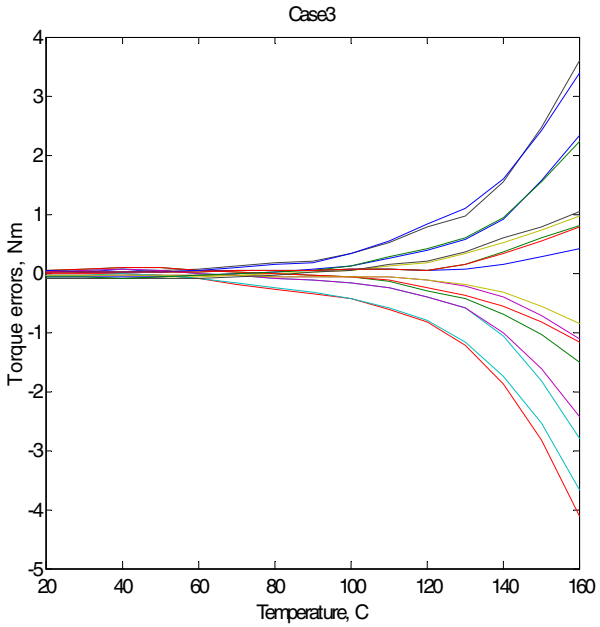

Figure 7. Torque measurement errors in the case C.

At the final stage of refinement of the calibration method it is proposed to calculate the reciprocal sensitivities according to the following rule:

$$C_{p,n}(T) = C_{p,n}(T_0)\frac{C'_{p,n}(T)}{C'_{p,n}(T_0)} \quad (7)$$

where $C_{p,n}(T_0)$ are found from the room temperature calibration and $C'_{p,n}(T)$ are taken from Table 2. In other words, the scaled generic thermal characteristics of the reciprocal sensitivities are used for each individual sensor. The rest of the calibration parameters are found the same way as in the Case C.

Fig. 8 shows the torque measurement errors obtained for the sensor No. 46 in this case. One can see that the errors are considerably smaller at higher temperatures than they were in the Case C. In fact they are almost the same as in the case of the full individual sensor calibration (compare with Fig. 5). Thus, at least for the given unit, the method described in the sub-section D gives an acceptable result in terms of accuracy.

IV. Discussion of the Proposed Calibration Method

To summarize the results presented in the previous section, the proposed method of calibration of the temperature compensated SAW torque sensors in the case of high volume production is as follows.

(1) At the development stage, a sufficiently representative number of the units (20 to 40) are fully calibrated in a number of temperature points (five to nine). Generic calibration parameters $C'_{p,n}(T)$ are found by averaging of the reciprocal sensitivities of the individual sensors.

(2) At the production stage, each individual sensor is calibrated only at room temperature and $C_{p,n}(T_0)$ are determined.

(3) Then the values of $F_m(0, T)$ and $F_t(0, T)$ are measured for a batch of sensors.

(4) The complete set of the raw calibration data is generated for each sensor using (5) and (6) where a_3 is found from (3) and $C_{p,n}(T)$ are found from (7). Then all the calibration parameters are found by the LMS method.

(5) Occasionally, a limited number of the calibrated units are tested over the entire temperature range in order to check stability of the manufacturing process.

It has been shown in Section III that the above method gives small additional calibration errors in the case of one unit, sensor No. 46. It needs to be checked for other units of the same type. Fig. 9 shows the maximum torque measurement errors obtained for 17 units not included in the batch of 45 units used to find the generic calibration parameters. The errors are presented for two temperatures, 125°C and 160°C, and four different calibration methods corresponding to the Cases A-D. One can see that the proposed calibration method (Case D) gives very consistent results for all sensors in the group and the errors, especially at T ≤ 125°C, are very close to those achieved in the case of full calibration (Case A). If the variation of the offset F_{m0} and the sensitivity with temperature is ignored (Case B) then the errors can be as high as 7.5% FS at 160°C.

Similarly, one can plot the maximum temperature measurement errors (see Fig. 10). Again, the proposed calibration method gives consistent results for all sensors with maximum errors not exceeding 2.5°C at T ≤ 125°C which is sufficient for an accurate temperature compensation of the torque readings.

The method under consideration can be applied not just to the KERS torque sensors but also to other types of SAW torque sensors such as flexplate transducers for measuring the engine output torque, driveshaft torque sensors and sensors

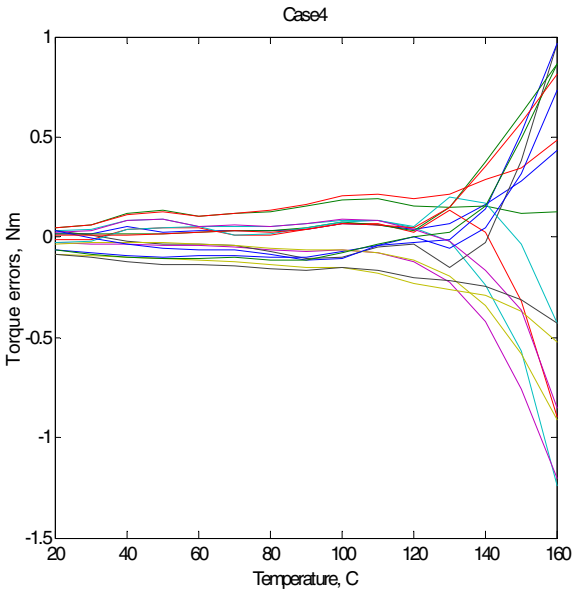

Figure 8. Torque measurement errors in the case D, the final version of the calibration method.

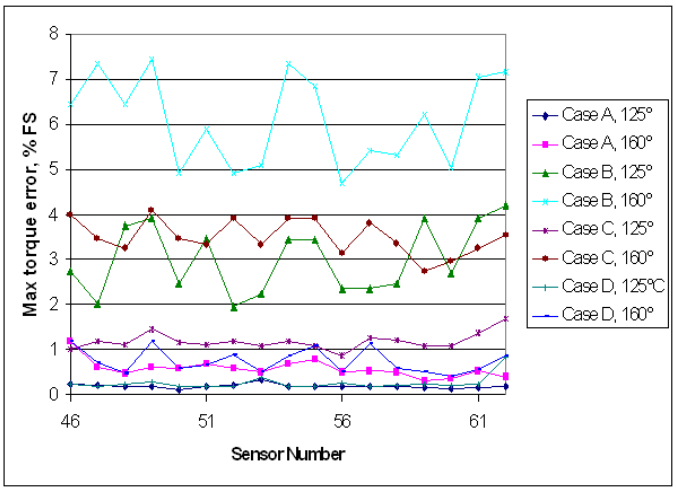

Figure 9. Torque measurement errors for 17 units at different temperatures and for different calibration methods.

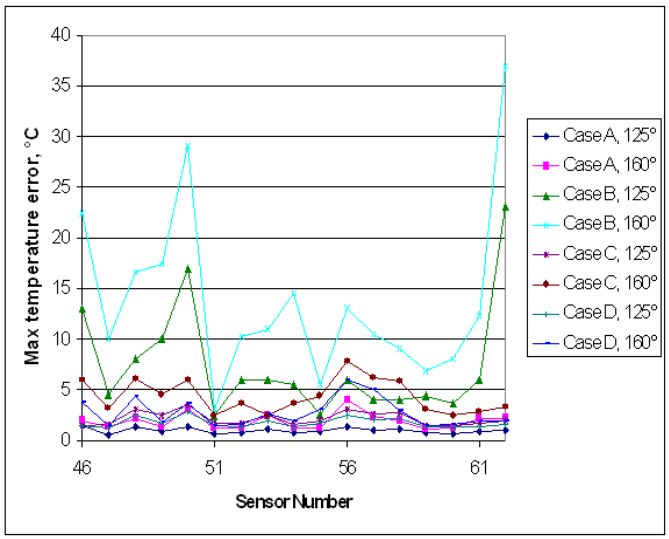

Figure 10. Temperature measurement errors for 17 units at different temperatures and for different calibration methods.

for electric power assisted steering. One should bear in mind that most of the applications do not require operation at temperatures above 125°C and, depending on the specified accuracy, the method described in the Case C may also be suitable. Operation at the negative temperatures should not create any problems because the glue bond stiffness does not drop and the sensitivity variation with temperature is minimal at $-40°C < T < 0°C$.

It is quite possible that a similar method can also be developed for other types of temperature compensated physical SAW sensors and even sensors based on other types of sensing elements. However, a careful analysis of the spread of calibration characteristics and the errors caused by their variation from unit to unit has to be performed in each case.

V. Conclusions

A calibration method for high volume manufacturing of the temperature-compensated resonant SAW torque sensors has been proposed requiring individual calibration of each unit only at room temperature. It is shown that the total torque measurement errors can be as high as 7.5% FS at 160°C and 4.2% FS at 125°C due to the spread of the temperature characteristics from one unit to another one if the individual temperature characteristics of the sensors are ignored. However, if the variation of the difference frequency offsets with temperature is measured on the individual basis then the torque measurement errors can be reduced to 4% FS at 160°C and 1.7% FS at 125°C. The best results are achieved if the thermal variation of the torque sensitivity is also taken into account on the basis of the generic calibration data obtained for a limited number of units at the development stage. In this case, the torque measurement errors can be as low as 1.2% FS at 160°C and 0.4% FS at 125°C. This is very close to the errors that can be achieved in the case of full calibration of each unit in a number of temperature points.

Abstract — The present work describes a high sensitivity multi-anti-resonance CMOS process compatible MEMS liquid dielectric capacitive tilt sensor. The dual frequency excitation of four electrode structure enables anti-resonance at equally spaced multiple frequencies and capability of measuring the tilt with enhanced sensitivity along with the direction of tilt.

I. INTRODUCTION

In the past twenty years MEMS technology has matured to provide 3-dimensional structures with multifunctional capabilities obtained through the interface with microelectronic circuits [1, 2]. A noticeable turning point from sensor research toward MEMS research was demonstrated in 1988 though the development of micro-machined movable parts [3], gears and turbines [4] on silicon chip. Since then, the micro-machined devices and system are being identified as the area of thrust for their capabilities of providing miniaturization, multiplicity, and micro-system integration [5, 6]. In the initial stage, MEMS research was directed towards the development of silicon based accelerometers where the change in capacitance caused by the deflection of proof mass is used to measure the angle of inclination by measuring the acceleration due to force of gravity [7]. A novel structure without using the solid proof mass for acceleration and tilt sensing was proposed by Dao et al. [8]. These devices operate on the principle of effect of acceleration on the natural heat convection from heated resistive wires in a gas surrounding the device. A convection based inclinometer with 0.05 degree resolution, an angle range of ±30 degree, and 45 mW of power consumption has been demonstrated by Billat et al. [9]. Leung et al. [10] proposed the first micro-machined accelerometer based on free convection heat transfer of a tiny air bubble in a closed chamber. This was followed by the development of electrolytic tilt sensors [11-13], which are based on the principle of measuring the unbalance voltage in Wheatstone bridge due to the tilt of the sensor. However, these sensors suffer from the draw-back of low sensitivity, and need compensation for hydrophilic nature of oxide layer to reduce the surface tension and optimizing the frequency of operation to avoid the electrolysis process. Identically the sensors based on the concept of convection of heat transfer [7-9] have poor sensitivity and consume more power. In 2006 a MEMS capacitive bending sensor was proposed by Aebersold et al. [14] for monitoring the physiological function (intravascular pressure, intraocular pressure).

The applications of sensors as a medical device, which could be implantable or attached to a body worn instrument, require that the sensor be light weight having smaller power budgets in the form of a single chip. The interrogation and sensing of real time accurate data can be used for therapy for correcting the vestibular balance disorder. An ultra-low-power MEMS tilt sensor using hybrid two chips (MEMS microstructure/CMOS vision chip) solution has been implemented by Constandinou et al [15] for use in health care. The objective of the present study is a step towards developing a new liquid dielectric capacitive tilt sensor which is small, rugged, has low power requirement, and provides very high sensitivity and does not have any moving part. The development of such a device is being aimed for health care for monitoring the movement of a patient in post-operative state and incorporating the sense system for implantable prosthetics and body worn instrument.

II PRINCIPLE OF OPERATION AND TECHNOLOGY

The challenge in the design and development of MEMS based sensor technology is driven by the medical science, where monitoring of physiological functions plays a vital role in the recovery process. An important application is vitro-retinal surgery, where the eye is temporally filled by SF6 and its absorption requires that the head and eye are kept in a position which allows proper recovery [16]. Other very important application is monitoring strain of the instrument in

978-1-61284-110-6/11/$26.00 ©2011 IEEE

the spinal fusion process by an orthopedic surgeon [14, 17]. Therefore, the need arises for the development of light weight, low power, highly sensitive tilt sensors, which could work in a noisy environment to provide safe and secure health care aid to patients in the recovery process. This can be accomplished using the non-power dissipative capacitive elements in the senor and using an innovative dual frequency sensing scheme for reducing the noise. In this process the temperature dependence of angle of tilt, viscosity effects of the liquid used and problems caused by electrolysis process in the electrolytic tilt sensor are eliminated. This makes the obvious choice for a capacitive accelerometer / tilt sensor, where the technology and sensing scheme is to be carefully designed.

A. Dual Frequency Operation of Tilt Sensors

It is know that noise in slurry or low conductivity fluid measurement is a function of 1/f noise, therefore lower the frequency greater is the noise. In the conventional Wheatstone bridge measurement technique of convection or electrolytic tilt sensors, the unbalanced voltage caused by the tilt is sensed across the detector. The obvious limitation of such a technique is its inability to provide the information on the axis of tilt. Therefore, the need arises to develop a sensing system which can provide additional information on axis of tilt while using the advantages of dual frequency excitation. This approach is based on using four electrodes which are simultaneously excited by two frequencies which are twice of the other. The four electrodes a, b, c, and d are arranged in such a way that two orthogonal axis are along the diagonals of a→c, and b→d as shown in Fig 1.

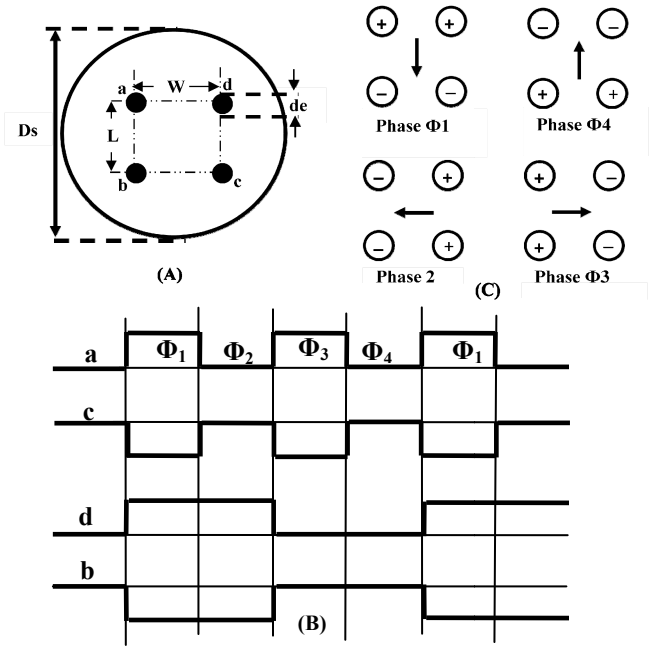

Fig. 1(A) Top view of the capacitive tilt sensor (B) Phase sequenced waveform applied to four electrodes a, b, c, and d (C) Direction of electric field between two electrodes

The frequency of excitation is selected on the basis to prohibit the electrolysis process and reducing the 1/f noise. The top view of the four electrode capacitive tilt sensor is shown in Fig 1(A) and the waveforms applied to the electrodes for dual axis measurement scheme is shown in Fig.1 (B), and the potential difference between four electrode structure used for measuring the tilt is show in Fig 1(C). The potential difference between two electrodes on account of phase sequencing, and choosing one of the frequencies to be twice of other frequency shows that dual axis information can be obtained by such a scheme. This information is contained in the direction of current flow between two posts defining the individual capacitive elements submerged in the liquid dielectric. The potential difference between the electrodes a→b (V_{ab}) and d→c (V_{dc}) or the current flowing between these two set of terminals (I_{ab} or I_{dc}) can be arbitrary chosen to represent –Y axis. Similarly, the voltage difference / current flowing between capacitive sensing electrodes d→a and c→b can be chosen to represent the – X axis. Since, the direction of current flow is in reference with the physical location of the electrodes, therefore these currents starts identifying the direction of tilt. These axes are defined arbitrarily and can be selected on the basis of mount / fixing of the sensor and the electrode structure. In the stable and un-tilted condition the differential current / signal can be sensed using a differential amplifier and the initial adjustment / calibration can be performed. Any tilt along the ±X axis and ± Y axis, synchronized with the clock generated from the exciting signal can be used to identify the axis and measure of tilt along the respective axis.

B. Fabrication Process

The starting wafer is both side polished, <100> n-type, silicon – on – insulator (SOI) wafer. Initially, 1 µm thick oxide layer is grown using wet oxidation process, thereafter 300nm thick silicon nitride layer using low pressure chemical vapor deposition (PCVD) is deposited. Thereafter, photo-resist is coated on the front side of the wafer and mask #1 is used to define the window in nitride and oxide layers. This is followed by etching silicon from the front side of the wafer for a depth of 25µm using Deep Reactive Ion Etching System (DRIE). This is required to have the hermetic sealing on the front side. Remove oxide and nitride layer from both sides of the wafer. Deposit both the sides of the wafer with fresh oxide layer (approx.1 µm thick by wet oxidation), and 300 nm silicon nitride layer by LPCVD technique. Use mask # 2 for opening the windows on the back side of the wafer for etching silicon and the buried oxide layer for taking contact from the back side of the wafer. Etch silicon and buried oxide layer from the back side of the wafer using Deep Reactive ion Etching. Deposit oxide layer on both the sides of the wafer by decomposing tetra ethyoxy silane (TEOS) in oxygen. This oxide on the front side gets deposited on top of oxide and nitride layers deposited earlier. In this process the entire front side of the wafer will get covered by additional oxide layer and groves etched earlier on the back side will also get covered by silicon dioxide layer.

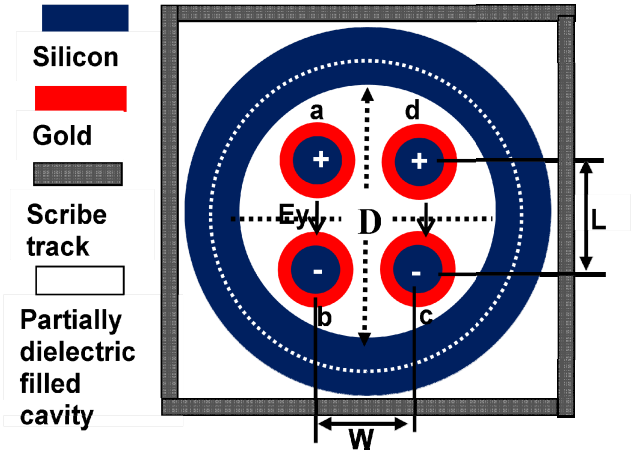

Fig.2. Die of a capacitive tilt sensing structure showing excitation of four electrodes for one of the phase sequenced state

Now use ion milling technique for removing the oxide layer from the front side of the wafer and the bottom of the groove formed by reactive ion etching. After this perform n+ diffusion for making the contact from the back side of the wafer. At this stage the front side of the wafer has 1µm thick oxide layer and 300 nm thick silicon nitride layers, and on top of this we have oxide layer deposited using the LPCVD technique by decomposing TEOS. Coat photo-resist on the front side of the wafer and define pattern in silicon nitride layer for etching deep well for defining the four electrode capacitive structure. This is followed by depositing Cr/Au by sputtering or ALD process. This deposition process is carried out on both sides of the wafer. In this deposition process the entire area of front side along with the electrodes gets covered by Cr/Au layer. This completes the process for taking the contact from the back side of the wafer from four electrodes. On the front side of the wafer nitride layer is removed, while retaining nitride layer on the back side. This is used to open four windows to take contact from four electrodes, which have been defined on the front side. This is followed by etching of 50 µm silicon in KOH using oxide as the mask. This is followed by using second mask on the front side to define the inner and outer rings of the four electrode capacitive sensor structure. A uniform etching of about 50µm of silicon in KOH is carried out. In this process the front side will get etched 50µm whereas the back side will get etched by 100 µm from the side to define the inner and outer rings of the capacitive sensor. This is followed by ion milling of frnt side using nitride as the mask for removing the Cr/Au deposited earlier, which was also existing on the bottom surface. In this process all the four electrodes gets isolated and the device is ready for bonding and packaging. A typical unit cell of the capacitive tilt sensor is shown in Fig. 3.

III MATHEMATICAL MODELLING OF STRUCTURE

An accurate analysis of the unit cell in Fig.3 has been carried out using the finite element tool of COMSOL Multiphysics Ver 4.1, which is elaborated in section IV. However, an insight on the functional behavior of the structure is obtained by considering a rectangular well which houses four stud like structure (electrodes). The inner wall of the well is at ground potential (electrical wall) and it is the partitioning wall between the electrodes that could be either an electrical wall or magnetic wall depending on the charge on the adjacent electrode, which is determined by the phase of excitation. The unit cell shown in Fig. 3 will always have the electrical wall at x = 0 and y = L/2, whereas y = 0 and x = W/2 can have the combination of either an electrical and magnetic wall or magnetic wall and electrical wall depending upon the phase sequence at a particular instant of time of the dual frequency excitation scheme adopted. The assumption of considering the rectangular wall is valid, because does not require any fabrication process change. The structure shown in Fig.3 is analyzed using clockwise rotation of standard Cartesian coordinate system. The structure is analyzed using Green's potential function for converting the differential equation to an integral equation for an unknown quantity of charge density. The analysis is carried out for a unit charge located x = x_0 and y = y_0, and one of three possible combinations of boundary conditions of electrical wall at y = 0 and magnetic wall at x = W/2 are chosen. For a unit charge located at (x_0, y_0) the Green's function, for a media having the dielectric constant ε satisfies the Poisson's equation in (x, y) plane.

$$\nabla^2 G_n (x , y \mid (x_0 , y_0) = - (1 / \varepsilon) \delta (x - x_0) \delta (y - y_0) \quad (1)$$

The Green's function can be expressed as the sum of the products of elementary function with separated variable [18]:

$$G_n (x, y) = \sum_{n=1}^{\infty} G_n (x) G_n (y) \quad (2)$$

Before solving (1) for potential function, we need to obtain the expression for $G_n(x)$ from the Dirichlet and/or Neumann boundary conditions which defines the unit cell. The Neumann type boundary condition at width x=W/2 forces the derivative of the potential function to be zero ($\partial G / \partial n = 0$), whereas the Dirichlet boundary condition at x=0 forces the potential function to be zero (G=0). The potential function $G_n^x(x)$ for electrical wall at x=0 and magnetic all at x = W/2 is expressed as:

$$G_n^x (x) = \sin \frac{(2n+1)\pi x}{w}$$

$$G_n^x (x) = \sin \beta_n \; x \; for \; n = 1, 2 \ldots . \infty$$

Where $\beta_n = (2n+1)\pi / W$

Since the electrode diameter is assumed to be much smaller than the electrode length, therefore the variation of field quantities along Z-axis can be neglected and potential function expressed as sum of the products of elementary functions with separated variables $G_n^x(x)$ and $G_n^y(y)$ using (2) can be expressed as:

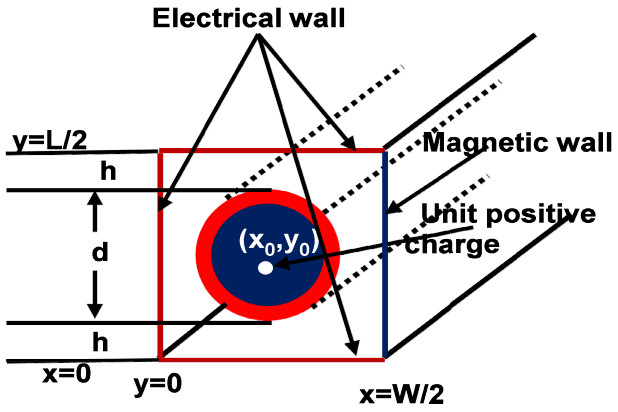

Fig.3. Unit cell of the capacitive sensor showing the formation of electrical and magnetic wall for a specific phase sequence.

$$\frac{d^2G_n(y)}{dy^2} - {\beta_n}^2\, G_n(y) = \frac{4}{\epsilon W} \sin\beta_n\, x_0\, \delta(y - y_0) \qquad (3)$$

The differential equation (3) is solved for the boundary conditions for the "i[th]" layer for the continuity of tangential component of potential function and continuity of the normal component of displacement density.

$$G(x, y_{i-o}) = G(x, y_{i+o})$$

$$\epsilon_i \frac{\partial G(x, y_{i-0})}{\partial y} = \epsilon_{i+1} \frac{\partial G(x, y_{i+0})}{\partial y}$$

After applying these boundary conditions the solution for the Green's potential functions $G(x_o, y \mid x_o, y_o)$ is:

$$G(x_o, y \mid x_o, y_o) = \sum_n \frac{4}{\beta_n W Y|_{y=0}} sin\beta_n x\, sin\beta_n x_o \quad (4)$$

This describes the Green's potential function in the (x, y) plane for a unit charge located at (xo, yo). The admittance $Y|_{yo} = 2\,\varepsilon_o \coth(\beta_n L/4)$ is obtained by using the analogy of permittivity with characteristic admittance of a transmission line. The variational approach adopted by Siddharth [19] for computing the capacitance of unit cell predicts dependence on the electrode width "d", for X-axis separation of "W", and Y-axis separation of "L". An easier expression for computing the capacitance per unit cell has been derived [19] for normalized electrode width "d", and length "L" w. r. t. width "W" of the sensor. The complete expression for the capacitance of a unit cell obtained by this technique is:

$$c = \sum_n \frac{1}{4} \frac{[\beta_n (d/2)]^2}{\cos^2[\beta_n (d/2)]} (2n+1)\,\pi\, Y|_{xo} \quad \text{F/meter}$$

Where $\beta_n = \frac{(2n+1)\pi}{W}$

$Y|_{yo}$ is input admittance of short circuited transmission defined by electrical walls located at L/4 from the unit charge, which is is expressed as: $Y|_{yo} = 2\,\epsilon_o \coth(\beta_n L/4)$.

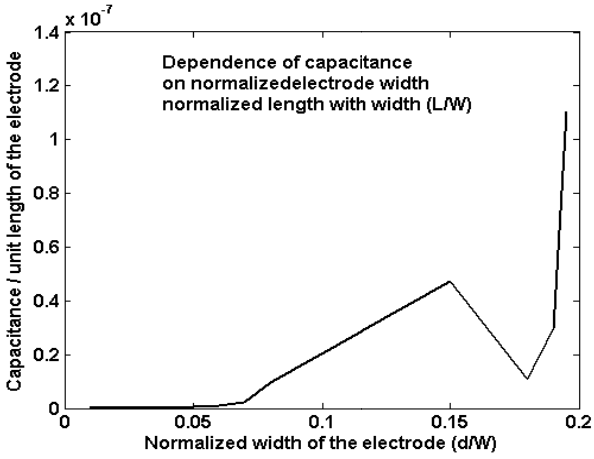

Fig.4. Dependence of the capacitance on the normalized electrode width

The results in Fig. 4 show that the maximum sensitivity is observed for d/W of 0.2. It is apparently the dimension for which the structure is likely to show resonant behavior. This implies that the capacitance has to increase, which will minimize the impedance for the dual frequency measurement scheme thereby maximizing the current. The resonant behavior can be fully exploited for getting very high sensitivity and the differential sensing to reject the common mode signal.

IV. FEM ANALYSIS OF THE STRUCTURE

A capacitive tilt sensor as shown in Fig. 1(A) consists of a hollow metallic cylinder terminated at both ends with insulating material. Four electrodes are placed symmetrically inside the cylinder such that they form four vertices of a square. The electrodes 'a' and 'c' are excited with same frequency 'f_1' but with a phase difference of 180 degrees. Similarly, the electrodes 'b' and'd' are excited with frequency 'f_2' and with a phase difference of 180 degrees. The frequencies f_1 and f_2 are chosen such that $f_2=2f_1$.

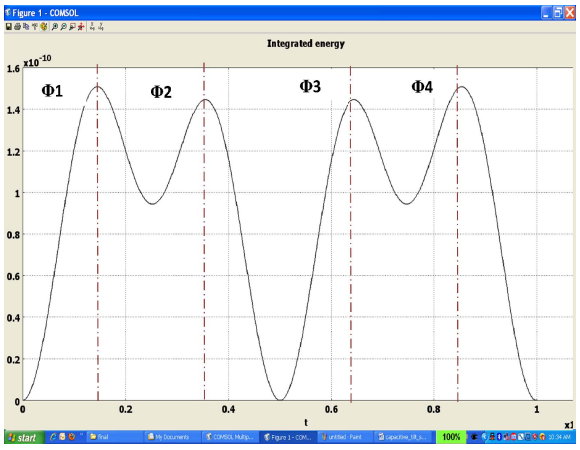

Fig.5. Energy stored in the cavity during different phases for w≠L

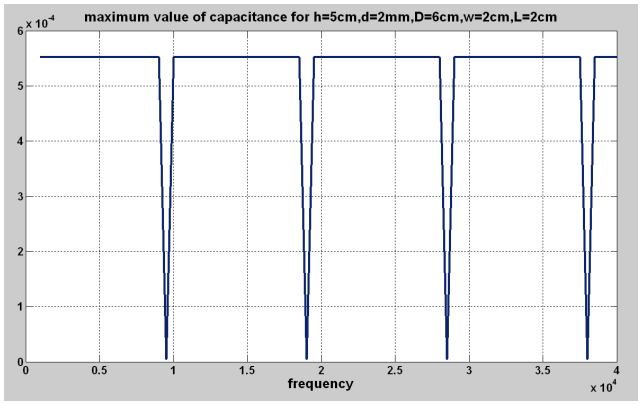

Fig.6. Cylindrical resonant wave guide resonant behavior of the tilt sensor

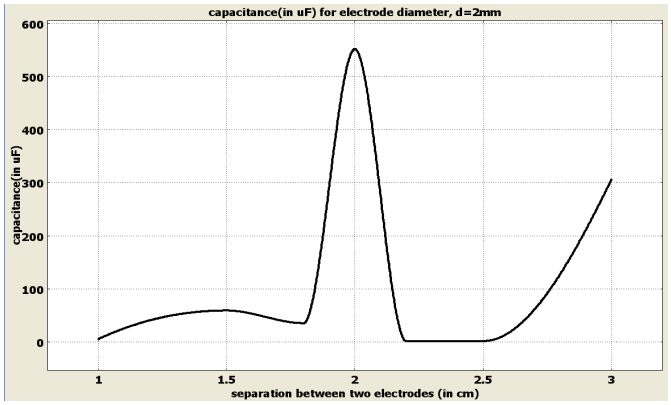

Fig.7. Dependence of resonant cavity capacitance on the electrode separation

The selection of $f_2=2f_1$ forms electric/magnetic walls between the electrodes which keeps changing according the phase sequencing at a particular instant of time. Fig. 1(B) shows the phase sequenced signal applied to four electrode structure and the direction of resultant electric field corresponding to each phase directing towards +X-axis,-X-axis, +Y-axis and –Y-axis is shown in Fig. 1(C). The analysis of the structure is carried out using the FEM Tools COMSOL Ver. 4.1 for analyzing the dependence of the total energy stored in the cavity for W=L and W ≠ L. Fig.5 shows the energy stored in the cavity for the case W≠ L. Since, the phase Φ_1 and Φ_4 have same amplitude of electric field strength therefore the total energy stored in the cavity will be equal for these two phases. A similar behavior is observed for phase Φ_2 and Φ_3, which have the same electric field strength. However the energy stored in phase Φ_1, Φ_4, is higher as compared to Φ_2 and Φ_3. Therefore the structure for maximum capacitance and resonance behavior is considered only for the case of W=L.

The formation of electric wall and magnetic wall by the phase sequencing scheme adopted and the cylindrical cross section of the structure establishes it resemblance with the cylindrical waveguide cavity. Therefore, it was expected to exhibit multi-resonance due the formation of electric and magnetic walls and equally spaced resonant frequencies on account of cylindrical cross-section. The simulation results shown in Fig.6 supplements the anticipated behavior of the structure, which predicts the presence of harmonics of 9 KHz, with a typical 3 dB bandwidth of 100Hz. As a consequence high Q of approx. 30 is obtained at the fundamental frequency, which will increase depending on the harmonic frequency selected for operating the device. Since, the excitation signals are 180 degrees out of phase, there will be anti-resonance, which will reduce the energy stored in the cavity at the resonant frequencies. This phenomenon will lead to almost zero energy stored in the capacitor at the resonance frequency, which corresponds to open circuit behavior of the cavity and a maximum value of $|S_{11}|$ = 0 dB, is expected at the anti-resonant frequencies. Since the energy stored in the cavity for each phase will be equal for the case of W=L.

The maximum value of capacitance is approximated to be 600 µF for the optimized parameters of the geometry of W=L = 2cm, for an electrode diameter of 2mm and internal diameter of the resonant cavity of 6 cm. This is the macro-model of the actual device to be implemented in silicon for which the simulation has been carried out. This macro model device will be tested for validating the concept before implementing the structure on silicon. The dependence of the capacitance on the separation between the electrodes is shown in Fig. 7 for the cavity height of 5cm. However, the behavior of the capacitance of the cavity will be independent of height of the cavity. The macro-model used in the evaluating the performance and the basic concept will be scaled down using the process steps outlined in section II for realizing the structure on the silicon wafer.

V. DEVICE CHARACTERIZATION RESULTS AND DISCUSSIONS

The theoretical analysis and FEM simulations are carried out for the clocking phase sequence φ_1, where electrodes “a”, “d” assumes the positive charge and electrodes “b”, “c” assumes negative charge. This defines an electrical wall between the electrodes “a” and “b” and electrodes “d” and “c” and magnetic wall between electrodes “a” and “d” and electrodes “b” and “c”. In this phase sequencing we will get the information on the tilt angle along the – y-axis. The measurements were performed on the macro device (scaled version of the device to be implemented on the silicon wafer) designed for the optimum performance for the electrode diameter of 2mm, inner diameter of the cylindrical wall of 6 cm, width and length defining the separation between two electrodes of 2cm. The analytical results in Fig. 4, showing the dependence of capacitance on normalized diameter of the electrode (d/W), predicts maximum sensitivity for d/W of 0.2. These results are supplemented by the FEM analysis carried out using the COMSOL Ver. 4.1, MEMS design tools, which show the maximum value of capacitance of 580 µF for d/W ratio of 0.2. This supplements the theoretical formulation to be consistent with FEM analysis.

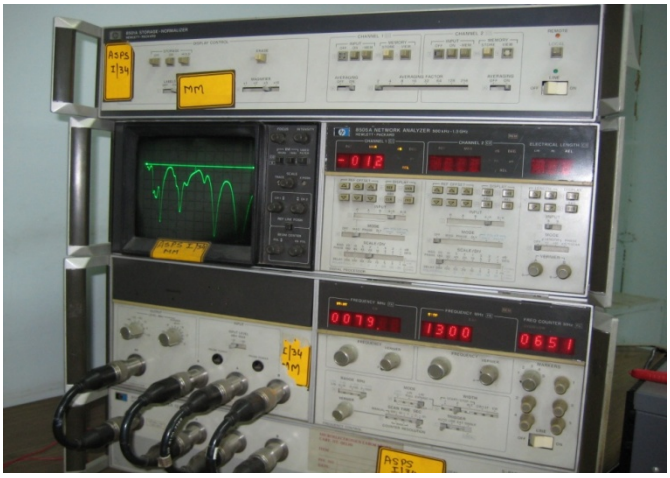

Fig.8: Measured |S11| parameter of the macro device showing formation of multi resonant cavity.

The macro structure is characterized using the 500Khz - 1300 MHz frequency range, HP8505A network analyzer by measuring the $|S_{11}|$ parameter. The measured results in Fig. 8 are consistent with the resonant behavior of forming the multi-resonant cavity predicted using the theoretical formulation and MEMS based simulation tools.

The sensitivity of the structure is primarily determined by the Q of the resonant cavity. An enlarged view of the resonant of |S11| plot shown in Fig.9 measured at the centre frequency of 1140 MHz is observed have 3 dB bandwidth of 20 KHz, predicting the resonant Q of 57, which is close to the value of Q=90 predicted by the FEM tools. The macro device was the first prototype developed for such as study and has considerable scope of improvement, which will bring closer agreement between the measured performance and the simulated results.

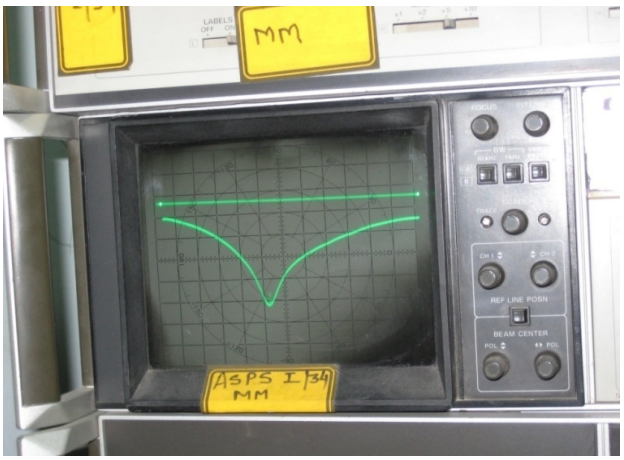

Fig 9. Enlarged peak of $|S_{11}|$ predicting the resonant Q of 57

ACKNOWLEDGMENT

The authors will like to thank Indo French Collaborative Program for Advanced Research (IFCPAR), India Habitat Centre, Lodhi Road, New-Delhi, India for providing the financial support to carry out the investigations reported in the paper. The authors are thankful to Prof. Boris Murmann, Department of Elect. Engg, Stanford University USA, for providing the opportunity to work on this problem.

Abstract— Quartz sensor is promising as a gravity sensor. This paper describes an improved technique of gravity sensor, based on the VCXO and crystal properties from the principle of the quartz motion sensor. The size of prototype sensor is around 27.0x12.0x1.0 mm. The sensor is used in the experiment, which give the gravity change. The experimental results show the relationship between gravity change and load resonant frequency. Then, from these results, we show that the load resonant frequency changes in direct proportion to gravity change.

I. INTRODUCTION

The Quartz crystal device is one of gravity sensors, which has high sensitivity. The crystal sensor, which is already realized, is pressure, power, gyros, chemistry, biochemistry, environment and etc.

When comparing with other sensors and such a crystal sensors, the crystal sensors are often responsible for the most sensitive range. Then, when assorting functions of the crystal sensors, It works as not only the physical sensors but also chemical ones.
Generally, the crystal blank for physical sensors is Z-cut. As for form, a Tuning-Fork type or a Double-Ended Tuning Fork type is used. The chemical sensor is the AT-cut, which surface is flat.

The AT-cut sensors are used for chemistry, biochemistry, biology and etc. For example, it is QCM (Quartz Crystal Micro-balance). The crystal blank for QCM has two pair of electrodes. Mr. Takeru Mutoh and Dr. Mitsuaki Koyama were authors who proposed the twin sensor. This sensor is one crystal blank and it has two pairs of electrodes [1].

On the other hand, for AT-cut quartz resonator, Mr. Mitoshi Umeki reported that the first application of MEMS technology. We believe in it [2].

Based on this background, the mineral exploration field, MEMS demanding the realization of the gravity sensor crystal technology is applied. Sensitivity of this specification is the gravity change of 0.5mgal, and this sensitivity is while moving the sensor.

Gravity is sensitive user specification that value is 0.5mgal, so to achieve such crystal sensor specifications; user requirement is at least 0.1mgal. To satisfy this requirement, there are four proposals as follow.

(1) Double-Ended Tuning Fork type sensor is one of the choices to achieve such high sensitivity sensors. Then we confirmed that this sensor was not sensitivity of 0.1mgal by simulation.
(2) By the structure of Double-Ended Tuning Fork type, it is difficult to realize purpose sensitivity of sensor alone. Therefore it comes true by the combination with a mechanical device. Some of these sensor configurations, the crystals may be realized. We do not expect the appearance of this crystal, which name is a twin. When presented with the temperature difference between the sensor and the pressure difference, this behavior occurs. Then, this sensor has uneasiness in reliability.
(3) Gravity changes the shape of the crystal blank is slightly deformed. The stress change accompanying this modification is measured as change of resonance frequency. This method has a too small change of resonance frequency. And this method has the influence of electronic noise. For this reason, predetermined sensitivity is not obtained.
(4) The capacitance is changed by motion of a crystal blank into crystal sensor. And, as the crystal sensor, the load resonance frequency change is measured. This method uses the principle of VCXO. And this sensor is a structure, which has a variable capacitor with a crystal oscillator. Furthermore, the crystal blank is changed easily, and is important to realize such a structure. This uses the principle of the motion sensor. This proposal is studied.

In this paper, the above proposals are shown in (4) is applied. MEMS (Micro Electro Mechanical Systems)

technology applied to the proposed AT-cut crystal structure of the gravity sensor, and the experimental results are shown.

II. TECHNICAL DESCRIPTION

A. Drawing of a crystal sensor

Figure 1 shows the concept drawing of the crystal sensor. This is cantilever of the single-sided support structure of AT-cut crystal blank with electrodes. This cantilever has a drive electrode and sensing electrode. Driving electrodes is interposed between the cantilevers. Sensing electrodes comprise a variable capacitor. Electrode A and B, it used as the sensing part, realize the variable capacitor. Electrode A for sensing is prepared in the end of this cantilever. Electrode B for sensing is formed also in the inside of the enclosure by the side of the contrary of the electrode. After this, Sensor name is Capacitive-type Quartz Sensor (CQS)

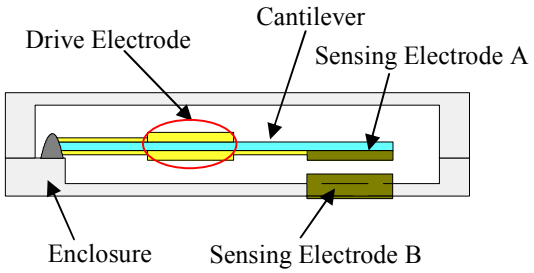

Figure 1. The basic structure drawing of a crystal sensor (cross section)

B. Equivalent circuit

Figure 2 shows the equivalent circuit, and is based on IEC 60122-1 [3].

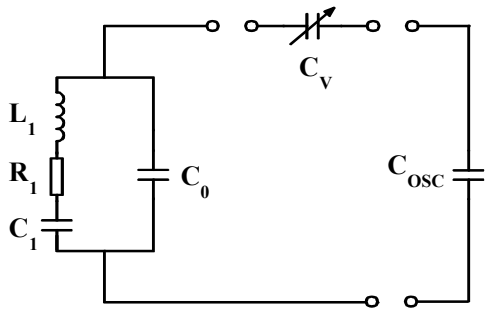

Figure 2. Equivalent Circuit

Figure 2 shows the symbol and symbols related to ; R_1, C_1,L_1 , and C_0: equivalent circuit constant of a crystal unit, C_V: capacitance ingredient of a gravity sensing part, C_{OSC}: capacitance ingredient of an activity circuit, Fr: the electric resonance frequency of a crystal unit, d: distance used as the standard which determines the capacitance of cantilever, δd : distance sensor is displaced by gravity change, S: effective electrode area of a sensor part, ε: dielectric constant. Then, C_L: capacitance of sensor area by the side of a crystal unit, and this combined capacity is the capacitance of the active circuit component C_{OSC} and the sensor capacitance component C_V.

Next, when F_L is oscillation frequency,

$$F_L = F_r \times \left\{1 + \frac{C_1}{2 \times (C_0 + C_L)}\right\} \quad (1)$$

where,

$$C_L = \frac{1}{\frac{1}{C_V} + \frac{1}{C_{OSC}}} \quad (2)$$

and

$$C_V = \frac{S \times \varepsilon}{d} \quad (3)$$

Using from equation (1) through equation (3), the cantilever is changed from d to d +δd, the difference between the load resonant frequencies is

$$\Delta f = F_r \times \frac{C_1}{2} \times (A - B) \quad (4)$$

where,

$$A = \frac{S \times \varepsilon + C_{OSC} \times (d + \delta d)}{C_0 \times C_{OSC} \times (d + \delta d) + S \times \varepsilon \times (C_0 + C_{OSC})} \quad (5)$$

$$B = \frac{S \times \varepsilon + C_{OSC} \times d}{C_0 \times C_{OSC} \times d + S \times \varepsilon \times (C_0 + C_{OSC})} \quad (6)$$

That is, the cantilever "d" from "d +δd" when a change to the difference between the load resonant frequency is larger. This is that sensitivity is high.

Then, figure3 shows in that the AT-cut crystal blank, as a motion sensor is not broken easily. The spring constant of AT- cut crystal blank is about 1800Ns/m. Therefore, no crack or/and no chipping AT-cut crystal blank is not easily broken by bend. This situation photograph shows figure 3, and, this crystal has realized by MEMS technology.

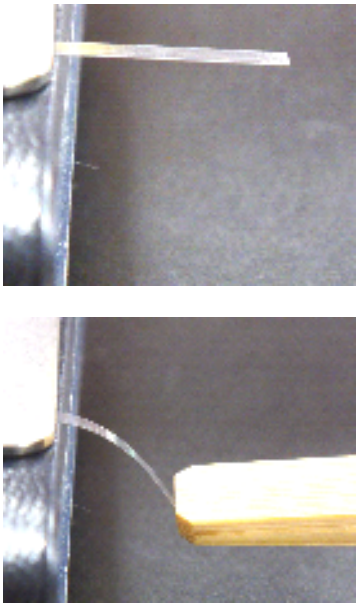

Figure 3. Bent test of AT-cut crystal blank
Crystal blank size : 20mm (L) , 1.6mm (W) , 0.02mm (H)

C. Specification and Trial

Specification of the crystal sensor is as follows.

Frequency	:	73 MHz
Mode	:	Fundamental vibration mode
Culture quartz	:	IEC60758 grade Aa
Surface	:	Polishing
Crystal blank dimensions	:	20.0×1.6 mm
Electrode	:	Cr, Au
Enclosure dimensions	:	27.0 × 12.0 × 1.0 mm

Based on such design specification, the crystal sensor is made as an experiment. Prototype sensor is shown in figure 4. Package materials for the prototype sensor are crystal. Crystal blank, package, and other wet-etching are applied, which technology is one of the MEMS.

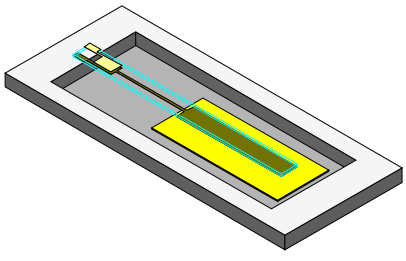

Figure 4. Prototype Sensor

D. Measurement system

Measurement system is constructed with sensor module, , Digital control equipment, and frequency counter. The sensor module is integrated with Crystal Sensor, Oven, and Oscillator Circuit. Figure 5 is the frequency temperature characteristics of the crystal sensor measured by IEC 60444-1 [4].

Temperature range is from +25 degrees C to +60 degrees C, which is a quadratic curve. Then, oven temperature is decided at +54 degrees C with the small amount of frequency change.

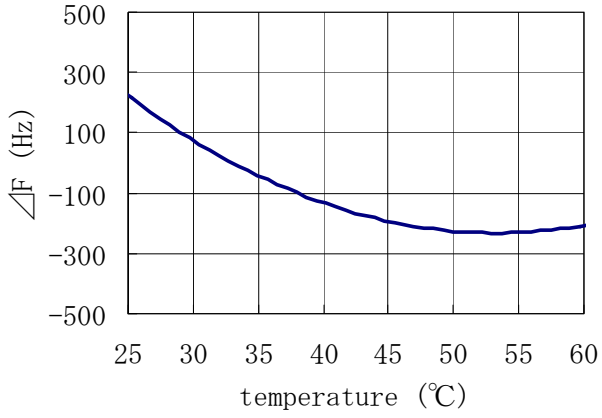

Figure 5. temperature characteristic result of the gravity sensor made as an experiment

Generally in measurement equipment, a cooling fan is used. Vibration of the cooling fan is from 0.05Hz to 5Hz, which is frequency noise of background vibration. Therefore, this cooling fan does not use it.

E. Relation of an inclination angle and gravity change

The structure of the gravity sensor has directivity in sensitivity. Therefore the sensitivity evaluation by the inclination angle is possible. The relation of an inclination angle and gravity change is shown in figure 6.

The gravity of the earth is 980gal. In the case of inclination angle θ=0 degrees, acceleration "a" applied to a sensitivity axis is

$$a = 980(\text{gal}) \times \cos\theta = 980(\text{gal}) \qquad (7)$$

On the other hand, in the case of inclination angle θ=Δθ degrees, acceleration "b" applied to a sensitivity axis is

$$b = 980 \times \cos\Delta\theta(\text{gal}) \qquad (8)$$

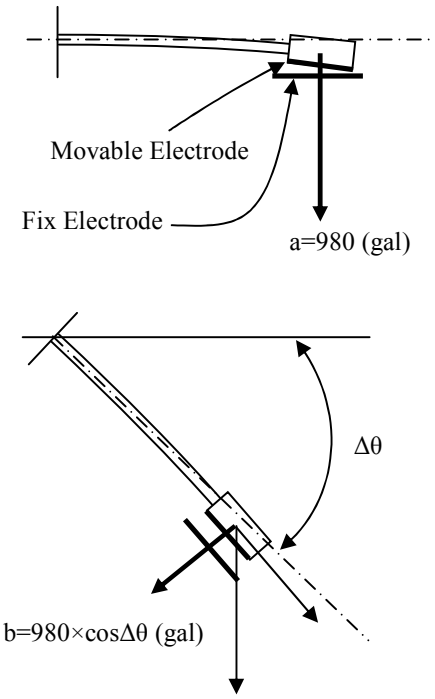

Figure 6. Gravity change by the inclination angle

III. EXPERIMENTAL RESULTS and DISCUSSIONS

A. Relation between gravity and frequency

Gravity change of 20mgal to 230gal is given to the sensor. The relation of gravity and load resonance frequency is shown in figure 7. Then, when gravity change becomes large, load resonant frequency is reduced. That is, load resonance frequency and gravity changes are involved.

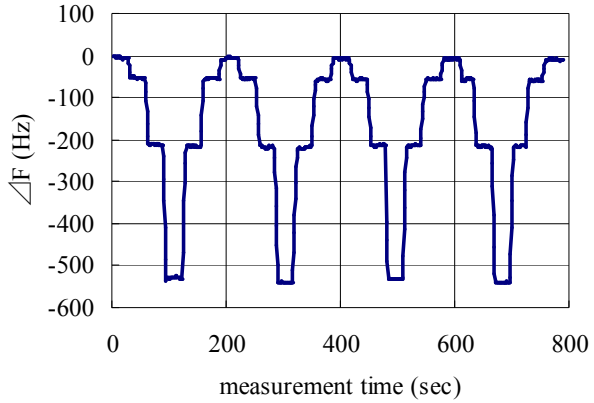

Figure 7. Gravity change and the relation of an amount of frequency variation

B. Relation of inclination angle and frequency

This is a definition, which load resonant frequency is equivalent to the oscillation frequency. The sensor is tilted at an angle from 0 degrees (980gal) to 30 degrees (849gal) to a change. This step change is 10 degrees. The oscillation frequency is measured continuously. Figure 8 is the result.
In Figure 8, the oscillation frequency changes over a maximum of 500Hz. Furthermore, it is reproducible.

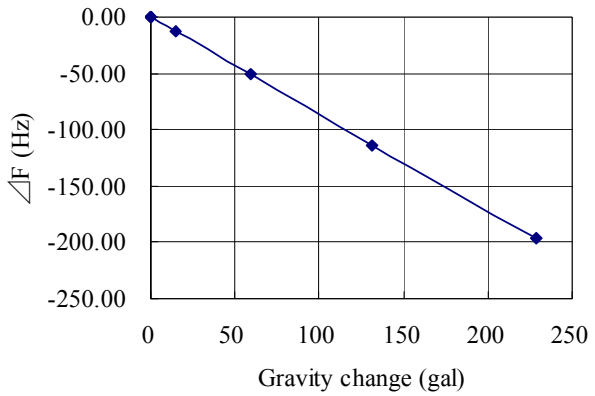

Figure 8.Oscillatory frequency deviation vs. Inclination angle

Gravity changes are given 20mgal sensors. Figure 9 is a waveform measurement. In figure 9, the measurement time 00:52-01:18 and 00:09-00:26 the frequency difference is the same -0.06Hz.

On the other hand, the change in measurement time is 00:52 and 00:09; the frequency drift is 0.02Hz. One of the factors of frequency drift is the temperature. This is not examined.

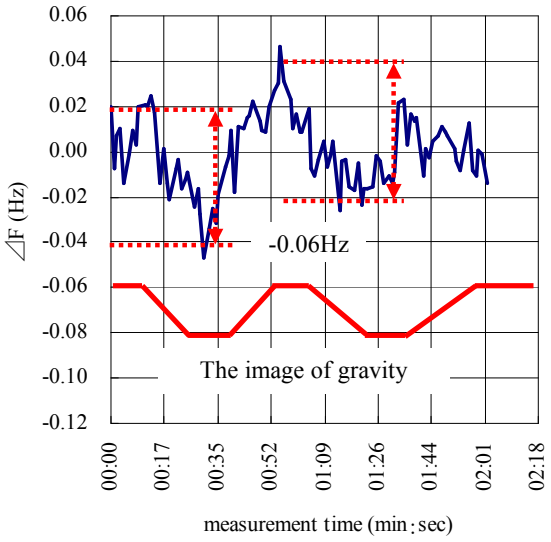

Figure 9. Frequency deviation vs. Time

IV. CONCLUSION

In this paper, AT-cut crystal blank is cantilever. The drive electrode and the sensing electrode are prepared on this cantilever. And the crystal gravity sensor, which changes capacitance, is proposed. Gravity sensitivity 20mgal is detected in the result of the experiment.

In the future, 0.1mgal is a realization of gravity sensitivity. Therefore, the crystal sensor structure and frequency drift is a challenge to improve. And we will study sensor structure and the effective Q value of the oscillation system.

***Abstract*—The thin-film acoustoelectric effect in surface acoustic wave (SAW) devices describes the interaction of electrical energy between a SAW in a piezoelectric medium and a thin-film placed in the wave's propagation path. The real-time observation of the thin-film acoustoelectric interaction is useful in the design and characterization of SAW-based thin-film chemical and physical sensors (i.e. temperature, humidity, viscosity, voltage, current, hall effects, etc.). An in-situ test fixture was designed to be mechanically, thermally and electrically stable. Data has been taken for many SAW devices and over a wide range of frequencies. The results show that the use of the in-situ procedure yielded: good agreement between theoretical predictions and the measured data, characterization a SAW-H_2 gas sensor in real-time and various methods to calibrate the film deposition system and procedure. This paper presents the approach taken in configuring an electron beam evaporation system for ultra-thin-film characterization and the design of test fixtures, data acquisition configuration, and experimental procedures to extract and analyze SAW parameters in real time, and to extract the thin-film properties under test.**

I. INTRODUCTION

The interaction between a surface acoustic wave (SAW) traveling in piezoelectric and a thin-film in the acoustic path may cause a measureable change in the SAW's amplitude and velocity. In the acoustoelectric regime, the magnitude of the change is dependent upon the electrical properties of the film. In-turn, the film's electrical properties may be dependent on a variety of physical parameters such as thickness, temperature, pressure, gas/chemical presence, etc. Hence, if properly implemented the SAW-thin-film acoustoelectric interaction is useful in the analysis of the properties of thin-films as well as thin-film physical sensors [1, 2]. Particularly, this work is a portion of a continuing effort to develop a passive wireless orthogonal frequency coded (OFC) SAW RFID-tag hydrogen (H_2) gas sensor [3-5], a schematic of which is presented in Fig. 1.

Real-time, in-situ observation of the acoustoelectric effect has been reported by previous authors [2]. However, they recommended that measurement of the entire frequency response of the SAW device should be avoided, because the time required for the sweep would be in the order of one to several minutes. Consequently, these authors [2] used SAW delay line sensors in an oscillator configuration. This type of system prevents the simultaneous measurement of multiple harmonics of the SAW device which is advantageous when attempting to characterize the dispersion characteristics of thin-films. Furthermore, the authors [2] omitted the experimental detail for duplicating or enhancing a similar system. The purpose of this paper is to present the approach taken using an electron-beam (e-beam) film evaporation system, test fixture and software, and the experimental procedure used to observe and measure the SAW-thin-film acoustoelectric interaction in real-time during the deposition (in-situ) of a thin palladium (Pd) film. The test thin-film, palladium (Pd), was chosen for the design and characterization of SAW-based hydrogen (H_2) gas sensors. The SAW-Pd-H_2 gas interaction was also observed via with the use of the test fixture and data acquisition system.

The paper to be presented is structured as follows: section 2 discusses the acoustoelectric-effect theory, section 3 details the test fixture, software design, and experimental considerations, section 4 details the experimental procedure, section 5 is a discussion of results and finally section 6 concludes the report and comments on prospective research applications.

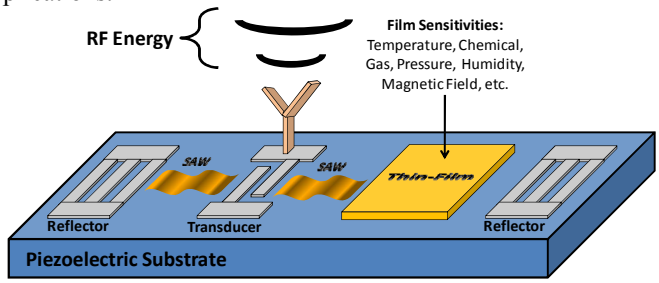

Figure 1 shows a schematic of a passive wireless SAW RFID-tag sensor. If properly designed the SAW propagation parameters are modulated by the presence and the properties of the thin-film.

II. THEORY

The piezoelectric substrate which was used in this work is Y-cut, Z-propagating lithium niobate (YZ-$LiNbO_3$), which was chosen because of its high electromechanical coupling coefficient, and self collimating properties. The acoustoelectric interaction occurs because a SAW traveling in a piezoelectric is accompanied by a traveling electric field (Fig. 2). The moving electric field creates only displacement currents in the piezoelectric (assuming that it is a lossless dielectric) and both conduction and displacement currents in the film (assuming that it is a semiconductor) (Fig. 2). The magnitude of the ratio of the conduction to displacement current is called the loss tangent of the interface. The acoustoelectric equations for SAW propagation in a piezoelectric medium and beneath a thin-film, predicts the wave propagation loss and velocity as a function of the loss tangent of the film-substrate interface.

If the thin-film is a metal, the conductivity is purely real consequently only conduction currents are generated in the

This work was partially supported through NASA-KSC STTR contract NNK04OA28C, in collaboration with Mnemonics Inc., the McKnight Doctoral Fellowship Program and the FHTIC Corridor Matching Research Program.

film and is given by $J_F = \sigma_F E$, where σ_F is the DC conductivity and E is the magnitude of the electric field. Assuming that the substrate is a lossless dielectric then current is a displacement current given by $J_S = j\omega\varepsilon_p E$, where $\omega=2\pi f$ is the angular frequency and ε_p is dielectric permittivity of the piezoelectric substrate. Hence, the loss tangent of the film-substrate interface is given by $\|J_F/J_S\|=\sigma_F/\omega\varepsilon_p$ and $\omega\varepsilon_p=\sigma_S$ may be considered substrate's reactive conductivity.

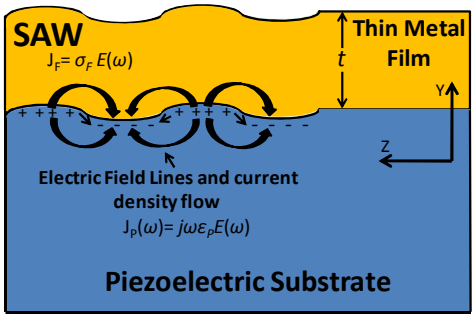

Figure 2 Schematic of SAW propagation in a piezoelectric crystal, beneath a thin-film. This is a cross-section of the film-substrate interface of the SAW device shown in Fig. 1. The subscripts, 'F' and 'P' represent the thin-film and the piezoelectric substrate respectively. σ is the DC electrical conductivity, ε electrical permittivity, ω is the angular frequency of the SAW, and J is the current density.

The acoustoelectric propagation loss, α, is given by (1) and phase velocity, v_p, is given by (2) as

$$\alpha = -\frac{\omega \cdot k^2}{2v_{sc}} \frac{\left\|\frac{\sigma_F}{\sigma_S}\right\|}{\left(1+\left(\left\|\frac{\sigma_F}{\sigma_S}\right\|\right)^2\right)} \quad (1)$$

$$v_p = v_{sc}\left(1+\frac{k^2}{2}\frac{1}{\left(1+\left(\left\|\frac{\sigma_F}{\sigma_S}\right\|\right)^2\right)}\right) \quad (2)$$

where, v_{sc} and k^2 is the short circuit velocity and electromechanical coupling coefficient of the piezoelectric substrate; for YZ-$LiNbO_3$, k^2=4.6%, v_{sc}=3408m/s, and $\varepsilon_P=51\varepsilon_0$. A full derivation of the acoustoelectric equations is provided by [2, 5-9], and will not be revisited here.

A strong interaction between the film and SAW occurs when the magnitude of the conduction to displacement currents at the film-substrate interface are equal (i.e. loss tangent = 1) (Fig. 3). This results in a large propagation loss in the SAW and a shift the velocity to half-way between the open and short-circuit velocities of the substrate. The open-circuit case occurs when the film's conductivity is very small in comparison to the substrate's conductivity hence open circuited and the short-circuit case occurs when the film conductivity is very high in comparison to the substrate's conductivity, consequently short-circuiting the electric field, E, and eliminating the piezoelectric effect at the surface of the piezoelectric.

The DC conductivity, σ_F of most films is dependent on the film's thickness, t, absolute temperature, T, and other physical parameters such as, gases, humidity, pressure, magnetic field, electrostatic potential etc. Thus, the properties of thin-films and their response to various stimuli may be studied through real-time observation of the acoustoelectric effect.

For this study the acoustoelectric interaction was observed by measuring the film's thickness and conductivity, and the SAW's propagation loss and velocity simultaneously. The open to short-circuit transition of the acoustoelectric effect may be observed by depositing a thin-film in the SAW's propagation path and measuring the aforementioned parameters during the film's growth. In metal films, the conductivity transitions from zero to high conductivity (i.e. open to short-circuit) as the film is deposited and the thickness, t, increases. In this experiment, Pd films were deposited in the propagation path on a z-propagating SAW in YZ-$LiNbO_3$ while the propagation loss and velocity were measured at the SAW's 1st and 2nd harmonics (54.5 and 109MHz) simultaneously. The design of the fixture is discussed in the next section.

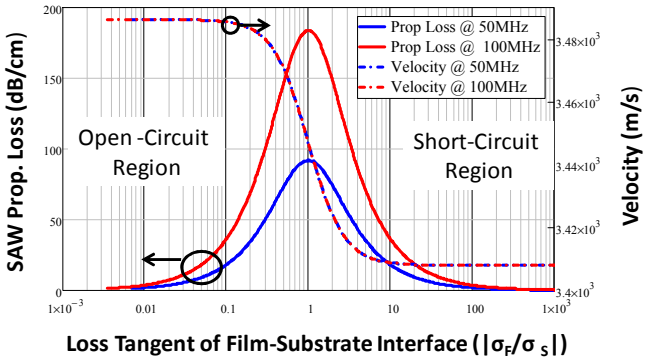

Figure 3 shows a plot of the SAW propagation loss (solid lines) and velocity (dashed lines) as a function of the loss tangent of the film-substrate interface.

III. SYSTEM DESIGN AND CONSIDERATIONS

A. Test Fixture

An in-situ fixture was designed to mask the SAW device so that the film is only deposited in the desired area (Fig. 4). The fixture was placed inside an electron-beam thin film deposition chamber, where RF cables where connected to fixture in order to interrogate the SAW, and measure film resistance (Fig. 5). The RF cables were connected to the measurement equipment via a high vacuum feedthrough which was constructed from an aluminum (Al) nut and bolt, semi-rigid coaxial transmission lines, and high-vacuum epoxy.

The test fixture was designed to be mechanically, thermally and electrically stable by using a (2cm x 7.5 cm x 4cm) brass base (Fig. 6). Sub-miniature version A (SMA) connectors were used to make connection between the RF cables and the probes. The RF probes were designed for stable electrical and mechanical contacts, which eliminates the need for bond wires and packaging. The probes were constructed using small hinges (for vertical motion), PCB, copper prongs (for the probes), and solder (connects PCB and probes) (Fig. 6). Threaded screws were used to apply a vertical force on the probes and hold SAW device die in place in order to

create good electrical and mechanical contact to the SAW device.

A picture of the YZ-$LiNbO_3$ SAW die which was used in these experiments is shown attached to the base in Fig. 6, a detailed schematic of the die is provided in Fig. 7. The schematic of the die shows a one-port differential delay device with large Al probes pads to facilitate easy contact and low electrical contact-resistance. The thin-film in the SAW propagation path makes contact with a set of Al bus-bars which are used to measure the film's sheet resistance, from which, the conductivity may be calculated using the thickness and area of the film. In a similar fashion two-port delay lines were also constructed. There are two RF probes on the fixture which allowed the measurement of a one-port device and film resistivity simultaneously or a two-port device. A secondary fixture was created which allowed both two-port measurement and film resistivity simultaneously.

The shadow mask for the fixture is shown in Fig. 8, and was also constructed from brass. For stability, the shadow mask was attached to the base with threaded screws. The length of the film in the propagation path was controlled using the width of the via-hole, which was controlled using a 56 thread-per-inch screw (i.e. 0.454mm lateral movement per revolution). An electrically controlled shutter (constructed using a DC motor and Al sheet metal) was positioned on the shadow mask to expose or block the evaporating material from the device. This function is important as it allows precise stop and start times for the film deposition on the substrate, and the possibility of deposition automation through computer controls.

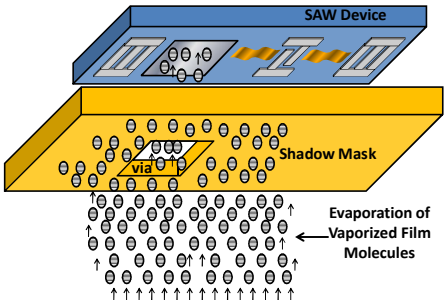

Figure 4 shows a schematic of the shadow masking of a SAW device, which allows deposition of the film precisely on the SAW propagation path.

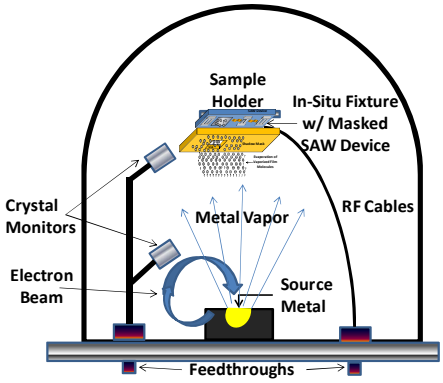

Figure 5 shows a schematic of the shadow mask inside the e-beam film deposition system, with dual quartz crystal monitors, and high-vacuum RF feedthroughs.

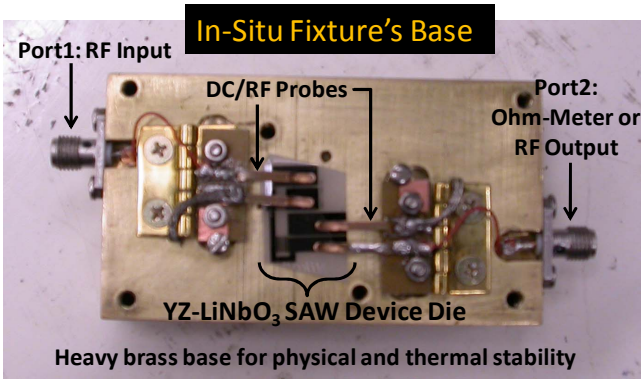

Figure 6 is a picture of the base of the test fixture. The fixture is designed to be mechanically, thermally and electrically stable by using a (2cm x 7.5 cm x 4cm) brass base. SMA connectors were used to make connection between the RF cables and the probes. The RF probes were designed and constructed for stable electrical and mechanical contacts, which eliminates the need for bond wires and packaging. The probes were constructed using small hinges (for vertical motion), PCB, copper prongs (for the probes), and solder (connects PCB and probes).

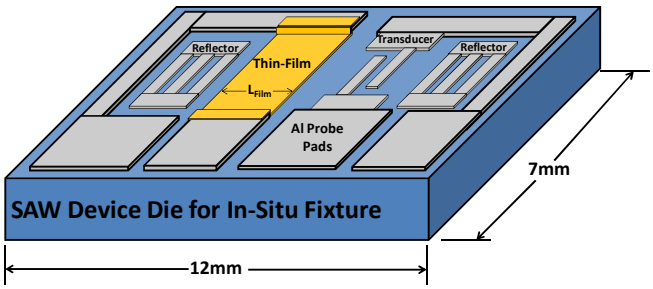

Figure 7 shows a schematic of the SAW die which was design for the in-situ fixture. It is a one-port differential delay device which large Al probes pads to facilitate easy contact and low electrical contact-resistance. The thin-film in the SAW propagation path makes contact with a set of Al bus-bars which are used to measure the film's sheet resistance, from which the conductivity may be calculated using the thickness and area. In a similar fashion two-port delay lines were also constructed.

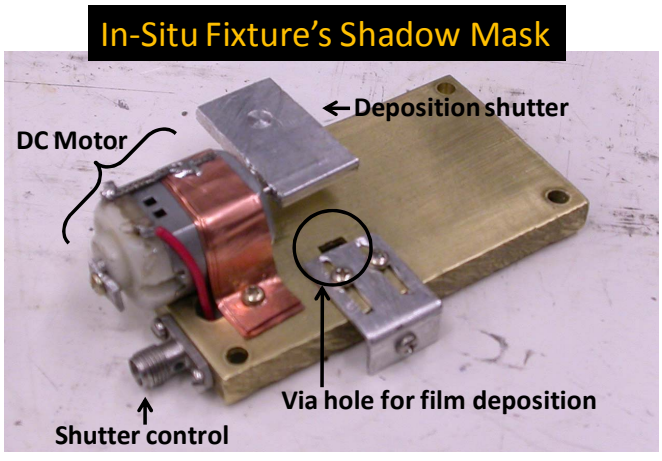

Figure 8 is a picture of the shadow mask for the test fixture. The length of the film in the propagation path was controlled using the width of the via hole, which was controlled using a 56 thread-per-inch screw (i.e. 0.454mm lateral movement per revolution). An electrically controlled shutter (constructed using a DC motor) was positioned on the shadow mask to expose or block the evaporating material from the device.

B. Software Design

The equipment used to acquire data are as follows: a vector network analyzer (VNA) to measure S-parameters, multi-meter (MM) measures film resistance, power supply (PS) which outputs constant voltages for IV sweeps and a quartz crystal monitor (QCM) to measure film thickness. The measurement equipment was controlled with a program created in Visual Basic and MATLAB. Microsoft's Visual Basic was used to control equipment and grab data because, Agilent, the manufacturer of the VNA, MM and PS supplied free sample code for each machine, which was combined and modified to make one central control program. Since Visual Basic is limited in its data analysis capability it was necessary to export the data to MATLAB where it was analyzed in real-time. In the MATLAB toolbox there is a program called "exlink", which allows MATLAB to be controlled via Visual Basic. This functionality was essential in order to achieve the real-time analysis capability.

C. Experiment Considerations

The goal is to measure SAW propagation loss and velocity, thus, it is important to maintain a signal to noise ratio (S/N) which is greater than 0dB. Since the maximum propagation loss of the SAW is controlled by the length of the film in the propagation path, it is necessary to design for a film length that will not bury the SAW response in noise. From (2), the maximum attenuation occurs when the magnitude of the displacement and conduction currents are equal, thus reducing (2) to

$$\alpha_{\max} = -\frac{\pi \cdot f \cdot k^2}{2v_{sc}} \tag{3}$$

The maximum attainable propagation loss in dB is given by

$$PL_{\max\_dB} = -20\log_{10}\left(\exp(\alpha_{\max} \cdot L_{film})\right) \tag{4}$$

where L_{film} is the length of the film in the propagation path. Fig. 9 shows a plot of the maximum theoretically attainable propagation loss as a function of the length the film in the SAW propagation path at 50, 100 and 1000MHz. For the experiments performed in this paper L_{film} = 1mm.

IV. EXPERIMENTATION

Prior to film growth, the lithium niobate (YZ-$LiNbO_3$) substrate was cleaned with an ultra-sonic bath in acetone, rinsed in methanol, then de-ionized water, and finally plasma irradiated with O_2 gas at 150W for a minute. Experimental observation has shown that it is important to keep a consistent cleaning and preparation procedure in order to decrease variability between experiments.

Films were deposited using electron beam evaporation, at a growth rate of 0.1Å/sec, in a bell jar which was evacuated to 10^{-6}Torr. The film thickness was monitored using dual quartz crystal monitors, and the film resistance was monitored during growth (in-situ). A picture of the equipment set-up is shown in Fig. 10; the VNA, MM, PS and control computer are all positioned beside the e-beam chamber.

The VNA was used to sweep a wide frequency range and capture data at multiple SAW harmonic operation points (54.4 and 109MHz). This function is useful when evaluating the dispersion characteristic of the thin film. The SAW propagation loss was extracted by measuring the ratio of reflected wave amplitude with the film to the reflected wave amplitude without film. The group delay was extracted by gating the time domain response and performing a FFT of the time gated response to obtain the frequency response. From which, the group delay is the derivative of the phase with respect to frequency *(-dθ/dω)*, from which, the velocity beneath the film was extracted since L_{film} is known.

A screen shot of the data output from the MATLAB software is shown in Fig. 11. The upper left plot is the time domain response of the SAW, which and transformed to the frequency domain in the upper right plot. This plot is then truncated to the 1dB bandwidth of the SAW response (middle left) from which the SAW propagation loss (middle right), center frequency (lower left) and group delay change (lower right) are extracted. The data was sampled at a rate of 3sec/sample, and at a growth rate of 0.1 Å/sec, resulted in a sample every 0.3 Å. A post processed plot of the SAW propagation loss and velocity as a function of Pd film thickness at 54.5 and 109MHz is given in Fig. 13.

A secondary experiment was performed in order to characterize the response of the SAW-Pd-H_2 gas interaction as a function of time. In this experiment the Pd film deposition was stopped near maximum SAW attenuation, removed from the high vacuum environment, and exposed to 2% H_2 gas (balance N_2) in multiple on/off cycles. The result of the SAW-Pd-H_2 gas interaction is presented in Fig. 14.

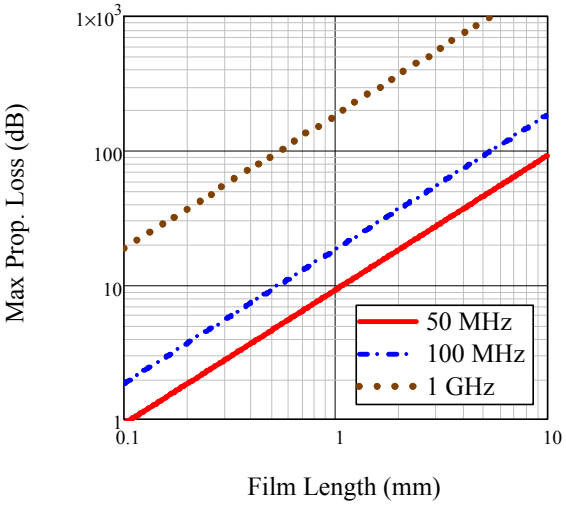

Figure 9 is a plot of the maximum attainable acoustoelectric propagation loss of a z-propagation SAW on YZ-$LiNbO_3$ as a function of the length of the film in the propagation path.

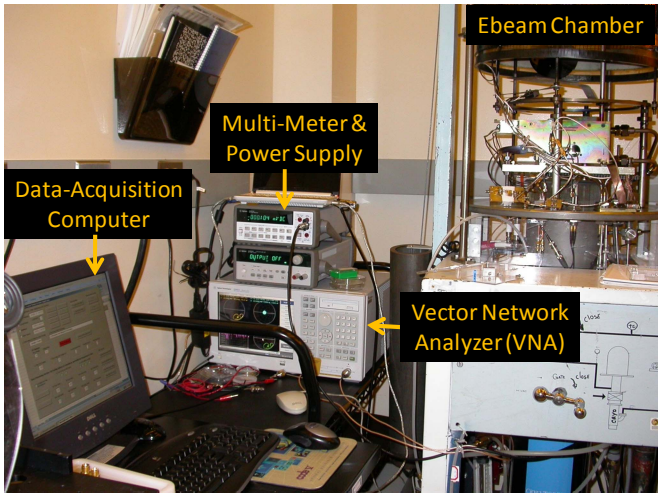

Figure 10 is a picture of the e-beam system, text fixture and data acquisition set-up in class 100 cleanroom.

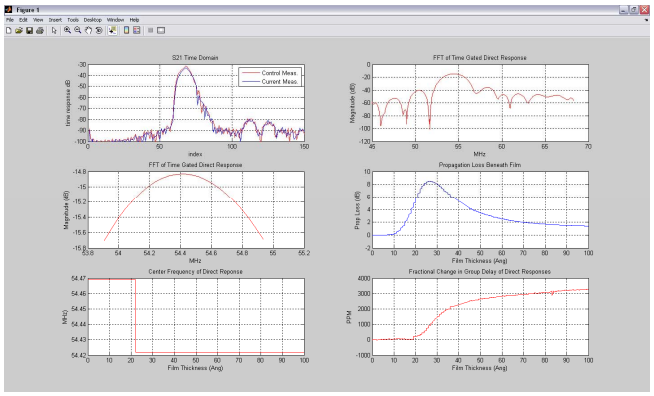

Figure 11 shows the real-time output of data acquisition software; measured S-parameters which are processed to extract propagation loss and delay shift during growth of a Pd film in the SAW propagation path. The plots are updated in real time as film thickness changes.

V. DISCUSSION

A comparison of the predictions (Fig. 3) and the measured data (Fig. 13) shows satisfactory agreement with some differences. One notable difference is the disparity between the predicted and measured maximum attenuation at 54.5 and 109MHz. From (4) the predicted maximum attenuation at 54.5 and 109MHz is approximately 100 and 200dB/cm respectively, whereas, the maximum measured propagation loss is approximately 85 and 165dB/cm respectively. This discrepancy is most likely due to the non-uniform distribution of the film. A light meter was used to infer the film's thickness distribution by measuring the fraction of light which was absorbed by the film as a function of position on the film. Ideally as the film gets thicker a greater percentage of light is absorbed. The film's thickness distribution was found to follow a Gaussian distribution (Fig 12). Another notable difference is between the predicted and measured short-circuit velocity. The short-circuit velocity is predicted to have limit of 3408m/s on YZ-$LiNbO_3$ however the measure velocity gradually decreases to 3320 m/s (Fig 13). The measured data includes both acoustoelectric and acoustoelastic interactions between the film and substrate, whereas, the predictions only account for the acoustoelectric mechanisms. Thus, the decrease of the measured SAW velocity below the theoretical limit is most likely due to acoustoelastic (i.e. in this case mass loading) effect. There may be also be acoustoelastic effects on the SAW propagation loss and other second order effects such as bulk or other generated modes which interfere constructively and de-constructively with the SAW amplitude and velocity at 1st and 2nd harmonic.

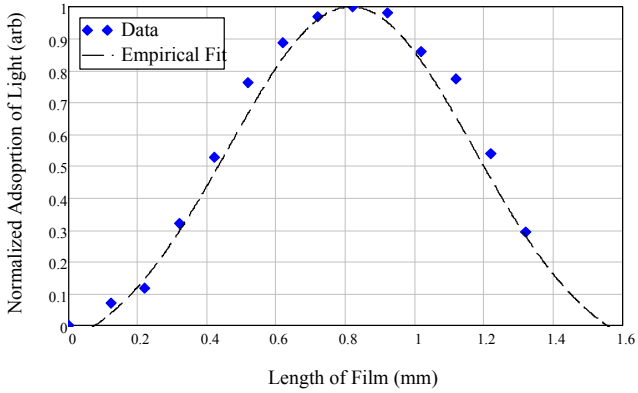

Figure 12 shows the thickness distribution of a 60Ang Pd film deposited through a 1mm aperture. The thickness distribution was extracted from light reflection measurements across the film.

The fixture and software was also used to characterize the SAW-Pd-H_2 gas interaction (Fig. 14). When exposed to 2% H_2 gas, there was a sharp decrease in film resistivity which caused an increase in the SAW propagation loss. The resistivity increased with each exposure to H_2 gas and was accompanied by a gradual increase in resistivity over time. If the increase in resistivity associated with H_2 gas exposure is excluded, there remains a gradual increase in resistance, caused by the aging of the ultra-thin Pd film in ambient atmosphere [10]. Thus, the SAW-Pd-H_2 gas sensor operation appears to be governed by the acoustoelectric effect. Thorough experiments into this interaction may lead to better understanding of the Pd-H_2 gas adsorption and desorption, and conduction mechanisms. Furthermore, this method may be used to evaluate the parameters of delicate ultra-thin films without need for contact from probes (which may damage samples and/or add experimental error).

These results suggest that this software and fixture is suitable tool for SAW sensor research where the knowledge of the real time response is necessary. Furthermore, this system has been used for other purposes such as determining the optimal settings for the VNA (i.e. adjust frequency span, IF BW, averaging, sweep time and/or output power until scatter is minimized). This is necessary when attempting to minimize measurement error. The system was also useful as high vacuum gauge since there is a measureable decrease in SAW propagation loss at high vacuum (10^{-6}Torr) as compared to 1atm [11, 12]. Lastly, the system was used to calibrate the e-beam film deposition procedure that is to develop a procedure to obtain reproducible results.

VI. CONCLUSIONS

The design of a test fixture and data acquisition software for the real-time measurement and analysis of the SAW-thin-film acoustoelectric interaction was demonstrated. The fixture allows measurement of SAW propagation loss, velocity and film resistivity simultaneously. The fixture uses RF and DC probes which eliminate the needs for bonds wires and packaging. Measured results show good agreement with the theoretical predictions. Research applications for the system include: SAW substrate parameter extractions, thin film material characterization, thin film physical and gas sensors, and deposition procedure developement.

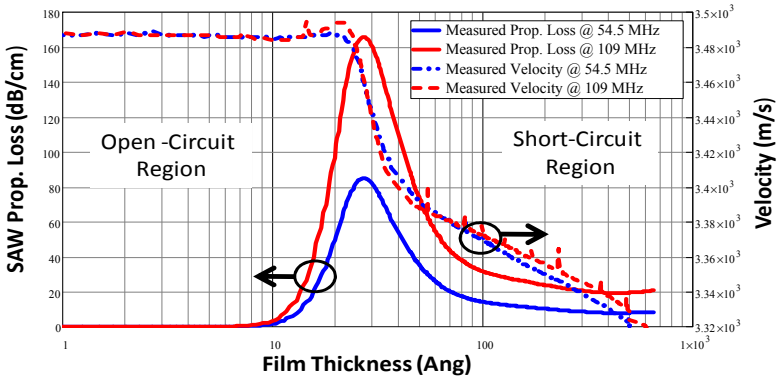

Figure 13 shows a plot of the SAW propagation loss (solid lines) and velocity (dashed lines) at 54.5 and 109MHz as a function of the Pd film thickness. Pd film's conductivity changes due to the film's thickness. Consequently, the SAW propagation loss and velocity is modulated via the acoustoelectric effect.

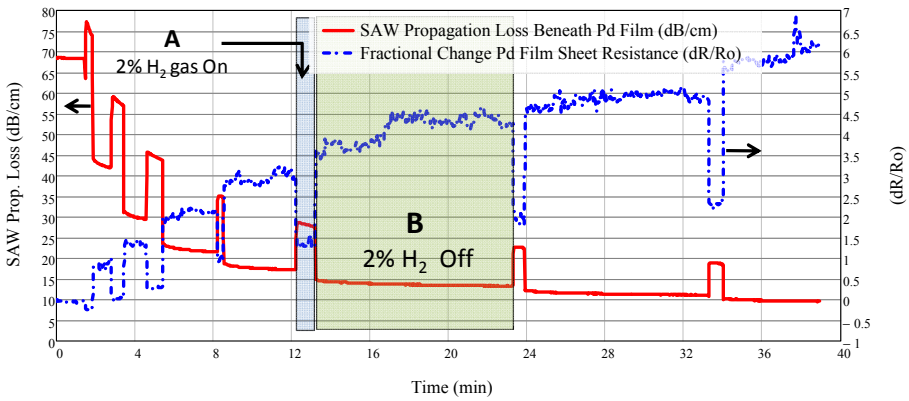

Figure 14 shows the real-time observation and measurement of the modulation of Pd film's conductivity in the presence of H_2 gas. Consequently, the SAW propagation loss is also modulated via the acoustoelectric effect. A: The blue shaded area shows the response of the SAW when the Pd film is exposed to 2% H2 gas. B: Green shaded area shows the response when the film is not exposed to 2% H_2 gas.

Clock Current State Estimation with a Kalman-Like Algorithm Employing Measurement of Time Errors

Yuriy S. Shmaliy and Oscar Ibarra-Manzano

***Abstract*—To meet the needs of the IEEE Standard 1139-1999 in part of the estimations of clock state, we propose using a fast recursive p-shift unbiased estimation algorithm employing measurement of the time interval error. A special feature of this algorithm is that it has the Kalman-like form, although ignores both the clock and measurement noise sources and allows for any initial clock state. The algorithm can straightforwardly be applied to provide unbiased filtering ($p = 0$) and smoothing ($p < 0$) of clock state, also to predict ($p > 0$) its future behavior. An application is given for a master clock.**

I. Introduction

The IEEE Standard 1139-1999 [1] suggests that the clock has three states, namely the time interval error (TIE), fractional frequency offset, and linear frequency drift rate. Accurate clock estimation faces two main factors. Firstly, noise in free-run clocks has slow and very slow flicker (colored) and random walk components making TIE nonstationary on a finite interval even with zeroth second and third states. Secondly, ignoring the higher order states may cause uncertainties. We notice that the latter effect is still not well studied. The problem is complicated with both the measurement noise and uncertainties when the reference source of time is removed, as in the Global Navigation Satellite Systems (GNSS).

Under such conditions, the Kalman algorithm derived for white noise and adapted for clocks in [2] may demonstrate divergence [3], become unstable [4], [5], and even noisy [6]. There is one more important obstacle preventing using such an algorithm for accurate estimation in clocks. For the Kalman algorithm to be optimal, the noise covariances must be known exactly. It is known, however, that the phase noise power law is hard to measure close to the carrier and the covariance function is also hard to specify. The clock model thus does not suites the Kalman estimator exactly and the latter typically never gives us estimates better than weighted averaging widely employed in time scales, although not in state space. This fact was neatly demonstrated experimentally in [7], meaning that some more robust solutions are desirable.

Examining the trade-off between the infinite impulse response (IIR) recursive Kalman algorithm and finite impulse response (FIR) ones, Jazwinski summarized in [4] that the limited memory filter, having FIR, appears to be the only device for preventing divergence in the presence of unbounded perturbation in the system. That means that the optimal FIR filter, having an imbedded bounded input/bounded output (BIBO) stability, is more robust against the Kalman one [8]. On the other hand, the Standard [1] states that "an efficient and unbiased estimator is preferred." Referring to and aimed at overcoming the problems with the Kalman filter, transversal FIR filtering has been employed in [5] to design an unbiased estimator for clocks and then investigated in detail in [6], [9]–[11]. As a result, an optimal FIR estimator was proposed for clocks in [12]. It has also been shown in [5] that an unbiased FIR filter allowing noise to have any distribution and covariance becomes virtually optimal in the mean square error (MSE) sense if averaging is provided on a large interval of $N \gg 1$ points [11], as it is in GNSS-based timekeeping. Below we shall show that the unbiased FIR estimator discussed in [12] in a batch form has an efficient Kalman-like algorithm that, in applications to clocks, outperforms the Kalman filter.

II. Unbiased Estimator

In discrete time n, the clock TIE x_n is commonly measured by a precise time interval counter as s_n with a sampling (averaging) time τ for some reference time scale [7]. The measurement noise v_n is typically negligible with direct measurement and must be accounted for if the reference source is removed, as in GNSS.

Following [1], we characterize the clock with three states and model in state space with the time-invariant state and observation equations, respectively, as

$$\mathbf{x}_n = \mathbf{A}\mathbf{x}_{n-1} + \mathbf{w}_n \,, \tag{1}$$

$$s_n = \mathbf{C}\mathbf{x}_n + v_n \,, \tag{2}$$

in which the 3×1 state vector is given by

$$\mathbf{x}_n = [x_n \, y_n \, z_n]^T \,, \tag{3}$$

where x_n is the first state (TIE), y_n is the second state (fractional frequency offset), and z_n is the third state (linear frequency drift rate). The 3×3 matrix $\mathbf{A}$ projects the nearest past state $\mathbf{x}_{n-1}$ to the present state $\mathbf{x}_n$ employing the finite-degree Taylor series expansions,

$$\mathbf{A} = \begin{bmatrix} 1 & \tau & \tau^2/2 \\ 0 & 1 & \tau \\ 0 & 0 & 1 \end{bmatrix} \,, \tag{4}$$

and the 1×3 observation matrix is $\mathbf{C} = [1\,0\,0]$, for measurement s_n of x_n. The 3×1 vector of the clock zero-mean noise,

978-1-61284-110-6/11/$26.00 ©2011 IEEE

$$\mathbf{w}_n = [w_{xn}\, w_{yn}\, w_{zn}]^T\,, \tag{5}$$

has the covariance $\mathbf{\Psi} = E\{\mathbf{w}_i \mathbf{w}_j^T\}$ with supposedly arbitrary components formed by different clock noise sources (white and flicker) and high-order states. The measurement noise v_n is commonly zero-mean, $E\{v_n\} = 0$, with the variance $E\{v_n^2\} = \sigma_v^2$. Most generally, v_n can also have arbitrary distribution and covariance.

Because the clock model is time-invariant and noise has flicker and random walk noise components, estimation gives particularly accurate results if provided over all data available, from zero to the current point n, thus on a full averaging horizon. It follows from [5], [10], [11] that the relevant full-horizon p-shift unbiased FIR estimate[1] $\bar{\mathbf{x}}_{n+p|n}$ of $\mathbf{x}_n$ at the point $n+p$ employing measurement s_n has the batch discrete convolution form of

$$\bar{\mathbf{x}}_{n+p|n} = \mathbf{A}^{n+p}(\mathbf{C}_n^T\mathbf{C}_n)^{-1}\mathbf{C}_n^T\mathbf{S}_n\,, \tag{6}$$

where $\mathbf{A}^{n+p}$ is the power of $\mathbf{A}$ specified with (4). Here $\mathbf{C}_n$ and the measurement vector $\mathbf{S}_n$ are given by, respectively,

$$\mathbf{C}_n = \left[(\mathbf{C}\mathbf{A}^n)^T\,(\mathbf{C}\mathbf{A}^{n-1})^T\,\ldots\,(\mathbf{C}\mathbf{A})^T\,\mathbf{C}^T\,\right]^T\,, \tag{7}$$

$$\mathbf{S}_n = [s_n\, s_{n-1}\,\ldots\, s_0]^T\,. \tag{8}$$

As can be seen, the unbiased estimator (6) ignores noise and initial conditions, unlike the Kalman one requiring both of them to be white and known. Although (6) can universally be used for unbiased filtering ($p = 0$), prediction ($p > 0$), and smoothing ($p < 0$) of clock state employing all the data available, the computational problem arises when measurement is provided on a large horizon of $N \gg 1$ points.

III. Kalman-like Unbiased Estimator

To reduce the computational complexity and make possible for the estimate $\bar{\mathbf{x}}_{n+p|n}$ to exist in real time associated with the one pulse per second (1PPS) measurement, the batch algorithm (6) can be substituted with the recursive one justified in Appendix A to have the blocks listed below.

Given the number K of clock states and a time shift p:

1) Set auxiliary matrices :

$$\mathbf{\Xi} = \mathbf{A}^T\mathbf{C}^T\mathbf{C}\mathbf{A}\,, \tag{9}$$

$$\mathbf{P}_{K-1} = (\mathbf{C}_{K-1}^T\mathbf{C}_{K-1})^{-1}\,, \tag{10}$$

$$\mathbf{F}_{K-1} = \mathbf{A}^{K-1}\mathbf{P}_{K-1}(\mathbf{A}^{K-1})^T\,. \tag{11}$$

2) Compute the initial clock state at $K-1+p$:

$$\bar{\mathbf{x}}_{K-1+p|K-1} = \mathbf{A}^{K-1+p}\mathbf{P}_{K-1}\mathbf{C}_{K-1}^T\mathbf{S}_{K-1}\,. \tag{12}$$

3) Update:

$$\mathbf{F}_n = \mathbf{A}\mathbf{F}_{n-1}\mathbf{A}^T - \mathbf{A}\mathbf{F}_{n-1}(\mathbf{I}+\mathbf{\Xi}\mathbf{F}_{n-1})^{-1}\mathbf{\Xi}\mathbf{F}_{n-1}\mathbf{A}^T\,, \tag{13}$$

$$\bar{\mathbf{x}}_{n+p|n} = \mathbf{A}\bar{\mathbf{x}}_{n-1+p|n-1} + \mathbf{A}^p\mathbf{F}_n\mathbf{C}^T \times(\mathbf{s}_n - \mathbf{C}\mathbf{A}^{1-p}\bar{\mathbf{x}}_{n-1+p|n-1})\,. \tag{14}$$

Instantly one indicates that (14) is the Kalman-like estimate, in which $\mathbf{A}^p\mathbf{F}_n\mathbf{C}^T$ plays the role of the Kalman gain. A remarkable engineering property of this algorithm is that it needs only two parameters, K and p, and does not depend on noise and initial error. For filtering the current clock state with $p = 0$, the algorithm (9)–(14) can be applied straightforwardly. For prediction with a step $p > 0$ or smoothing with a lag $p < 0$, p must be considered as a new variable as related to each fixed n. Below, we give an application for this algorithm to a Master Clock.

IV. Current State Estimation of the NIST MC

The NIST has published on the WEB site the UTC – UTC(NIST MC) time differences (285 points) measured each 10 days in 2002–2009, as issued monthly by BIPM [units are in Modified Julian Dates (MJDs) and nanoseconds]. For this measurement, we form the time scale starting with $n = 0$ (52279 MJD) and finishing at $n = 284$ (55129 MJD). The measurement is shown in Fig. 1a (circles).

Supposing that the NIST MC has two states, $K = 2$, the algorithm (9)–(14) was developed for $n \geqslant K$ with $\tau = 8.64\times 10^5$ s to

$$\mathbf{\Xi} = \mathbf{A}^T\mathbf{C}^T\mathbf{C}\mathbf{A}\,, \tag{15}$$

$$\mathbf{F}_1 = \mathbf{A}(\mathbf{C}_1^T\mathbf{C}_1)^{-1}\mathbf{A}^T\,, \tag{16}$$

$$\bar{\mathbf{x}}_{1+p|1} = \mathbf{A}(\mathbf{C}_1^T\mathbf{C}_1)^{-1}\mathbf{C}_1^T\mathbf{S}_1\,, \tag{17}$$

$$\mathbf{F}_n = \mathbf{A}\mathbf{F}_{n-1}\mathbf{A}^T - \mathbf{A}\mathbf{F}_{n-1}(\mathbf{I}+\mathbf{\Xi}\mathbf{F}_{n-1})^{-1}\mathbf{\Xi}\mathbf{F}_{n-1}\mathbf{A}^T\,, \tag{18}$$

$$\bar{\mathbf{x}}_{n+p|n} = \mathbf{A}\bar{\mathbf{x}}_{n-1+p|n-1} + \mathbf{F}_n\mathbf{C}^T(s_n - \mathbf{C}\mathbf{A}\bar{\mathbf{x}}_{n-1+p|n-1})\,, \tag{19}$$

where, by (7), we have

$$\mathbf{C}_1 = \begin{bmatrix} 1 & \tau \\ 1 & 0 \end{bmatrix}.$$

Figure 1 sketches the filtering estimates $\bar{x}_{n|n}$ and $\bar{y}_{n|n}$ of x_n and y_n, respectively, provided by (15)–(19), and we notice that this algorithm produces estimates appreciably faster than the batch one (6) or (11b) discussed in [16].

For a comparison, we also give estimates obtained with the standard 2-state Kalman filter described in [5] (see Appendix B). Because the NIST MC exhibits excellent etalon properties, we set for the Kalman filter zeroth initial conditions, $x_0 = 0$ and $y_0 = 0$. For the resolution of 0.1 ns in the published data, the digitization noise was supposed to be distributed uniformly and its variance calculated as $\sigma_v^2 = 0.05^2/3$ ns^2 $= 8.33\times 10^{-4}$ ns^2.

[1] Here and in the following, $\bar{\mathbf{x}}_{n+p|n}$ means the unbiased estimate at $n+p$ via measurement from the past to n.

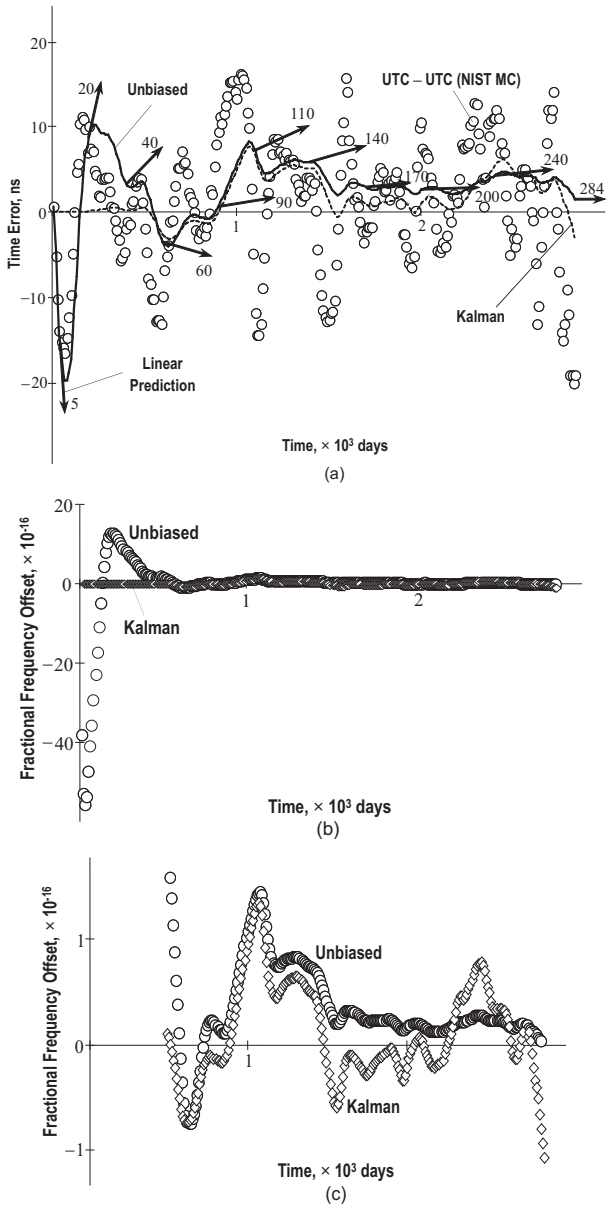

Fig. 1. Estimates of the NIST MC current state via the UTC – UTC(NIST MC) time differences (285 points) measured in 2002–2009 each 10 days: (a) first state x_n, (b) second state y_n, and (c) second state y_n (scaled).

Current estimates of the first state are shown in Fig. 1a along with the linear prediction of time errors depicted with arrows. Since the unbiased estimator gives us the best linear unbiased fit, the first arrow coincides in the direction with several initial measurement points. Increased n, prediction depicts possible behaviors of future errors. Although, the process shown in Fig. 1a looks like rather stationary, prediction reveals some positive average angle resulting in a positive frequency offset diminishing with time (Fig. 1b and Fig. 1c).

Observing these figures, one can arrive at a conclusion that the Kalman filter is lesser suitable for the clock current state estimation. In fact, owing to transients, the Kalman filter does not provide a real picture with a small number of measurements. In the intermediate region (about the point of 1×10^3 days), both filters produce consistent estimates. Finally, the Kalman-like filter (15)–(19) keeps smoothing the data above the intermediate region, whereas the Kalman one exhibits qualitatively the same error picture, being time-invariant.

V. Conclusions

We proposed and examined a Kalman-like p-shift recursive unbiased FIR estimation algorithm intended for filtering ($p = 0$), prediction ($p > 0$), and smoothing ($p < 0$) of the clock state space model via all measurement data available. The algorithm provides the best unbiased fit for the measurement data and is fast, unlike its batch origin. Its remarkable engineering property resides in the independence on noise and initial conditions. As an application, we estimated the current state of the NIST MC employing the UTC – UTC(NIST MC) time differences (285 points) measured each 10 days in 2002–2009, as issued monthly by BIPM. A comparison with the 2-state Kalman filter is also provided and we state that the latter is lesser suitable for clocks than the proposed Kalman-like one.

Appendix A
Full Horizon Recursive Unbiased FIR Estimation Algorithm

Consider the batch unbiased estimate (6). Following the derivation developed for recursive least squares [14], assign $\mathbf{P}_n^{-1} = \mathbf{C}_n^T \mathbf{C}_n$ and expend this matrix to

$$\begin{aligned} \mathbf{P}_n^{-1} &= \sum_{i=0}^{n} \left(\mathbf{C}\mathbf{A}^{n-i}\right)^T \mathbf{C}\mathbf{A}^{n-i} \\ &= \sum_{i=1}^{n} \left(\mathbf{C}\mathbf{A}^{n-i}\right)^T \mathbf{C}\mathbf{A}^{n-i} + \left(\mathbf{C}\mathbf{A}^{n}\right)^T \mathbf{C}\mathbf{A}^{n} \\ &= \mathbf{P}_{n-1}^{-1} + \left(\mathbf{C}\mathbf{A}^{n}\right)^T \mathbf{C}\mathbf{A}^{n} . \end{aligned} \tag{A.1}$$

Using the matrix inversion lemma [15]

$$(\mathbf{A}+\mathbf{C})^{-1} = \mathbf{A}^{-1} - \mathbf{A}^{-1}(\mathbf{I}+\mathbf{C}\mathbf{A}^{-1})^{-1}\mathbf{C}\mathbf{A}^{-1} ,$$

represent the inverse of (A.1) as

$$\begin{aligned} \mathbf{P}_n &= \mathbf{P}_{n-1} - \mathbf{P}_{n-1}(\mathbf{I} + \mathbf{A}^{nT}\mathbf{C}^T\mathbf{C}\mathbf{A}^n\mathbf{P}_{n-1})^{-1} \\ &\quad \times \mathbf{A}^{nT}\mathbf{C}^T\mathbf{C}\mathbf{A}^n\mathbf{P}_{n-1} . \end{aligned} \tag{A.2}$$

Expend the product $\mathbf{C}_n^T\mathbf{S}_n$ in (6) as follows:

$$\begin{aligned} \mathbf{C}_n^T\mathbf{S}_n &= \sum_{i=0}^{n} \left(\mathbf{C}\mathbf{A}^{n-i}\right)^T \mathbf{S}_{n-i} \\ &= \sum_{i=1}^{n} \left(\mathbf{C}\mathbf{A}^{n-i}\right)^T \mathbf{S}_{n-i} + \left(\mathbf{C}\mathbf{A}^{n}\right)^T s_n \\ &= \mathbf{C}_{n-1}^T\mathbf{S}_{n-1} + \left(\mathbf{C}\mathbf{A}^{n}\right)^T s_n . \end{aligned} \tag{A.3}$$

Now rewrite the estimate (6) at $n-1+p$ as

$$\bar{\mathbf{x}}_{n-1+p|n-1} = \mathbf{A}^{n-1+p}(\mathbf{C}_{n-1}^T\mathbf{C}_{n-1})^{-1}\mathbf{C}_{n-1}^T\mathbf{S}_{n-1}\,,$$

use the identities produced by $\mathbf{P}_n^{-1} = \mathbf{C}_n^T\mathbf{C}_n$ and (A.1), respectively,

$$\begin{aligned}\mathbf{P}_{n-1}^{-1} &= \mathbf{C}_{n-1}^T\mathbf{C}_{n-1}\,,\\ \mathbf{P}_{n-1}^{-1} &= \mathbf{P}_n^{-1} - \mathbf{A}^{nT}\mathbf{C}^T\mathbf{C}\mathbf{A}^n\,,\end{aligned}$$

and express $\mathbf{C}_{n-1}^T\mathbf{S}_{n-1}$ as

$$\begin{aligned}\mathbf{C}_{n-1}^T\mathbf{S}_{n-1} &= \mathbf{C}_{n-1}^T\mathbf{C}_{n-1}\mathbf{A}^{-n+1-p}\bar{\mathbf{x}}_{n-1+p|n-1}\\ &= \mathbf{P}_{n-1}^{-1}\mathbf{A}^{-n+1-p}\bar{\mathbf{x}}_{n-1+p|n-1}\\ &= (\mathbf{P}_n^{-1} - \mathbf{A}^{nT}\mathbf{C}^T\mathbf{C}\mathbf{A}^n)\\ &\quad\times\mathbf{A}^{-n+1-p}\bar{\mathbf{x}}_{n-1+p|n-1}\,. \qquad \text{(A.4)}\end{aligned}$$

By $\mathbf{P}_n^{-1} = \mathbf{C}_n^T\mathbf{C}_n$ and (A.3), the estimate (6) can now be rewritten as

$$\begin{aligned}\bar{\mathbf{x}}_{n+p|n} &= \mathbf{A}^{n+p}\mathbf{P}_n\mathbf{C}_n^T\mathbf{S}_n\\ &= \mathbf{A}^{n+p}\mathbf{P}_n[\mathbf{C}_{n-1}^T\mathbf{S}_{n-1} + (\mathbf{C}\mathbf{A}^n)^T s_n]\,. \qquad \text{(A.5)}\end{aligned}$$

Taking $\mathbf{C}_{n-1}^T\mathbf{S}_{n-1}$ from (A.4) and then providing the transformations lead to

$$\begin{aligned}\bar{\mathbf{x}}_{n+p|n} &= \mathbf{A}\bar{\mathbf{x}}_{n-1+p|n-1} + \mathbf{A}^{n+p}\mathbf{P}_n\mathbf{A}^{nT}\mathbf{C}^T\\ &\quad\times\left(s_n - \mathbf{C}\mathbf{A}^{1-p}\bar{\mathbf{x}}_{n-1+p|n-1}\right)\,. \qquad \text{(A.6)}\end{aligned}$$

Further assign

$$\mathbf{F}_n = \mathbf{A}^n\mathbf{P}_n\mathbf{A}^{nT}\,,$$

multiply (A.2) with $\mathbf{A}^{n-1}$ and $(\mathbf{A}^{n-1})^T$ from the left-hand and right-hand sides, respectively, provide the transformations, and finally arrive at the fast recursive Kalman-like algorithm:

$$\boldsymbol{\Xi} = \mathbf{A}^T\mathbf{C}^T\mathbf{C}\mathbf{A}\,, \qquad \text{(A.7)}$$

$$\mathbf{F}_{K-1} = \mathbf{A}^{K-1}(\mathbf{C}_{K-1}^T\mathbf{C}_{K-1})^{-1}(\mathbf{A}^{K-1})^T\,, \qquad \text{(A.8)}$$

$$\mathbf{F}_n = \mathbf{A}\mathbf{F}_{n-1}\mathbf{A}^T - \mathbf{A}\mathbf{F}_{n-1}(\mathbf{I}+\boldsymbol{\Xi}\mathbf{F}_{n-1})^{-1}\boldsymbol{\Xi}\mathbf{F}_{n-1}\mathbf{A}^T\,, \qquad \text{(A.9)}$$

$$\begin{aligned}\bar{\mathbf{x}}_{n+p|n} &= \mathbf{A}\bar{\mathbf{x}}_{n-1+p|n-1} + \mathbf{A}^p\mathbf{F}_n\mathbf{C}^T\\ &\quad\times(\mathbf{s}_n - \mathbf{C}\mathbf{A}^{1-p}\bar{\mathbf{x}}_{n-1+p|n-1})\,, \qquad \text{(A.10)}\end{aligned}$$

in which K is the number of clock states. Update (A.9) and (A.10) for $n \geqslant K-1$, because the inverse in (A.8) does not exists otherwise.

The initial state estimate $\bar{\mathbf{x}}_{K-1+p|n-1}$ for (A.10) can be found using (6) as

$$\bar{\mathbf{x}}_{K-1+p|n-1} = \mathbf{A}^{K-1+p}\mathbf{P}_{K-1}\mathbf{C}_{K-1}^T\mathbf{S}_{K-1}\,. \qquad \text{(A.11)}$$

Note that the batch computation (A.11) does not take much time, because the number of the clock states is limited in [1] with $K = 3$.

***Abstract*—The time transfer link between NIM and PTB was for the first time calibrated using a travelling GPS receiver developed by NIM The calibration uncertainty was estimated to about 2 ns. The result obtained could be compared to the result derived from differential calibrations made by BIPM in previous years. Both results agree well within 1 ns.**

I. Foreword

In order to contribute to the realization of TAI, a calibration of the time transfer link between National Institute of Metrology (NIM), P. R. China, and Physikalisch-Technische Bundesanstalt (PTB), Braunschweig, Germany, is needed. A self-developed traveling GPS (Global Positioning System) receiver of NIM, NIM acronym IMEU, which is based on a JAVAD E_GGD receiver has been assembled and operated as traveling GPS receiver (TR) at PTB and NIM in succession for that purpose. After the suitability for the purpose of the IMEU receiver had been verified [1], the method using it for link calibrations has been developed [2]. The operation mode of IMEU differs from that of the GTR50 receiver which was used in previous successful calibration campaigns [3,4]. There are, however, several similarities.

II. Description of the link calibration method

When a GPS time transfer link between two timing labs, designated as timing lab 1 and timing lab 2 has been established, usually neither the antenna delays nor the internal receiver delays of the GPS receivers involved in the link are known. Both quantities are difficult to measure absolutely even though some groups have investigated absolute internal receiver delay calibration successfully [5~7]. Therefore the time transfer results including the difference of internal receiver delays and the difference of the antenna delays do not represent the true time difference between the two time scales or clocks involved. The GPS link thus needs to be calibrated. For this aim, we can use one TR that records GPS measurement data in succession on both sites. This link calibration method is described below. Firstly we do the common clock difference (CCD) experiment with TR and the GPS receiver R1 that is used for time transfer on this link at timing lab 1, and $C1$ is obtained, as illustrated in Figure 1. Then we do the same CCD experiment at timing lab 2 with TR and the GPS receiver R2 that is used for time transfer on this link at timing lab 2 and $C2$ is obtained. At the same time, we should take the reference delay difference RDD of TR at the different labs into account: At timing lab 1 the reference delay of TR is $RD1$, and at timing lab 2 the reference delay of TR is $RD2$, and the reference delay designates the time difference between the on-time reference point of the local time scale and the input signal provided to the receiver. If TR is operated when its time scale is locked to the external reference frequency input, the difference $XO1$ minus $XO2$, each representing the differences between the internal reference and 1PPS input of TR at the respective timing labs, designated XOD, should also be taken care of. Immediately after the operation at lab 1 and lab 2 the same CCD experiment at timing lab 1, called closure experiment, should be repeated to check for any change of the internal receiver delay of TR. Any observed change of $C1$ that is the difference between $C1$ and $C3$ would have to be accounted for in the uncertainty evaluation. By calculating the single difference of two CCD experiments, the time transfer result of the GPS link except the difference of two time references connected to two receivers can be acquired, and this is the calibration value C that can be calculated from (1) ~ (4) and we need indeed. Figure 1 illustrates the whole concept.

$$RDD = RD1 - RD2 \tag{1}$$

$$XOD = XO1 - XO2 \tag{2}$$

$$CorD = RDD + XOD \tag{3}$$

$$C = C1 - C2 + CorD \tag{4}$$

Sponsored by AQSIQ plan project 2010QK387

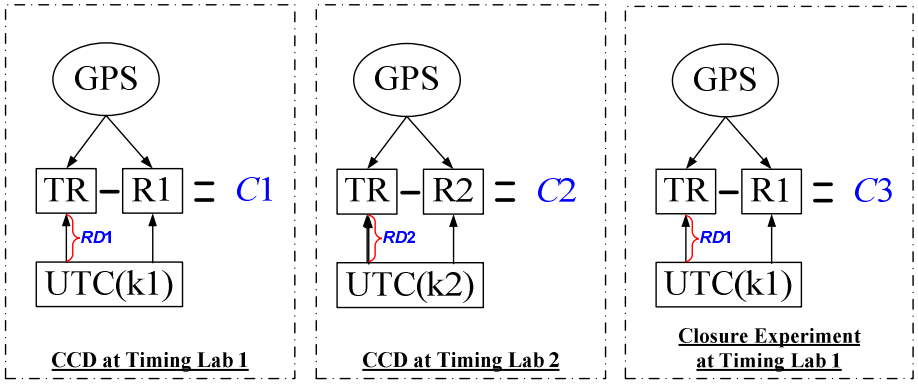

Figure 1. Schematics of a link calibration by a travelling GPS receiver TR

Once *C* has been determined, the time transfer results of the link should be corrected by this value *C* and we speak of a calibrated link. Furthermore, the calibrated GPS link can be used to calibrate a TWSTFT (Two-Way Satellite Time and Frequency Transfer) link or any other existing GPS link using different equipment. This option is particularly attractive because a mobile TWSTFT station is hard to get for making a calibration and some TWSTFT links cannot be calibrated by a mobile TWSTFT station. The latter situation had prevailed for the TWSTFT link between Asian and European institutes established through the IS-4 satellite until spring 2010 [8].

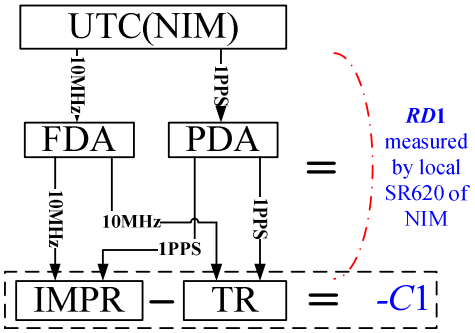
III. Experimental setup of the Link calibration between NIM and PTB

IMEU has been installed and operated as TR at NIM and PTB for time transfer link calibration between NIM and PTB as illustrated in Figure 2. The receivers used in the CCD experiments at NIM and PTB are listed in Table 1.

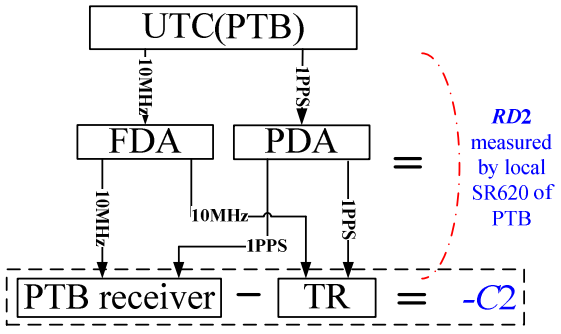
TABLE I. STATIONARY RECEIVERS USED FOR THE NIM-PTB LINK CALIBRATION

Timing lab	Receiver name	Receiver model
NIM	IMPR	Septentrio PolaRx2eTR
PTB	PTBB, PTBG	Ashtech Z12-T
PTB	TTS3	AOS TTS-3

The first CCD was made at PTB from MJD 55265 to MJD 55275. After TR had come back to NIM, we did the CCD experiments at NIM from MJD 55289 to MJD 55302. The schemes of the CCD experiments at NIM and PTB are shown in Figure 2. Due to some reasons, there is not any closure experiment to be reported here. During the link calibration, the 30-s RINEX files were recorded by all the receivers. The P3 code CGGTTS files of TTS3 which are generated and recorded automatically by the receiver and the P3 code CGGTTS files of PTBB and PTBG which are available on the BIPM Time Department FTP server were used in the calibration. In addition we used R2cggtts V4.3 [9,10] to convert the RINEX files of IMEU and IMPR to P3 code CGGTTS files that were used in the calibration.



(a) CCD at NIM



(b) CCD at PTB

Figure 2. Hardware set-up during the link calibration experiments

The reference delays *RD*1 and *RD*2 of TR were measured by SR620 Time Interval Counters (TIC), the difference *RDD* of *RD*1 and *RD*2 that were calculated according to (1) and the corresponding standard deviations of the measurements are given in TABLE II.

TABLE II. REFERENCE DELAYS (*RD*) OF TR

Timing lab	Reference delay	Measurement (ns)	Standard deviation (ns)
NIM	*RD*1	40.294	0.010
PTB	*RD*2	100.637	0.007
NIM-PTB	*RDD*	-60.343	0.013

The internal reference delays *XO*1 and *XO*2 that were measured by SR620 TIC and the difference *XOD* of *XO*1 and *XO*2 that was calculated according to (2) and the corresponding standard deviations of the measurements are listed in TABLE III.

TABLE III. INTERNAL REFERENCE DELAYS (*XO*) OF TR

Timing lab	Internal reference delay	Measurement (ns)	Standard deviation (ns)
NIM	*XO*1	-4.015	0.017
PTB	*XO*2	-4.604	0.012
NIM-PTB	*XOD*	0.589	0.021

So *CorD* according to (3) and the corresponding standard deviation of the measurements are described as Table 4.

TABLE IV. CORRECTION (*CorD*) OF TR

Timing lab	Correction	Measurement (ns)	Standard deviation (ns)
NIM-PTB	*CorD*	-59.754	0.025

It is always considered as an option to use Common-View (CV) instead of All-in View (AV) data analysis to calculate the calibration value for the link as one can expect that most errors cancel in CV. We process measurement data of two kinds, code-based ionosphere-free P3 CV data and code-plus-phase combined RINEX data processed with Precise Point Positioning (PPP) software. GPS P3 CV means that we choose CGGTTS P3 measurement data of the common satellites for two stations at the same epoch to compare and then average the comparisons of all these satellites. PPP results are obtained from NRCan-PPP software [11]. By two methods of data processing, two kinds of link calibration values for the same pair of GPS receivers in operation are obtained. The calibration of the officially operational GPS time transfer link, however, which contributes to the TAI computation, is the more significant one. The main links between NIM and PTB in official operation are listed in TABLE V.

TABLE V. OFFICIALLY OPERATIONAL MAIN LINKS BETWEEN NIM AND PTB

Station	PTBB	PTBG	TTS3
IMPR	P3 CV and PPP	P3 CV	P3 CV

IV. Link calibration value

The results with P3 code and PPP of the CCD experiments using TR and IMPR at NIM are shown in Figures 3 and 4. The results with P3 code and PPP of the CCD experiments using TR and PTBB, PTBG and TTS3 at PTB are shown in Figures 5 and 6. All results of the calibration values are listed in TABLE VI. The calibration values can be computed via (4), and the uncertainty is evaluated as described in Section 4 and tabulated in TABLE VII.

TABLE VI. CCD RESULTS AT NIM AND PTB

Timing lab	Receiver pair	Processing type	CCD results (ns)	Standard deviation (ns)
NIM	IMPR and TR	P3	$C1_{CV}$(IMPR)=35.731	0.767
NIM	IMPR and TR	PPP	$C1_{PPP}$(IMPR)=32.214	0.347
PTB	PTBB and TR	P3	$C2_{CV}$(PTBB)= 111.903	1.092
PTB	PTBG and TR	P3	$C2_{CV}$(PTBG)= -398.090	1.201
PTB	TTS3 and TR	P3	$C2_{CV}$(TTS3)= 126.440	1.396
PTB	PTBB and TR	PPP	$C2_{PPP}$(PTBB)= -409.828	0.291

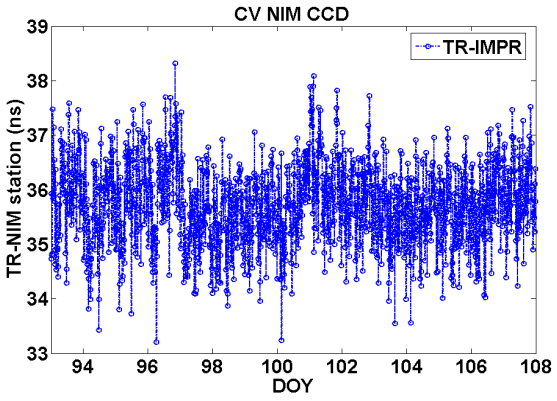


Figure 3. Results of P3 code at NIM

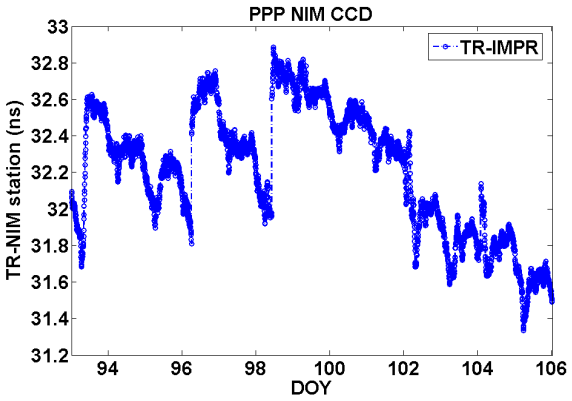

Figure 4. Results of PPP at NIM

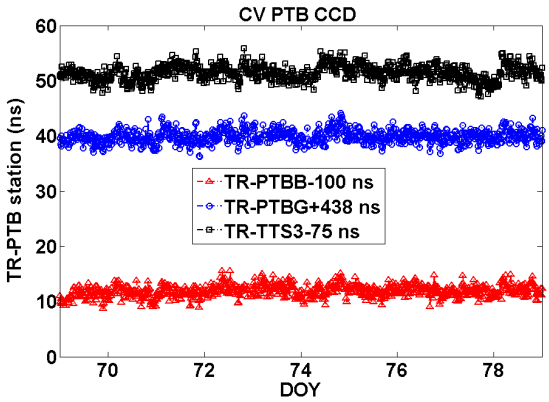

Figure 5. Results of P3 code at PTB

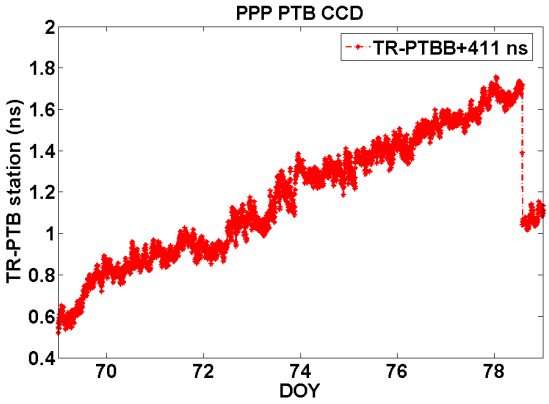

Figure 6. Results of PPP at PTB

The jumps of PPP CCD results might come from the data processing of the PPP software and be related to bad observations (mainly caused by tracking problems) of TR at NIM and PTBB at PTB. And the small drifts seen in the PPP CCD results have not been understood yet.

TABLE VII. CALIBRATION VALUES

Processing type	Calibration values (ns)	Uncertainty (ns)
P3	C_{CV}(IMPR-PTBB) = -135.9	1.8
P3	C_{CV}(IMPR-PTBG) = 374.1	1.9
P3	C_{CV}(IMPR-TTS3) = -150.5	2.0
PPP	C_{PPP}(IMPR-PTBB) = 382.3	1.4

For verification of the IMPR-PTBB P3 link calibration result, we can compare it to the previously obtained link calibration value of 135.8 ns, which is the difference between the total delays for the two stations as derived from the BIPM differential calibration results of IMPR and PTBB. The campaigns were made during MJD 55188~55194 in December 2009 at NIM [12] and during MJD 54566~54576 in April 2008 at PTB [13] covering IMPR and PTBB, respectively. For a meaningful comparison, the link calibration value from the BIPM results has to be corrected by the CGGTTS delay parameters (including the reference delay, the antenna cable delay, and the internal delay and antenna delay of the receiver) of PTBB because of the use of the original CGGTTS data of PTBB from the BIPM Time Department FTP server in our link calibration campaign. The two link calibration values from BIPM results and C_{CV}(IMPR-PTBB) apparently agree well within 1 ns after more than one year elapsed between the campaigns.

We used subsequently the calibration values to calibrate all time transfer links shown in TABLE V during MJD 55260 to 55310 and give a direct impression of the calibrated links depicted in Figure 7. The results show that all the links after calibration can agree well with one another.

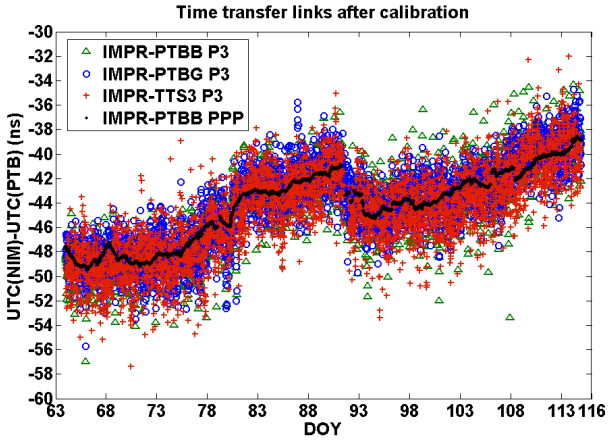

Figure 7.Calibrated time transfer links between NIM and PTB

V. Uncertainty Evaluation

For the GPS link calibration we can evaluate the uncertainty u_C as

$$u_C = \sqrt{u_A^{\,2} + u_B^{\,2}} \tag{5}$$

u_A is the evaluated uncertainty of type A, and u_B is the evaluated uncertainty of type B. They should be evaluated as

$$u_A = \sqrt{u_{A,1}^{\,2} + u_{A,2}^{\,2}} \tag{6}$$

and

$$u_B = \sqrt{\sum_{k=1}^{23} u_{B,k}^{\,2}} \tag{7}$$

$u_{A,1}$ and $u_{A,2}$ are the statistical uncertainties of the determination of the CCD results at NIM and PTB separately. $u_{B,1}$ and $u_{B,2}$ are the uncertainties due to the instability of the connections of the TR to UTC(NIM) and UTC(PTB), respectively. $u_{B,3} \sim u_{B,10}$ are the uncertainties from the measurements of the reference delay difference *RDD* of TR. $u_{B,11} \sim u_{B,16}$ are the uncertainties from the measurements of the internal reference delay difference *XOD* of TR (there is no contribution from systematic error of TIC because each *XO* would be acquired by the difference between two types of time interval measurements *X*1 and *X*2, i.e. *XO*=*X*2-*X*1, using the same TIC, by which the systematic error of the TIC cancels out). $u_{B,17}$ is the uncertainty due to the difference between the determinations of the reference points of UTC(NIM) and UTC(PTB). $u_{B,18}$ is the uncertainty due to the propagation (multipath). Atmospherical effects cancel out in a quasi zero baseline setup. $u_{B,19}$ is the uncertainty related to the instability of the antenna and its cable of TR. $u_{B,20}$ is the uncertainty due to the ambiguity estimation (only for PPP) for each receiver [14]. $u_{B,21}$ is the uncertainty due to the variation of the internal delay of TR that could be evaluated by the difference between the first CCD results and the closure CCD results. No closure measurement could be performed this time. Here we estimate instead as default value 0.80 ns which is more than the maximum corresponding value noted during the PTB-METAS link calibration [4]. $u_{B,22}$ and $u_{B,23}$ are the uncertainties due to the temperature effects (0.20 ns/degree and 0.24 ns/degree) on 1PPS output and GPS measurements separately of TR [1] at NIM and PTB, respectively. While the experiment was performed at NIM and PTB, the temperature variations at NIM and PTB were 0.8 degrees and 0.2 degrees, respectively. From that $u_{B,22}$ and $u_{B,23}$ was obtained by using (8).

$$u = \sqrt{(0.20 \times temperature\_stability)^2 + (0.24 \times temperature\_stability)^2} \tag{8}$$

The uncertainties of type B in this calibration campaign have been evaluated as listed in TABLE VIII.

TABLE VIII. UNCERTAINTY CONTRIBUTIONS OF TYPE B.

Uncertainty	Value (ns)	Description
$u_{B,1}$	0.10	Instability of the connection to UTC(NIM)
$u_{B,2}$	0.10	Instability of the connection to UTC(PTB)
$u_{B,3}$*	0.50	Systematic error of the local TIC for *RD*1 measurement at NIM
$u_{B,4}$*	0.50	Systematic error of the local TIC for *RD*2 measurement at PTB
$u_{B,5}$	0.06	TIC trigger level timing error for *RD*1 measurement at NIM
$u_{B,6}$	0.06	TIC trigger level timing error for *RD*2 measurement at PTB
$u_{B,7}$	0.01	Jitter of the TIC after 100 *RD*1 measurements at NIM
$u_{B,8}$	0.01	Jitter of the TIC after 100 *RD*2 measurements at PTB
$u_{B,9}$	0.10	TIC nonlinearities for *RD*1 measurement at NIM
$u_{B,10}$	0.10	TIC nonlinearities for *RD*2 measurement at PTB
$u_{B,11}$*	0.06	TIC trigger level timing error for *XO*1 measurement at NIM
$u_{B,12}$*	0.06	TIC trigger level timing error for *XO*2 measurement at PTB
$u_{B,13}$*	0.02	Jitter of the TIC after 100 *XO*1 measurements at NIM
$u_{B,14}$*	0.01	Jitter of the TIC after 100 *XO*2 measurements at PTB
$u_{B,15}$*	0.10	TIC nonlinearities for *XO*1 measurement at NIM
$u_{B,16}$*	0.10	TIC nonlinearities for *XO*1 measurement at PTB

$u_{B,17}$	0.02	Determination of the UTC reference point at PTB
$u_{B,18}$	0.30	Multipath
$u_{B,19}$	0.18	Antenna cable and antenna
$u_{B,20}$	0.30	Uncertainty of the ambiguity estimation(only for the PPP link)
$u_{B,21}$*	0.80	Instability of the internal receiver delay due to the loss of the closure experiment
$u_{B,22}$#	0.26	Temperature effects of TR at NIM
$u_{B,23}$#	0.07	Temperature effects of TR at PTB

Most evaluated uncertainties have a similarity with those described in [14]. The items with an asterisk do not exist in [14] due to the use of the local TICs at NIM and PTB and the TR in a different operation mode. The items with a pound have different values using the different evaluation methods from the ones in [14] because of the use of a different type of TR.

VI. Summary

The calibration of the GPS links between NIM and PTB with self-developed TR was successfully performed. The calibration uncertainty was estimated as about 2 ns. After that the result for the IMPR-PTBB P3 link in this campaign and the result for the same link by the differential calibration provided by BIPM have been compared. Both results agree well within 1 ns. The construction of the new clock room in the new campus of NIM will be finished soon, and the realization of UTC(NIM) will be transferred to the new campus. Then the TWSTFT links with NIM will be put into routine operation and calibrated based on the results presented in this contribution.

Abstract— **Heretofore, all precision clocks and oscillators have required one or more ovens to control the temperature of frequency dependent components. Ovens always add significantly to the power budget and limit the upper operating temperature. In the 1970s, Jack Kusters, et al. developed the dual-mode oscillator, which allows one mode to be used to measure temperature [1]. Then the other mode is made as frequency independent with temperature as can reasonably be done. The modes used are the B- and C-modes. With knowledge of the temperature behavior for these two modes, the B-mode measurements can be used to compensate the much smaller frequency dependent changes in the C-mode so that the output is temperature independent [2].**

In 1968, David W. Allan developed the time-scale algorithm for the atomic-clock ensemble providing time for the USA at the National Bureau of Standards in Boulder, Colorado. German and Allan have modified that algorithm to operate with a quartz-crystal oscillator ensemble. In addition, they have developed an algorithm that uses the ensemble to determine the temperature coefficients for each of the oscillators (clocks) in the ensemble – called automatic temperature compensation (ATC). The output of the ATC feeds the time-scale ensemble algorithm, which has the property of providing an output better than the best clock, and even the worst clock enhances the performance. With this configuration, flicker-floors of parts in 10^{12} have been obtained with only a gradual deterioration in stability in the long-term. The ensemble output also compensates for long-term frequency drift. To date, the EQUATE timing stability has demonstrated timing errors of less than 100 microseconds for prediction intervals out to 10 days. The ensemble operates without an oven, with micro-degree temperature measurement precision, has been tested over a temperature range of -40 to +85° C and can reasonably operate at even higher temperatures. This R&D system is now in its bread-board phase, and efforts are in progress to turn it into a small, low-powered, timing product [3].

This quartz-crystal oscillator timing ensemble is an essential part of the EQUATE technology package, which provides both precise timing as well as six-axis inertial sensing. We have demonstrated excellent frequency stability during large dynamic motion and during large temperature excursions. The whole timing and navigation package should be small and require very little power – well suited for a GPS denied environment.

I. OVERVIEW

There is a broad strategic need for high-accuracy INS (Inertial Navigation System) and for a high-accuracy clock system for GPS-Denied Navigation. The EQUATE technology (Ensemble of Quartz-clocks Adapting To the Environment) is a fully integrated ensemble of multiple (typically 6 or 7) precision, small, low-power quartz-crystal ***velocity-sensing*** and ***timing*** oscillators. The associated algorithms and measurement system compensate for temperature, shock/acceleration effects, and long-term drift. A lab proof-of-concept demonstration has been achieved for the EQUATE technology.

The highly stable timing portion of the technology is the main message of this paper. Since the other aspects of the EQUATE technology are relevant to successful timing, they will be discussed as they tie to the timing portion. One of the significant features of EQUATE timing is that excellent quality timing can be obtained in a dynamic environment both as to movement as well as to temperature.

The salient features of the EQUATE technology are: (1) atomic-clock like timing performance without a temperature controlling oven. The piezoelectric property of quartz makes it a good candidate for an (inertial measurement unit) IMU sensor as the oscillation frequency shifts with acceleration. One can configure the most sensitive directions for an ensemble of oscillators and achieve six-axes inertial sensitivity – thus providing (2) IMU capability. (3) In a shock or vibration scenario the clocks are configured to minimize these effects. Since gravity is an acceleration vector, a properly configured ensemble (4) can determine the local vertical. Because time is the integral of frequency and velocity is the integral of acceleration, (5) time or phase variations correspond to velocity variations in the EQUATE package; thus eliminating one level of integration errors as is common in all other inertial navigation system (INS) packages. These relative-velocity measurements can be made in all six-axes with high precision – (6) including the sensing of zero velocity in some scenarios. Because the local vertical can be determined and with an azimuthal reference (7) EQUATE has no coordinate drift within the small angles of measurement uncertainty. (8) EQUATE is being designed to operate over the full range of military environmental conditions. And (9) EQUATE has very high reliability using ensemble technology,

which includes a self-calibration capability to remove frequency drift errors and mal-performing clocks, – giving it a significant level of robustness.

The EQUATE technology brings together many proven technologies in a unique way – giving it several unique dimensions; i.e. ovenless operation, determining the local vertical, adaptively improving its performance as it learns from environmental changes, and combining precise timing and inertial sensing into one package.

II. TECHNICAL RATIONALE AND APPROACH

The time of the clocks are measured synchronously every second with sub-picosecond resolution – thus reducing the measurement noise to a negligible level [4]. This allows the measurement of systematic effects quickly and accurately. Each crystal's *in situ* temperature is transduced by measuring the frequency of the B-mode with typical sensitivity of ~ 26 ppm/°C. This technique greatly reduces any hysteresis effects. These measurements are then used to remove the temperature effects on the C-mode frequency. An algorithm has been developed that provides an automatic and adaptive estimates of the temperature coefficients for each of the clocks. The net of this is a temperature independent output from each of the clocks -- providing the input for the clock ensemble algorithm, which produces EQUATE's timing output. The crystal gamma (acceleration-sensitivity) vectors can be accurately determined for each EQUATE ensemble member and these are used for the IMU calculations and for the removal of motional effects in order to maintain good timing performance. The oscillators 1–6 are arrayed, as an example, with sensitivity directions +X, –X, +Y, –Y, +Z, and –Z on each face of a cube. This configuration also has the advantage, that for shock and vibration, opposite oscillators have first order cancelation benefits.

Clock-ensemble algorithms have been around for decades. One of the authors wrote the algorithm that generated time for the National Bureau of Standards in 1968 (NBS was renamed NIST). This algorithm (denoted AT1) with improvements is still used to generate time for the civil-sector of the nation's community. This algorithm is particularly adaptable to be used with clocks which have flicker noise, which is commonly observed as a good model in quartz-crystal oscillators. There are several papers that discuss the NBS/NIST AT1 algorithm. [5]– [9].

The EQUATE ensemble uses the virtues of the AT1 algorithm, with additional unique features added for quartz-crystal oscillators. The virtues of the EQUATE algorithm include: (1) the software computed time is more stable than the best clock in the ensemble; (2) even the worst clock enhances the computed time; (3) the time or phase of every clock is continually known with respect to the ensemble time and to every other clock; (4) ensemble robustness and reliability are inherent since if any one of the clocks mal-performs, it is rejected and its time and/or frequency is recalibrated; (5) the ensemble is adaptive as each of the clocks may improve or degrade with time (adapts to the environmental situation); (6) is optimized for both short-term and long-term performance; (7) is designed to work with environmental changes without an oven and at low power; (8) it is designed to ameliorate the effects of shock and vibration

Figure 1. 6 Member Dual-Mode Oscillator Ensemble in Thermal Chamber with Aluminum Plate for Thermal Substrate and RF Shielding for Isolation.

while measuring acceleration; (9) because the phase or time residuals are known for each of the ensemble members, both translational and rotational velocities are transduced; (10) having the ability to sense zero acceleration and zero velocity in some scenarios, it can use this information to recalibrate bias drift – resulting in a $t^{1/2}$ position error dispersion rate; and (11) both the random and the systematic parameters for each of the clocks are known and adaptively updated with time so that the EQUATE algorithms can minimize perturbing effects and maximize its performance in providing accurate position, orientation -- avoiding coordinate drift -- and providing precise short and long-term timing.

III. EQUATE TIMING EXPERIMENTS

EQUATE's ovenless timing has been tested over the military specification range of -40° to +85° C with rubidium clock like performance. In this experiment, the clocks were all placed on the same thermal substrate (see Figures 1 and 2). The temperature was held at each of the extremes for two hours, and then it was ramped up/down at a 2° C/minute rate. Figures 3 and 4 show the B-mode and C-mode fractional frequencies, respectively, over an interval of 3 days. The temperature is effectively measured for each clock in the ensemble to a precision of about a microdegree. The frequencies are measured every second with a precision of

Figure 2. Detail showing oscillator packages, aluminum foil used to provide shielding and plastic used to improve thermal uniformity & reduce transients.

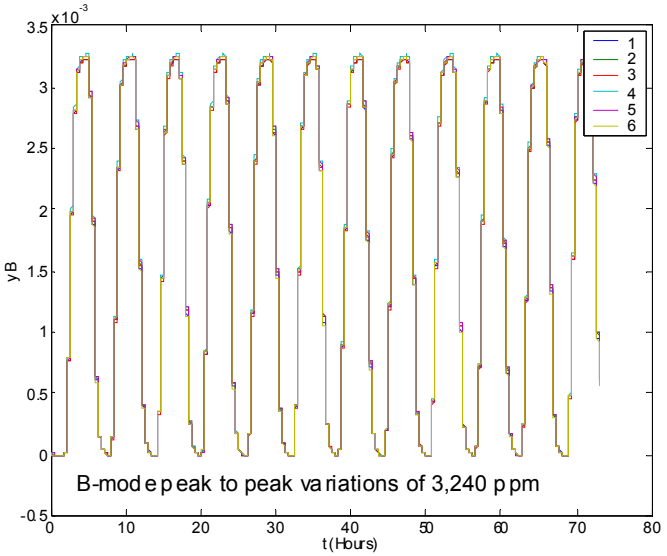

Figure 3. B-mode frequencies of the six clocks in the EQUATE ensemble.

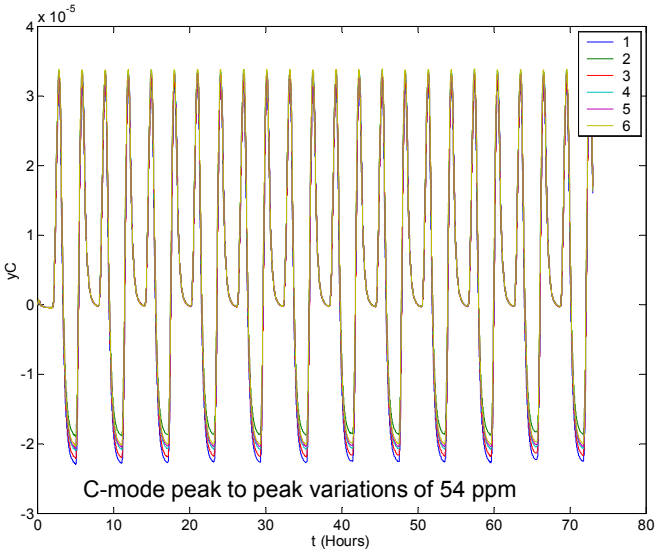

Figure 4. C-mode frequencies of the six clocks in the EQUATE ensemble.

about 1 x 10^{-12}. Figure 5 shows a plot of the fractional frequency output of the EQUATE timing algorithm. Figure 6 shows the EQUATE timing instabilities along with other well known frequency standards.

The Allan deviation instabilities (ADEV) shown in Figure 6 extend out for averaging times, τ, of the order of a day. The lower the value on the chart, the more stable the clock is. For example, if a clock has $\sigma_y(\tau) = 1 \text{ X } 10^{-11}$, then it has a time predictability of about 1 microsecond over a day. The stability comparisons in Figure 6 are like comparing apples, to oranges, to bananas because the EQUATE timing package is temperature modulated every six hours from -40° to +85° C, and the rubidium clock is in an ambient temperature environment and is phase-locked to GPS; the OCXO is free running and is in an ambient temperature environment.

So, Figure 6 demonstrates the excellent performance of the EQUATE timing package under very adverse temperature conditions, and EQUATE has the extremely valuable asset of needing no oven – in contrast to the rubidium and OCXO which both shield the temperature sensitive components in controlled ovens that limit their upper operating temperatures.

For these data, the EQUATE timing package was using an external reference to determine the temperature coefficients of the ensemble member clocks. The frequency drift has been subtracted from the EQUATE's timing package performance, as would happen in an application scenario in anticipation of moving into a self-calibration mode, when the reference is no longer available. The reference for all of the clocks in these stability plots is an HP 58503 GPS receiver – a highly stable ovenized quartz-crystal oscillator locked to the GPS atomic clock constellation.

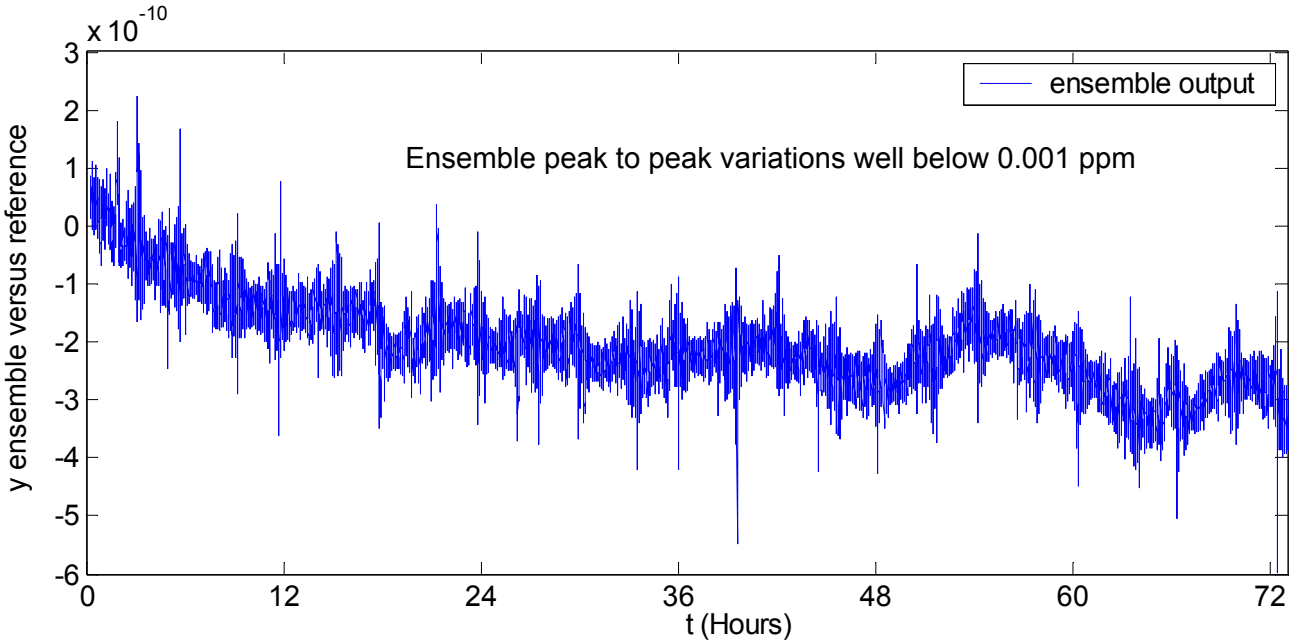

Figure 5. Fractional frequency output of the EQUATE timing ensemble.

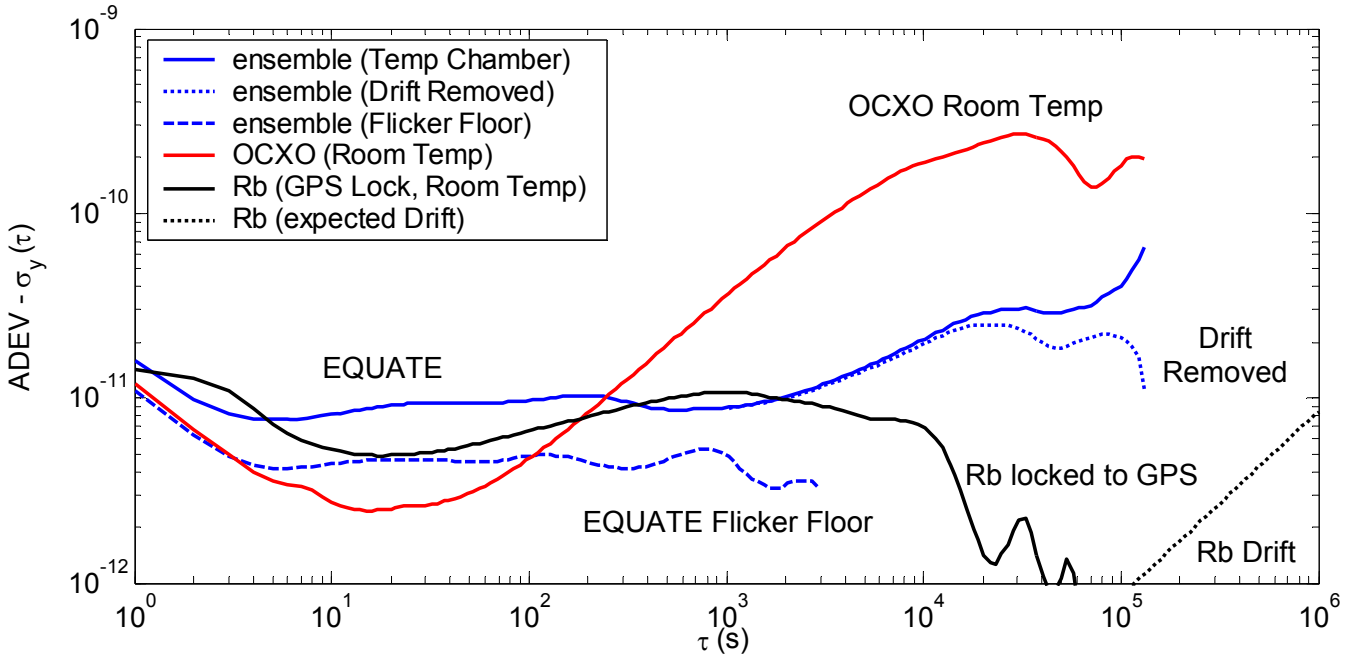

Figure 6. Frequency Stability plot for Ovenless EQUATE ensemble undergoing peak-to-peak temperature variations of 125° C (235° F) while the other clocks being compared are at ambient temperatures and the rubidium clock is phase locked to GPS.

OCXO Room Temp – The rise in the instabilities of the ovenized OCXO for larger averaging times is primarily due to diurnal temperature variations, which can be as large as 10 degrees C peak-to-peak; in comparison, the EQUATE timing package is going through a 125 degree C peak-to-peak oven cycle four times per day.

Rb locked to GPS (Room Temp) – The rise in the instabilities of the rubidium atomic clock – peaking at about 1,000 seconds averaging time – are the effects of the servo locking the rubidium to the GPS satellites' signals; then the fall off for larger averaging times is as its stabilities approach the GPS signal to which it is locking. The dotted line sloping up to the right is the typical instabilities introduced by a rubidium clock's frequency drift, when not locked to GPS.

EQUATE – The blue curves show the stabilities obtained for the EQUATE timing package. The flicker-floor dashed line which we believe from the theory will continue at this level of a few parts in 10^{12} for longer averaging times. Hence, we see that the EQUATE timing package can be as good or better than high quality commercial atomic clocks while consuming less than 1/1000th of the power and while going through a temperature range that is more than 10 times as large. The solid blue line instabilities are from EQUATE timing package data where some frequency drift was present along with frequency pops and jumps. The dotted blue line shows the effects of removing the frequency drift from these data in anticipation of self-calibrated drift.

EQUATE requires initial calibration. Once calibrated properly it can fly-wheel forward from its last known position, orientation and time. After calibration and when no external timing referencing is available, then EQUATE becomes its own source of precise and accurate time. Its atomic-clock timing stability is then available for the IMU portion of the EQUATE package. The blue curve in Figure 7 is an example of the long-term stability of the EQUATE timing package when it is self referenced while being modulated in temperature every six hours over 125 degrees C range. The black curve shows the EQUATE frequency stability when an external reference is available and the temperature is being modulated in the same way. In an application scenario, the black curve is the frequency stability obtained during the time when the EQUATE package is being calibrated. The blue curve is the long-term frequency stability when the external reference is removed and EQUATE becomes the primary reference. It is apparent that the self-referencing capability of the EQUATE timing package is a very important dimension of the EQUATE technology. These are the first results for self referencing. Theoretical indications are that the future holds improvements even over these excellent results.

Also, in Figure 7, for comparison in a similar temperature environment, the stability is plotted of an OCXO and of a commercial rubidium frequency standard, but over a reduced temperature range of -20° C to +65° C to conform with the specifications of the manufacturer of the rubidium clock. In this case, the OCXO and the rubidium clocks were subject to 40 C degrees less temperature variations than the EQUATE ensemble. In all three cases the temperature was held at the extremes for two hours and the ramp rates were two degrees per minute. The peak-to-peak phase or time modulation (x_{pp}) in an ADEV stability diagram is given by:

$$\sigma_y(\tau) = \frac{x_{pp}}{\tau}\, sin^2(\pi f_m \tau),$$

where f_m is the frequency of modulation. In these experiments, $1/f_m$ was about six hours. Some residual

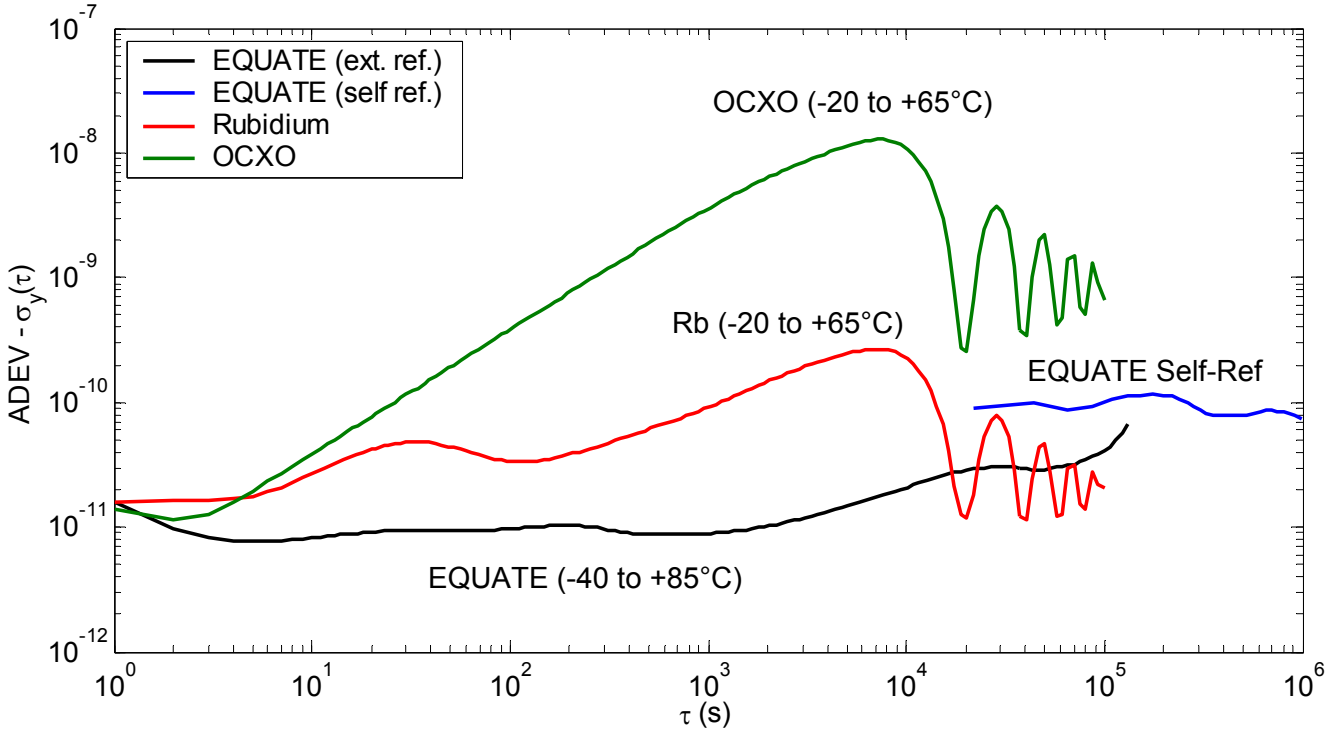

Figure 7. Frequency Stability plot with wide temperature modulation with about six hour periods: for ovenless EQUATE (-40° to +85° C), for a commercial rubidium, and an OCXO (-20° to +65° C)

temperature effects were present in the EQUATE output as can be seen by the hump at τ = 10,980 s (~3 hours) in the ADEV stability diagram shown in Figure 6. This equation assumes sine wave modulation. Using the data shown in Figures 6 and 7, x_{pp} was calculated for each of the three clocks, and under the assumption of sine wave modulation the estimated frequency dependence per degree C was 480, 9.2, and 0.63 parts in 10^{12}, respectively.

The time prediction error of a clock for flicker noise is given by $x_{pred}(\tau_p) = 1.2\ \tau_p\ \sigma_y(\tau_p)$, where τ_p is the prediction interval. The GPS Wing's desired prediction error in a GPS denied scenario is 100µs. Using this equation and the flicker floor level shown for the EQUATE timing ensemble indicates that the prediction error for EQUATE would be less than 100µs for prediction times out to ten days.

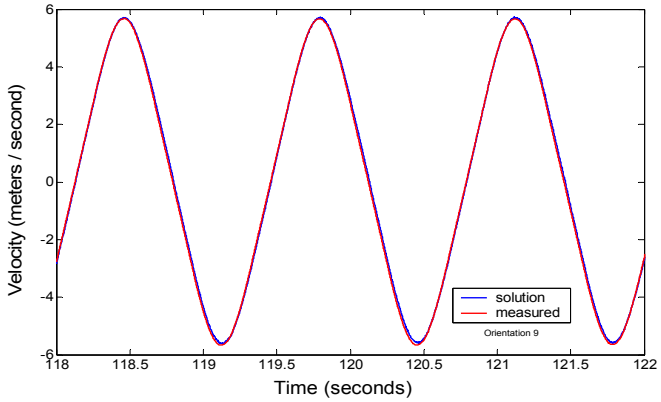

Figure 8. EQUATE measures velocity in six-axis pendulum configuration.

IV. EQUATE INERTIAL SENSING EXPERIMENTS

EQUATE is unique, as mentioned above, because it is both a precise timing package as well as providing inertial sensing capability. Most clocks shield against environmental temperature changes and against shock and vibration to get the best timing performance. Similarly, most INS packages may be adversely affected by these same environmental conditions. The EQUATE technology approaches these environmental perturbations very differently. Taking advantage of the piezoelectric effect and the high Q inherent in quartz – providing excellent short-term frequency stability – changes in temperature and motional effects are not shielded but utilized. The EQUATE algorithms measure the temperature with micro-degree precision; this precision is one reason for the success of the ovenless very stable timing approach. The piezoelectric effect in quartz with certain crystal cuts provides about a milli-g sensitivity to acceleration. Because time deviations correspond to velocity deviations, this gives significant advantage to this technology. So by precisely measuring and removing the effects of these environmental parameters gives the EQUATE technology the capability of having long-term frequency stability (excellent time predictability) as well as IMU capability. Hence, we see that temperature effects and motional effects are all integrated into the timing of the EQUATE technology.

The frequency stability of EQUATE has been measured under dynamic operation with a six-axis test bed. Six clocks were optimally configured around the perimeter of a light weight cube -- 20 cm on a side. This cube was placed on the

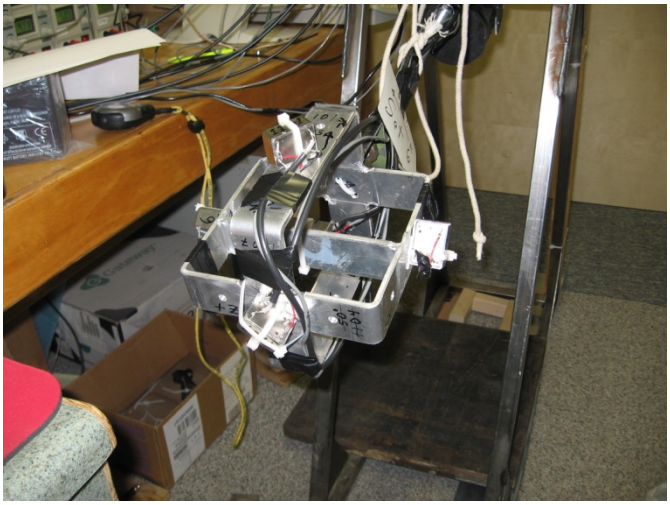

Figure 9. Cube /Pendulum Test Fixture for EQUATE Inertial Experiments.

end of a 60 cm rigid shaft. One end of the shaft was attached to a fulcrum and the other to the cube. Over 20 kilograms of lead were placed near the top of the shaft to give a whipping action at the end of the pendulum. The cube traversed about 5 meters during its period of 1.3 seconds and obtained accelerations of about 5 g's. The pivot point of the shaft was attached to a resolver to accurately measure the shaft angle. Our goal was to know the position of the quartz resonator in each clock in the cube to within 1 mm. The cube was made so that it can be rotated in any position on the end of the shaft to produce translation and rotation in all six axes. Clock frequency stabilities of parts in 10^{12} during these high dynamic conditions were measured, and the velocity was measured accurately as shown in Figure 8, and Figure 9 shows the cube/pendulum configuration.

The self-calibration capability of EQUATE leads to an *in situ* determination of each individual clocks temperature coefficients and a theoretical position-error dispersion rate going as $t^{1/2}$ in some scenarios. This dispersion rate was demonstrated for a linear tracking mode at a level of σ_s = 0.00078 meters $\tau^{1/2}$, where σ_s is the predicted error of position over a prediction time τ in seconds. Excellent timing stability was also demonstrated during this experiment when the effects of linear motion were subtracted. We are yet to perform the experiment combining high dynamics and large temperature variations. We have done each of them individually and obtained excellent timing stability, and the theory predicts that the EQUATE package should work well under these combined conditions also. That is yet to be proven.

V. CONCLUSIONS

The many unique features of quartz are the reason why over 2 billion quartz resonators are made per year. Yet its extremely high-Q properties have not been fully utilized. The EQUATE technology utilizes several of these unique properties to obtain frequency stabilities like an atomic clock, and to demonstrate the potential for inertial sensing as well. One of those properties is to remove coordinate drift, which plagues every other INS unit. EQUATE achieves the atomic-clock like, long-term frequency-stability timing performance by utilizing the outstanding high-Q, which readily yields excellent short-term stability, and then sensing systematic instabilities in an ensemble mode to remove these effects– thus obtaining excellent long-term stability as well.

Rather than shielding against environmental changes, EQUATE measures these environmental effects and removes them – adaptively improving its knowledge of these effects with time. The ovenless performance is one of the major benefits of this approach for lower system power. In the ensemble mode, EQUATE automatically determines the temperature coefficients for each of its member clocks and subtracts the effects due to temperature, which provides it with the unique characteristic of having temperature independence over extremely large temperature variations without an oven.

These temperature independent outputs from each of the clocks in the EQUATE ensemble are then fed to an NIST time-scale algorithm, uniquely modified to work with the features of quartz – rather than with atomic clocks – to generate outstanding long-term frequency stability performance. This translates to very small time prediction errors for long-term precise timing needs as well as providing an excellent timing reference for the IMU part of the EQUATE package. EQUATE's ovenless operation allows for reduced system size and power. The EQUATE technology approach has led to an improvement in frequency stability that is more than a hundred times better than the previous state-of-the-art, while also demonstrating the potential for INS capabilities with a non-drifting coordinate system. The EQUATE timing and INS package could be of major benefit in GPS denied environments as well as in a large number of other applications.

***Abstract*—This work presents a novel scheme to simulate a paper time scale by utilizing ensemble clock data of time laboratories in the eastern Asia-Pacific region. Based on integration of the above data with a neural-fuzzy prediction approach, the time difference with a local coordinated universal time is analyzed by a reference time scale devised in this work. Validity of the proposed scheme is investigated by undertaking a 250-day long neural-fuzzy predictor that is based on the calculated clock ensembles from Asian time laboratories. In the Asia-Pacific rim region, TWSTFT links from four laboratories, including the National Institute of Information and Communications Technology of Japan (NICT), the National Time Service Center of China (NTSC), the Korea Research Institute of Standards and Science of Korea (KRISS), and the Telecommunication Laboratories of Taiwan (TL), have formed a time transfer network based on use of multi-channel TWSTFT time transfer modems. Thus, a paper neural-fuzzy reference time scale by using the ensemble clock data among NICT, NTSC, KRISS, and TL in the Asia-Pacific region is simulated. Moreover, the performance of the proposed time scale is evaluated.**

I. INTRODUCTION

In the eastern Asia-Pacific rim region, TWSTFT links from four laboratories, including National Institute of Information and Communications Technology of Japan (NICT), National Time Service Center of China (NTSC), Korea Research Institute of Standards and Science of Korea (KRISS), and Telecommunication Laboratories of Taiwan (TL), have formed a time transfer network based on use of multi-channel time transfer modems as shown in Fig. 1. These four laboratories keep national standard time and are represented as local realizations of *UTC(lab)* in their countries. The Bureau International des Poids et Mesures (BIPM) Time Section coordinates the international time scale and publishes time difference results between *UTC* and *UTC(lab)* at the middle of the following month in Circular T [1]-[3]. However, to predict the real-time time differences for specific applications is necessary from the view of a particular region [4], [5] or time laboratories [6]-[8].

It is potentially to calculate a paper time scale in this region based on the clock difference information obtained from the aforementioned TWSTFT network and the BIPM ftp site. To provide a precise and reliable reference time source, this work attempts to devise a paper time scale in the eastern Asia-Pacific region with improved frequency stabilities by utilizing the neural-fuzzy prediction technique [9], [10].

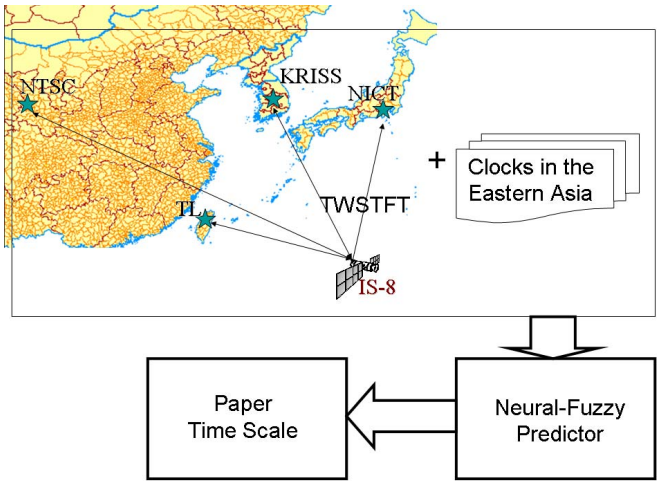

Fig. 1. Conceptual diagram of the proposed scheme.

This work was supported in part by the Bureau of Standards, Metrology & Inspection, Ministry of Economic Affairs, Taiwan under Grant 100-1403-05-05-13.

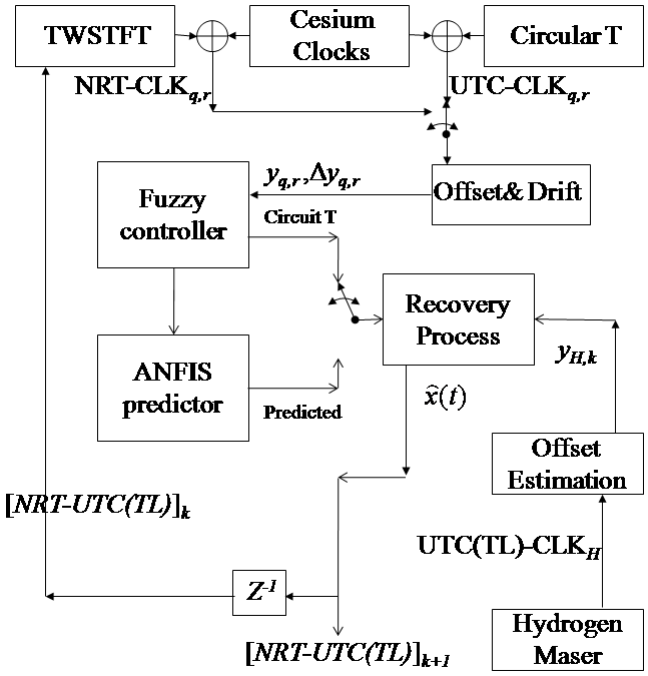

Fig. 2. System architecture of the proposed scheme.

II. PROPOSED SCHEME

Fig. 1 shows the conceptual block diagram of the proposed scheme. It consists of the TWSTFT network among the laboratories in the eastern Asia-Pacific rim region, atomic clock comparison data with respect to *UTC(lab)*, and neural-fuzzy predictor. Fig. 2 shows the system architecture diagram of the neural-fuzzy predictor applied in the proposed scheme. Furthermore, the frequency offset (y_k) and its change with respect to time (Δy_k) are fed into a fuzzy controller (as shown in Fig. 3) and an adaptive network-based fuzzy inference system (ANFIS) predictor (as shown in Fig. 4), respectively. It is worth noting that if the proposed scheme accompanies an active hydrogen maser and a microstepper as depicted in Fig. 2, it can be used as actualization of the simulated paper time scale to a physical clock.

A. *Fuzzy Controller*

In fuzzy controller, triangular-shaped membership functions (mfs) are chosen for the control input variables benefiting from their simple structure and computation. In this work, the input space is divided into five sets, i.e. negative big (NB), negative small (NS), zero (ZE), positive small (PS), and positive big (PB), for a frequency offset or its change. The sets are designed to be closer to the desired value of zero in order to provide precise control. The inputs to an if-then rule are the frequency offset (y_k) and its change (Δy_k). These rules can be expressed as

$$\textit{If } \{ y_k \textit{ is } \boldsymbol{Ar} \textit{ and } \Delta y_k \textit{ is } \boldsymbol{Bs}\}, \textit{ then } \{\boldsymbol{u} \textit{ is } \boldsymbol{Crs}\}, \quad (1)$$

where ***Ar, Bs***, and ***Crs*** denote the linguistic values defined by fuzzy sets on the universes of discourse.

The fuzzy-controller output is determined from the center-average method formulated as

$$\hat{y} = K_{out} \frac{\sum_{i=1}^{n} w_i u_i}{\sum_{i=1}^{n} u_i}, \quad (2)$$

where

K_{out} : output control gain;

$\hat{y}$: predicted output frequency offset;

w_i : grade of the *i*th output MF;

u_i : output label for the value contributed by the *i*th MF;

n : number of contributions from the rules.

B. *ANFIS predictor*

The ANFIS architecture used in this study is shown in Fig. 4. The number of membership functions (mf_i) assigned to each input of the ANFIS was arbitrarily set to 2, and so the rule number is 16. The ANFIS used here contains a total 104 fitting parameters, of which 24 are premise parameters and 80 are consequent parameters.

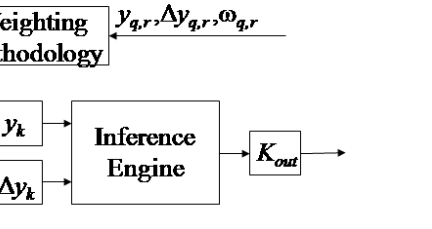

Fig. 3. Fuzzy controller architecture employed in this work.

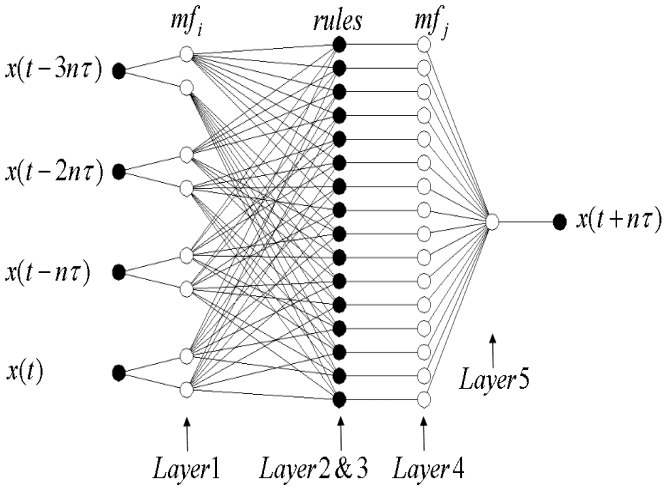

Fig. 4. ANFIS architecture employed in this work.

A Type-3 ANFIS employs a first-order, defined by the following rule base structure:

$$\text{if x is A and y is B, then } z = px + qy + r, \tag{3}$$

where A and B are fuzzy sets for the input and p, q, and r are constants. The node functions in Layer 1 are all bell-shaped with maximum equal to 1 and minimum equal to 0, such as

$$\mu_{A_i}(x) = \frac{1}{1 + [\left(\frac{x - c_i}{a_i}\right)^2]^{b_i}}, \tag{4}$$

where $\{a_i, b_i, c_i\}$ is the parameter set. Every node in Layer 2 multiplies the incoming signals and sends the product out. The output of this layer (w_i) is given by

$$\begin{aligned} w_i &= \mu_{A_i}(x(t-3n\tau)) \times \mu_{B_i}(x(t-2n\tau)) \\ &\times \mu_{C_i}(x(t-n\tau)) \times \mu_{D_i}(x(t)) \end{aligned}. \tag{5}$$

In Layer 2, each node output is then fed to Layer 3 to determine the individual rule's firing strengths as a ratio of all the rules firing strengths. For the nth node in this layer, the output of this layer (normalized firing strength) is given by

$$w_n = \frac{w_n}{w_1 + w_2 + \ldots w_i}. \tag{6}$$

Every node in Layer 4 multiple the normalized firing strengths by the consequent parameters:

$$\text{output} = w_i f_i \text{ , and } f_i = p_i x + q_i y + r_i, \tag{7}$$

where $\{p_i, q_i, r_i\}$ is the parameter set. The final layer (layer 5) which computes the weighted average of all the outputs to generate an overall output signal:

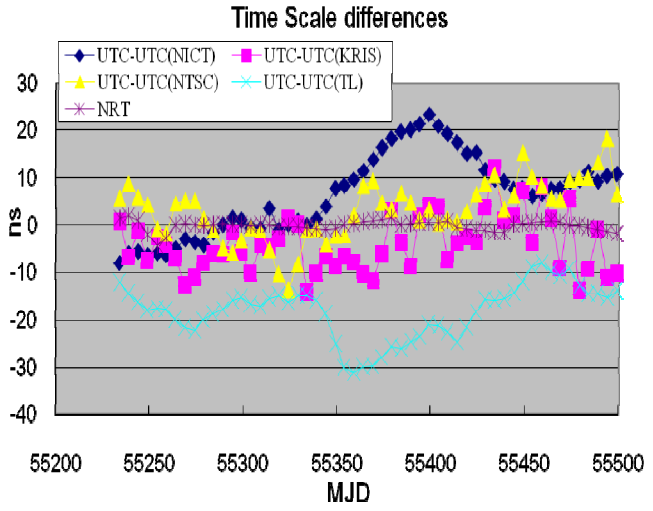

Fig. 5. Time scale differences of *UTC-UTC(TL), UTC-UTC(NICT), UTC-UTC(NTSC), UTC-UTC(KRIS)*, and *NRT*.

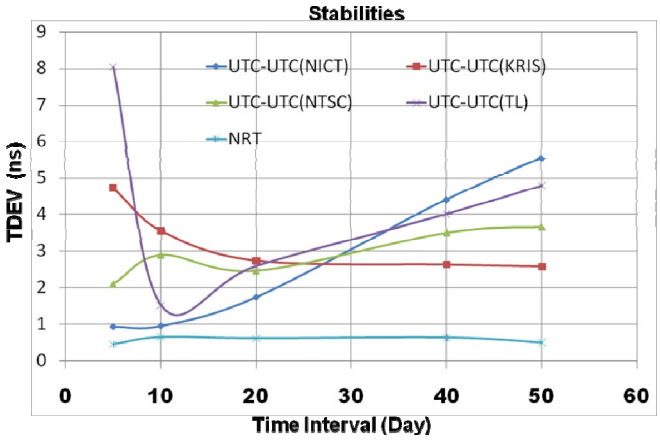

Fig. 6. Time stabilities of *UTC-UTC(TL), UTC-UTC(NICT), UTC-UTC(NTSC), UTC-UTC(KRIS)*, and *NRT*.

$$\text{Overall output} = \frac{\sum w_i f_i}{w_i} \tag{8}$$

III. Simulation Results

The neural-fuzzy reference time scale (*NRT*) was computed using the atomic clock and TWSTFT data from MJD=54959 to 55499 of time laboratories in the eastern Asia-Pacific region. For simplicity, 18 atomic clocks at NICT, 16 clocks at NTSC, 3 clocks at KRISS, and 11 clocks at TL, totally, 48 clocks were used for computation of our simulation. A 250-day long training set based on the aforementioned clock ensembles were used in the proposed neural-fuzzy predictor. In this work, we chose about five-month input-output data pairs of the following format:

$$\begin{aligned} &[x(t-3n\tau-m\tau), x(t-2n\tau-m\tau), x(t-n\tau-m\tau), x(t-m\tau) \\ &; \hat{x}(t+n\tau-m\tau)] \qquad \textit{and} \quad m = 0,1,2,3,4,5 \end{aligned}, \tag{9}$$

where

τ is equal to 5days;

n is equal to 6 for one month prediction;

$\hat{x}(t+n\tau-m\tau)$ is the predicted value.

Whenever the Circular T is published, equation (9) can predict NRT of the next month again.

Fig. 5 shows the time scale differences of the *UTC-UTC(k)*, and the predicted *NRT*, where *k* represents one of following laboratories: NICT, KRISS, NTSC, and TL. This figure shows a *UTC-UTC(TL)* time step jump from MJD=55339 to 55359, but our simulated *NRT* does not have such jump during the same period. This figure also shows a *UTC-UTC(NICT)* frequency change at MJD=55399, whereas our simulated *NRT* does not appear such frequency change at the same time. Besides, Fig. 5 shows the simulated time scale *NRT* is less than 5 ns.

Fig. 6 shows the time stabilities of *UTC-UTC(NICT), UTC-UTC(NTSC), UTC-UTC(KRIS), UTC-UTC(TL), and*

NRT. According to these results, the stabilities of *NRT* were the lowest (best). Quantitatively, the TDEV of *NRT* was lower than 1 ns for the whole time interval in Fig. 6.

IV. SUMMARY

This work has presented a novel scheme to generate a paper reference time scale by using the ensemble clock data among the TWSTFT laboratories such as NICT, NTSC, KRISS and TL in the eastern Asia-Pacific region. Experimental results show the performance of the simulated time scale *NRT* is less than 5 ns and the TDEV of *NRT* is lower than 1 ns.

ACKNOWLEDGMENT

Special thanks to NICT for the great job for the operation of the Asia-Pacific TWSTFT network. We would like to express our gratitude to NICT, NTSC, and KRISS colleagues for using their data and TL colleagues for their assistance.

***Abstract*—Two-way satellite time and frequency transfer (TWSTFT) is one of the most precise and accurate long-distance time transfer techniques nowadays. A C band multi-station satellite tracking system is developed based on TWSTFT in China. This system can not only measure the distance between a satellite with transponders and earth stations, but also realize the time synchronization between all earth stations. The satellite orbit can be determined by the distances. Five earth stations have been constructed in China. The master station is placed at the National Time Service Center (NTSC) in Lintong. There are a very small antenna terminal (VSAT) of 3.7 meters, up/down converters, a modem and an atomic clock in each station. The up and down link frequencies are 6GHz and 4GHz .The spread spectrum signal generated by the modem is 20MHz chip rate .The transmitter power is less than 1W. The results show that the accuracy of ranging, orbit determination and time synchronization between all earth stations is about 1cm，10cm and 0.1ns respectively.**

I. INTRODUCTION

A GEO satellite is placed at an altitude of 36000km and it can be kept in the fixed position above the equator, so it is the important part of the Chinese satellite navigation system. But it is more difficult to determine the orbit of GEO navigation satellites with high accuracy, because the geometry of the satellite and ground tracking stations is poor and the satellite's movement with respect to the earth station is very small[1]. Two-way satellite time and frequency transfer has been proven to be the most appropriate means of comparing time-scales and atomic frequency standards nowadays[2]. A C band multi-station satellite tracking system, i.e., a satellite orbit determination system by transfer, is developed based on TWSTFT by the NTSC[3]. There are five earth stations in China, the major station is at Lintong. The modem with multi-channel receiver is used in this system. It can not only range the distances between the satellite and earth stations, but also make the time comparison between every two earth stations by TWSTFT.

II. RANGING AND ORBIT DETERMINATION

A. Ranging

Ranging principle for multi-station satellite tracking system is that precise time signals from atomic clocks of earth stations are modulated with different pseudo noise(PN) code sequences, then the signals are transmitted to the satellite through an up-converter and a 3.7 meters VAST at *Tt*. When the satellite receives the signals from earth stations, the transponder processes and retransmits the signals. The earth stations receive the signals from the satellite through the 3.7 meters VAST and down-converter at *Tr*. Then the modem demodulates the signals and

978-1-61284-110-6/11/$26.00 ©2011 IEEE

computes the signal transmission time delay *t*. Fig. 1 is the principle block diagram of satellite ranging.

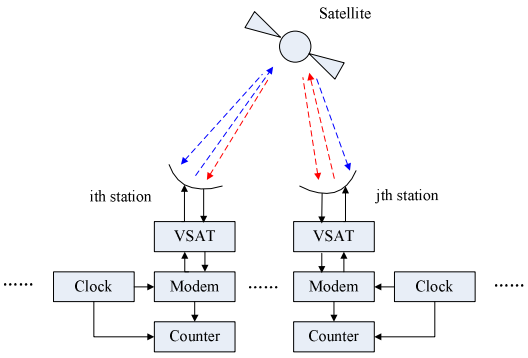

Figure 1. Principle of time delay of signals for both stations

The distances between the satellite and earth stations are determined by (1):

$$s = (c \times t) / 2 \qquad (1)$$

where: c is the speed of light

In the actual measurement, the time delay t includes ionosphere delay, troposphere delay, Sagnac effect, equipment delay and so on. These error delays must be subtracted from the delay t.

$$t=(T_r-T_t)/2+\Delta t_{ionosphere}+\Delta t_{troposphere}+\Delta t_{sagnac}+\Delta t_{transponder}+\Delta t_{equipment}+\varepsilon \qquad (2)$$

The ionosphere delay can be removed by ionosphere TEC models or dual-frequency method. The troposphere delay can be removed by troposphere empirical models[4]. The Sagnac effect can be canceled out by the Sagnac correction in the up/down links. The transponder delay can be measured before the satellite launched or solved as a parameter in the orbit determination. The equipment delay can be measured in real-time. ε is the measurement noise. As shown in Table I, the accuracy of raging is about 1 cm for the multi-station satellite tracking system.

Table Ⅰ. RANGE ACCURACY(1σ) FOR 5 STATIONS

station	accuracy(RMS)
1st station	6.0mm
2nd station	12.9mm
3rd station	6.1mm
4th station	8.3mm
5th station	12.8mm
Average of 5 stations	9.2mm

B. Satellite Orbit Determination

In the duration from 07 June 2005 to 09 June 2005, Sino-1 satellite was observed continually. The 12 sets of parameters, including 6 sets for satellite orbit parameters, 1 set for light pressure, 2 sets for experiential acceleration, 3 sets for transponder delays, were determined. The results show that the accuracy of orbit determination about 10cm. The Residuals (o-c) of 5 stations for orbit determination of Sino-1 satellite are as follows:

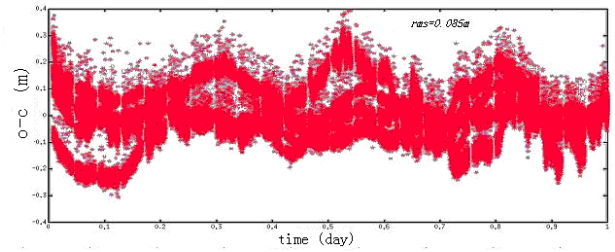

Figure 2. Residuals (o-c) of 5 stations for orbit determination of Sino-1 satellite in the duration of 7 June 2005, RMS=0.085m

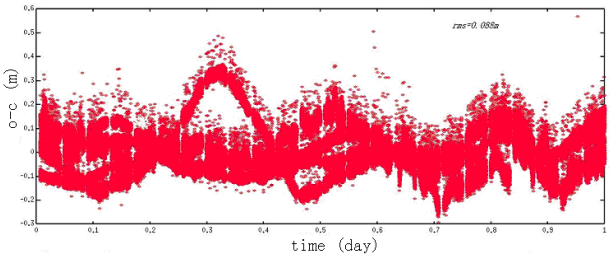

Figure 3. Residuals (o-c) of 5 stations for orbit determination of Sino-1 satellite in the duration of 8 June 2005, RMS=0.088m

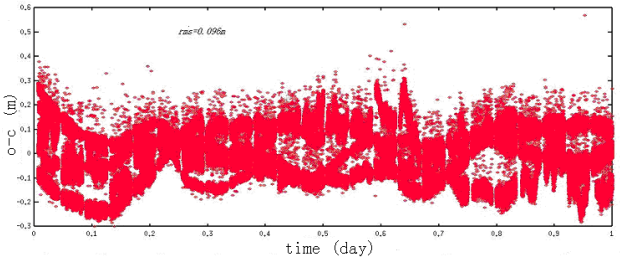

Figure 4. Residuals (o-c) of 5 stations for orbit determination of Sino-1 satellite in the duration of 9 June 2005, RMS=0.096m

III. TIME COMPARISON

The satellite tracking system is developed based on

TWSTFT. The multi-channel receiver is used in this system. It can not only range the distances between the satellite and earth stations, but also make the time comparison between every two earth stations. The time comparison is based on the exchange of timing signals through GEO between two earth stations. The time interval counter reading at station *i* is:

$$R_{ij}=T_j-T_i+\tau_i^U+\tau_j^D+\tau_s+\tau_i^T+\tau_j^R+\tau_j^{Sagnac} \quad (3)$$

$$R_{ji}=T_i-T_j+\tau_j^U+\tau_i^D+\tau_s+\tau_j^T+\tau_i^R+\tau_i^{Sagnac} \quad (4)$$

Where:

R_{ij}: the reading of the time interval counter at station *i* receiving signals from station *j*

T_i: local time-scale for station *i*

τ_i^U:signal path uplink delay for station *i*

τ_i^D: signal path downlink delay for station *i*

τ_s: satellite path delay through the transponder

τ_i^T: the equipment transmitter channel delay for the station *i*

τ_i^R: the equipment receiver channel delay for the station *i*

τ_i^{Sagnac}: Sagnac correction in the downlink

By subtracting (4) from (3), we get:

$$\Delta T_{ji}=1/2(R_{ji}-R_{ij})+1/2[(\tau_i^U+\tau_j^D)-(\tau_j^U+\tau_i^D)]+1/2[(\tau_j^R+\tau_i^T)-(\tau_j^T+\tau_i^R)]+1/2(\tau_i^{Sagnac}-\tau_j^{Sagnac}) \quad (5)$$

As shown in Fig. 5-7, the results of clock offset between the master station and slave stations by TWSTFT are given. The raw TWSTFT data had not been calibrated. The rubidium atomic clock is used in the 4th slave station. This station's clock offset is not shown.

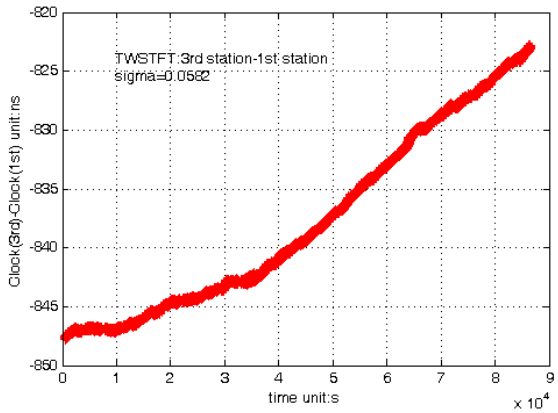

Figure 5. Results of clock(3rd)- clock(1st) in the duration of 7 June 2005

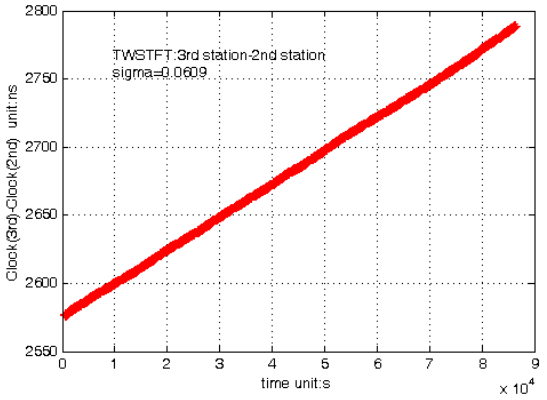

Figure 6. Results of clock(3rd)- clock(2nd) in the duration of 7 June 2005

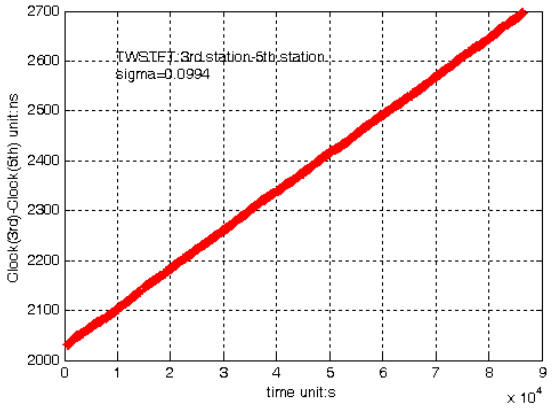

Figure 7. Results of clock(3rd)- clock(5th) in the duration of 7 June 2005

IV. CONCLUSION

The multi-station satellite tracking system based on TWSTFT can provide us with highly precise data of time and distance of GEO satellites with transponders. The orbit accuracy is improved greatly than other methods, e.g. The CCD and the United system for S Band (USB) technologies. This technology has been successfully used to the Chinese Area Positioning System, a satellite navigation system developed by China.

Abstract— **In this paper, a new, recently developed hardware for time transfer using passive listening and detection of SDH frame headers in fiber-optical networks is described. The method has been presented earlier, and results, using prototype equipment and an experimental fiber-link, have shown that time transfer with a precision of a few nanoseconds is possible over links with network distances exceeding 500 km. In order to further develop the method and make it available to regular users of time keeping equipment, it has been essential to minimize the space requirements of needed hardware and to make the implementation and installation more easily and straight forward.**

I. INTRODUCTION

The motivation of this work is to develop an alternative and complementary time transfer method using existing infrastructure, and to make it accessible to regular time and frequency users with precision and accuracy comparable to the commonly used satellite-based methods. It is well known that time transfer methods using global positioning systems, such as GPS (see e.g. [1] and references therein), are used in a variety of time and frequency applications. For applications requiring extended robustness and reliability, it is often necessary that complementary, backup methods are available with similar precision and accuracy. For instance, in international time metrology, two-way satellite time and frequency transfer (TWSTFT) (see e.g. [1] and references therein) using geostationary satellites, has been used for many years. Also, in recent years, time transfer methods using optical networks have been extensively studied and developed; see for example [2-4]. The fact that optical and radio-based transmission differ in signal frequency and infrastructure, make the combination of both types of methods much less vulnerable to intentional or unintentional disturbances.

As a contribution to the robustness and reliability of time and frequency transfer, SP Technical Research Institute of Sweden has developed a novel time and frequency transfer method based on passive listening and detection of SDH frame headers in fiber-optical networks. The method has been studied since 2005, see e.g. [4-6], and results, using several months of data and prototype hardware implemented in experimental fiber-links, have shown that time transfer with a precision of a few nanoseconds is achievable over links exceeding 500 km.

This paper describes a new hardware, which replaces the prototype equipment, which is essential for extended implementation and straight forward user installation. Section II will briefly review the method and its principles of operation. Section III goes through the details of the new hardware and its different components. Finally, Section IV lists some intended future work with discussions.

II. PRINCIPLES OF METHOD

The method is based on passive listening and detection of SDH frame headers, presently using an OC-192/STM-64 connection between core IP-routers at a nominal bit rate of 9953 Mbit/s, but is in practice with minor adjustments applicable to any STM line rate (or packet-based data transmission network).

SDH [7] defines the transmission of packets of data in nominally 125 µs long frames, where each frame starts with a well-defined sequence of A1 and A2 bytes that defines the beginning of a new frame, followed by frame information and finally the payload. The A1A2 sequence is chosen since it is extremely improbable that it occurs anywhere else in the bit stream and can therefore be used as a reference marker for the detection of the start of a new frame. At STM-64, this sequence is 192 A1 bytes followed by 192 A2 bytes.

In the time transfer setup, the reference marker is an electrical pulse which is generated at detections of a full A1A2 sequence. To succeed in an accurate time transfer, this operation must be performed both at the bit stream leaving the node, as well as the bit stream arriving at the node, i.e., in a two-way sense (see Fig. 1). The fundamental concept is to

This work is sponsored by the Swedish Post and Telecom Agency (PTS) under contract 04-9438.

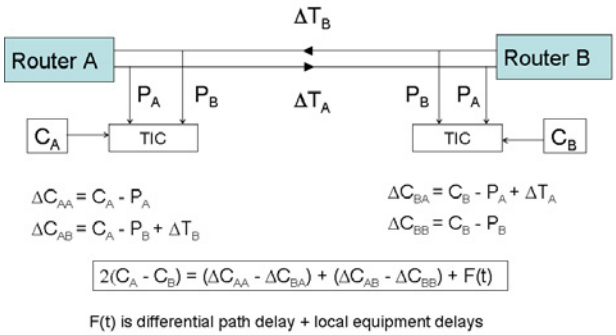

Figure 1. Principles of the two-way time transfer method. Optical signals are split-off to an O/E receiver. Frame headers are detected and pulses (P_A and P_B), based on the local oscillator in respective router, are generated. Time interval counters are used to relate pulses to local clocks (C_A and C_B) at both ends of a link. The two-way relation cancels most of the one-way delay variations leaving residual effects and a constant offset in F(t).

detect the time when this frame-start sequence is transmitted from a node in the network, in combination with the time when the same sequence arrives at the receiving node, where both time stamps are measured relative to the local clock at each node.

The transmission from a router is synchronized to a local oscillator (OCXO). The frequency stability of this clock source for the SDH framing do affect the performance of the time transfer by its jitter specification of less than 30 ps. This jitter is not notable in the present measurements; however, router oscillators could become a limiting component in future systems.

To implement the system, each fiber is equipped with two passive fiber-optic power splitters. At the transmitter, where the power level is high, 1% of the light is directed to the time analysis circuits, and at the receiving end, where the power level is low, 10% is split off to the circuits. The 11% added loss to the fiber transmission will decrease the power margin of the system, but it is anticipated that all systems are implemented with a far higher margin. All previous experiments have also validated this assumption.

III. Despcription of New Hardware

The recently developed hardware called Time Transfer Unit (TTU) is shown in Fig. 2. Each TTU contains custom-made printed circuit boards (PCBs) with different tasks and a single-board computer. The unit is 2U high, which is approximately 90 mm. The unit is equipped with two redundant fans attached to the back panel for necessary cooling. It will also work without the fans if a high enough air flow is available through the ventilation holes located in the front of the top- and bottom covers. Furthermore, with references to Fig. 3, which shows the modular design of the TTU, and Fig. 4, which shows more details of the internal functionalities, the following sub-sections describe each part of the new hardware.

A. Backplane

The cards are connected to slots on a backplane which supplies each card with necessary power. It distributes 1-pps

Figure 2. New, recently developed 2U (90 mm) hardware. Front panel and top view (without cover).

and 5/10-MHz signals from the oscillator card to the channel cards. It also serves the serial communication between each card and the single-board computer, necessary for example for measurement data, status bits, and Field Programmable Gate Array (FPGA) configuration updates.

B. Channel card

Up to 4 channel cards with 2 input channels each may be installed in the TTU. The incoming optical signal is converted to an electrical signal using an Avalanche Photo Diode (APD) receiver and is parallelized to 16 channels using a 1:16 DEMUX and then feed into an FPGA for analysis and frame header recognition (HR). The signal is thereafter serialized again in a 16:1 MUX and frame header pulses with a nominally frequency of 8-kHz are eventually generated based on the frame detection. The reason for parallelizing the signal is that the implemented FPGA is at its best working at 622 Mbit/s and the incoming signal is at 9953 Mbit/s. The alternative would have been to use an FPGA that could handle the fast bit stream without parallelizing, but at the time of development a faster FPGA was much more expensive and its jitter performance not yet analyzed.

Three PLLs are used in the setup, one for reconditioning of the incoming signal after the APD, which introduces jitter, and two PLLs in the FPGA on the Rx- and Tx-side, respectively. The two PLLs in the FPGA are essential in order to compensate for temperature variations in the FPGA.

The frame header pulses are used to stop a chip-scale 50-ps rms time interval counter (TIC) which is started by the 1-pps signals from the oscillator card. As explained later in sub-section G, several types of measurements are forwarded from the channel card to the serial bus. Each channel card contains two temperature sensors, one per channel. The front panel of the TTU contains one diode-lamp per channel to indicate

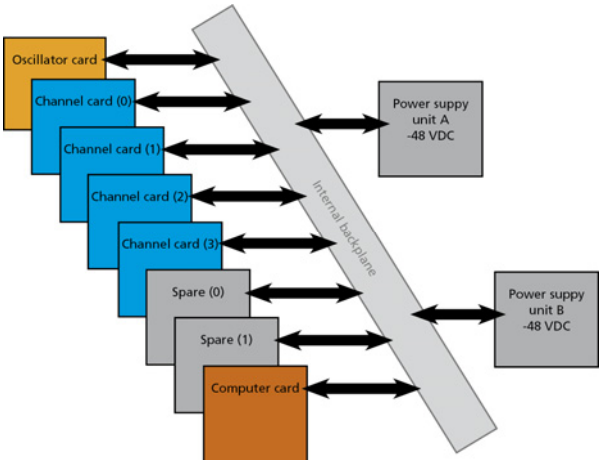

Figure 3. Principles of the modular TTU-design. A backplane connects each card powered from redundant -48 VDC power supply units.

synchronization to the incoming optical signal. It also contains outputs of the 8-kHz frame header pulses for testing and verification purposes.

C. *Oscillator card*

The oscillator card contains an OCXO which may serve as an intermediate clock bridging the asymmetry over multiple router links. At (end-user) sites, containing clocks or time scales to be compared, the connectors for external inputs located on the front panel are used to feed external 1-pps and 5/10-MHz signals to the TTU. The external signals are selected manually using jumpers located on the card.

Daisy-chain outputs (1-pps and 5/10-MHz) are available on the front panel, either, depending on the jumper settings, from the OCXO or the external clock. These may be used to connect TTUs at sites requiring more than 8 optical input channels. Two outputs (1-pps and 10-MHz) are also available on the front panel coming directly from the OCXO. Diode-lamps on the front panel indicate lock to the external clock signals. The OCXO may be steered in frequency and synchronized to the external 1-pps from the singe-board computer. A temperature sensor is available for monitoring.

D. *Single-board computer*

An Advanced RISC Machine (ARM) based single-board computer with a minimal GNU/Linux operating system is used to handle data collection, status requests, oscillator status and steering, as well as FPGA-updates. Application Programming Interfaces (APIs) have been written for these tasks. SSH (Secure SHell) data connections are available for remote login and data download. Ethernet, USB, and RS232 connectors are located on the front panel of the TTU. A Solid State Drive (SSD) is implemented large enough to store measurement data for a couple of weeks in case the Internet connection to the TTU temporarily goes down.

E. *Spare slots*

Two spare slots are available on the backplane for future

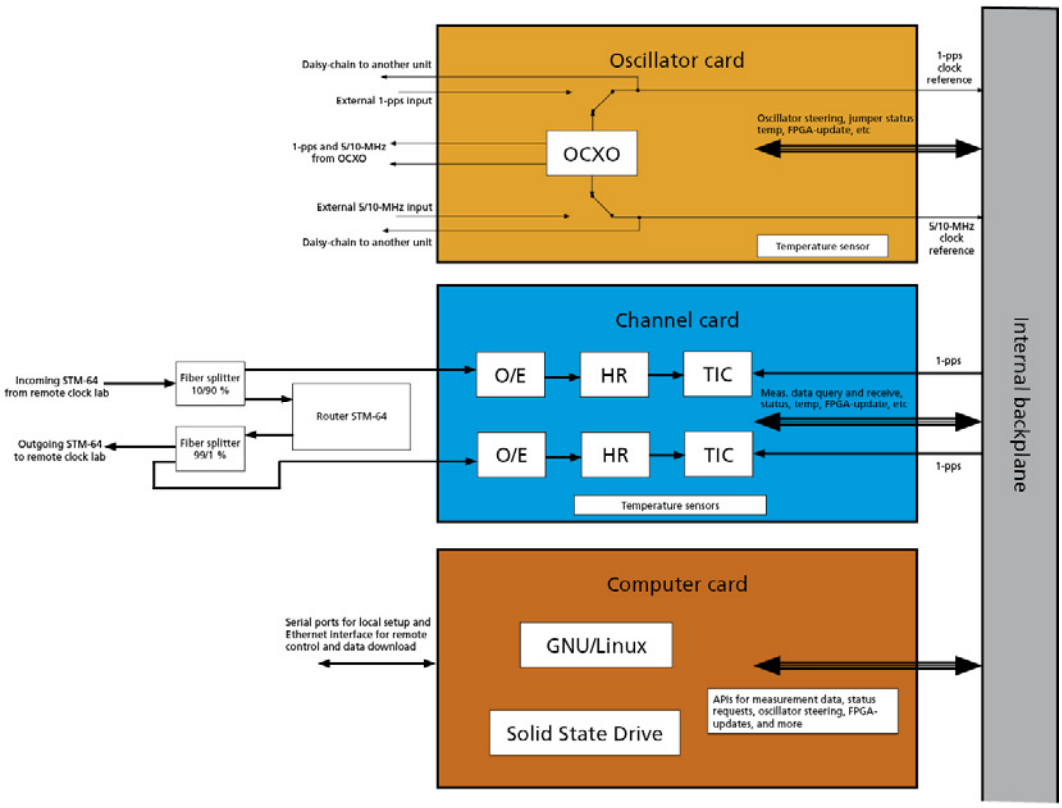

Figure 4. Details of the custom-made cards and the single-board computer. The SDH frame Header Recognition (HR) in the channel board contains DEMUX, FPGA, and a MUX.

implementation, such as for example bit-sequence generators and GNSS-receivers. Three out- or inputs are prepared on the front-panel to be used for this purpose.

F. Redundant -48 VDC power supply card

A power supply card containing two redundant -48 VDC supplies is installed in the TTU. The choice of -48 VDC is supported by the fact that many of the units will be installed in telecommunication facilities where -48 VDC is standard. Two diode-lamps on the front panel indicate the proper connection of power.

G. Measurement approach

To determine the time difference between two clocks (A and B) located at the two user ends of a two-way time transfer link, four time interval measurements are needed as shown in Fig. 1. In the prototype system [4], these measurements contained time intervals in the range of 0 to 125 μs as the TIC started on a 1-pps and stopped on a (SDH frame header) pulse train with a rate of 8 kHz.

In the new system, the approach is quite different and contains three measures. The first measure is a time interval measurement started with the 1-pps from the local clock and stopped by a pulse related to the detection of a frame header in the FPGA. In this way the principle is the same as the prototype system. However, the chip-scale TIC installed on the channel card can only measure time intervals in the range of up to 1.8 μs. The solution is to shift the frame header pulse with an integer number of a known time period (hereafter called HR-period) related to the optical bit-length so as the measured time interval is in the range of the TIC. The HR-period was chosen to be 12.86 ns which is presently 128 times the nominal bit-length (a choice also related to the capacity of the FPGA).

It is necessary to keep track of the number of HR-periods that has been added or subtracted. The second measure is thus the accumulation of HR-periods. The third measure that completes the measurement approach is a delay in the FPGA due to the parallelization of the incoming signal as mentioned above. This delay has a resolution of the nominal bit-length, which is roughly 100 ps in the present design.

IV. Future Work and Discussion

The largest error source for the method is presently asymmetric delay variations due to temperature variations in the two fiber-paths between routers. The size of the error is in the order of 2-4 ns peak-to-peak during a day. The different length of the Dispersion Compensation Modules (DSM) housed at intermediate amplifier sites in between routers, are the main cause for this [5]. In order to reduce this effect the temperature variations needs to be locally minimized or modeled.

As long as the mechanical lengths of the fibers in between routers are not changed, no phase change due to equipment will appear in the measurements described in Section III.G, even after restart or reboot of the TTU. This needs to be verified but means in principle that a constant asymmetry in the fiber path and local instrumental delays may be calibrated at installation, and the method could be used as a time transfer method as intended. A proper type of calibration method needs to be developed, for instance using a temporary or continuous GNSS-link.

One effect that will cause the need for a re-calibration, or otherwise compensated for, on certain fiber links, apart from mechanical fiber changes, is the loss of optical signal in between router paths. The receiving end could at these moments receive an optical signal not locked to the transmitting router oscillator which will cause a (slow) phase shift. Once the transmission is back to normal again the accumulated phase shift will remain and cause a phase jump in the link. This unwanted effect has not so far been investigated in detail.

In the near future, the intention is to establish time links between SP and different users. These links include both national and international users such as national metrology institutes, and these will first serve as test beds for the method and instrumentation, with the intention of becoming continuous time links.

The calculation of the time links using the prototype equipment has so far been in a post-processing mode for convenience. With the new TTU, a near real-time operation would be feasible in which measurement data is casted over the Internet to one or even several processing sites for redundancy.

Acknowledgment

The authors would like to acknowledge the continuous support from the Swedish University Computer Network (SUNET) and Peter Löthberg at STUPI AB. The authors would also like to thank InformAsic AB, Gothenburg, Sweden who made the theoretical ideas of the TTU realized in practice.

***Abstract*—In this paper the implementation of the method enabling computation of Maximum Time Interval Error in the real time is described. The results of implementation tests are presented and described.**

I. INTRODUCTION

The Maximum Time Interval Error (MTIE) is an important characteristic of timing signals in the telecommunication network [1, 2, 3]. MTIE recognizes maximal phase differences within considered observation intervals and therefore it is well suited for dimensioning of buffers (elastic stores) at the boundaries of the time scales. The point estimate of MTIE is commonly computed for a series of observation intervals using the sequence of time error samples measured at some network interface. The computation usually is performed off-line, after time error data measurement. However, in order to reduce the evaluation time of the timing signal, we can compute the MTIE in the real time, during the time error measurement process. Some methods enabling real-time MTIE computation were developed and tested by the authors of this paper [6, 7].

Computational ability of the methods proposed by the authors – DSDR method and EF method was analyzed and compared in some computational experiments performed off-line and simulating real-time performance [7, 8]. Both methods have presented very good performance for short observation intervals or time error data representing random behavior (e.g. WPM phase noise). However, for longer observation intervals and data series showing monotonic change of time error process the time of calculation was longer than sampling interval considered. Application of additional procedure controlling the computation progress allows to suspend the computation for some observation intervals and to make some toilsome operations later (for the successive sampling intervals), when smaller number of operations is executed, or at the latest, when the measurement is finished [9]. With this procedure applied the EF method has presented better performance during tests and therefore it was implemented for a real measurement and computation process.

In the paper the results of the implementation of the EF method enabling MTIE assessment in the real time are presented. To test this method in a real measurement process, a special time error measurement test module using FPGA technology was made. The results of the processes of measurement and calculation performed for different timing signals are presented.

II. MAXIMUM TIME INTERVAL ERROR

According to the international standards, the point estimate of the Maximum Time Interval Error is defined as the maximum peak-to-peak time error variation of a given timing signal, with respect to an ideal timing signal within a particular time period [1, 2, 3]. MTIE can be estimated from the formula

$$\hat{MTIE}(n\tau_0) = \max_{1\le k\le N-n}\left(\max_{k\le i\le k+n} x_i - \min_{k\le i\le k+n} x_i\right) \qquad (1)$$

where $\{x_i\}$ is a sequence of N samples of time error function $x(t)$ taken with sampling interval τ_0, $\tau=n\tau_0$ is an observation interval, and n can change from 1 till N–1 depending on the considered values of observation intervals.

MTIE point estimate is usually computed off-line, after the time error measurement process is completed. Following directly the formula (1) in order to find the estimate of MTIE for the observation interval τ, all intervals having the width of τ, existing within the sequence of N time error samples, must be reviewed. The window having the width of $\tau=n\tau_0$ and including n+1 samples is set at the beginning of the data sequence $\{x_i\}$ and then it is shifted with the step of τ_0 (one sample step) along the items of the sequence. For each window's location the peak-to-peak value of time error in the window is found. The maximum peak-to-peak value found for all existing locations of the window is the value of MTIE(τ) estimate. The process of the window reviewing does not depend on the data value. The complexity of calculation grows with n and therefore the direct method applied for

This work was supported by the Ministry of Science and Higher Education (project no. N N517 1645 33) and Poznan University of Technology (project no. 83-038/11 DS-PB).

computation of the parameter for the series of observation intervals is really time-consuming. The idea of direct search (plain computation) of MTIE is presented in Fig. 1.

Several time effective methods of MTIE assessment were proposed in order to avoid the time-consuming plain computation [4, 5]. Some different mechanisms were applied to reduce the complexity of computation. In the process of the MTIE search using the extreme fix (EF) method some window's locations are excluded from inspection if the peak-to-peak value for each of these locations is not greater than the value found until now, or if a greater peak-to-peak value may be found for the successive window's locations [5]. The EF method is based on fixing the positions of minimum and maximum samples for a given window's location. The general rule is that the next window's location is originated at the first extreme previously found. The reviewing process is performed only for the new samples that come into the window's location. The review of the whole window at its new location is performed only in the case of one-sample shift (the first extreme is first sample in the window's location), when the new sample appearing in the window is not a new extreme. The idea of EF method is presented in Fig. 2.

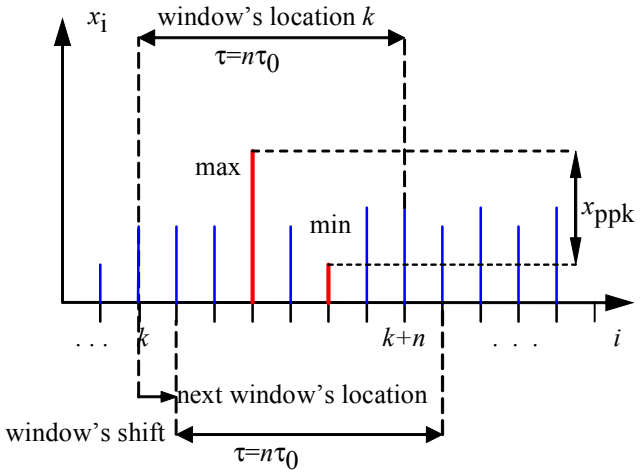

Figure 1. The idea of direct search for MTIE

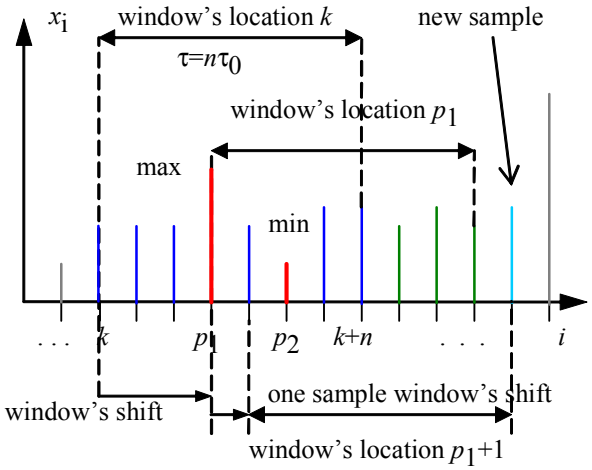

Figure 2. The windows shift in the extreme fix method

Another class of time effective MTIE computation methods contains the methods with sequential data reduction. The methods follow the suggestion according to which during the MTIE search process for some observation interval τ_i we find the extreme samples for some window's location from the set of extreme samples found previously during the MTIE search for the smaller observation interval τ_{i-1} ($\tau_i > \tau_{i-1}$). Therefore, we can reduce the number of time error samples used for the MTIE calculation. One of these methods, proposed by the authors of this paper – direct search with sequential data reduction (DSDR) – uses plain computation at each level of the procedure (for raw and reduced data) [6]. Other method, proposed by Bregni and Maccabruni [4], uses the rule of binary decomposition for reduction of time error data set used for computation.

III. Real-Time Methods of MTIE Assessment

Performing the MTIE computation in the real time, during time error measurement process, we can observe the current value of the parameter. Any possible wrong behavior of the analyzed signal (recognized if MTIE exceeds the limit) may enable applying proper activity of the network maintenance team.

In order to calculate the MTIE estimate simultaneously for several observation intervals in the real time, all necessary operations should be performed in the time period between two sampling instants, i.e. during the sampling interval τ_0. The ability of real time assessment depends on the several conditions, (e.g. number of observation intervals), but the computation method applied is very important.

The time effective methods of MTIE computation were adopted for the real-time computation by the authors of this paper. The results the experimental tests of the real-time MTIE computation using DSDR, EF, and binary decomposition methods were presented in [7, 8]. The experiments were performed in order to verify the maximum time spent for necessary operations within one sampling interval. The results of the experiments have shown very good performance of the method with binary decomposition, but this method has one obvious disadvantage – the number of samples in the observation intervals considered must be a power of 2. The performance of two other methods – EF and DSDR – was good for limited range of observation intervals – small number of intervals having short length, e.g. for the range from 0.1 s till 10 s. The maximum computation time for wider ranges of observation intervals (including longer observation intervals, e.g. between 100 s and 1000 s) has exceed the length of considered sampling interval for the EF and DSDR methods. Such situations result from the accumulation of computational procedures within one sampling interval caused by specific data arrangement.

In order to avoid these troublesome situations during the measurement and computation process performed in the real time, some procedures controlling the computation progress were introduced [9]. Using these procedures, the computation for a few longer observation intervals (belonging to the considered set of intervals) may be suspended in order to reduce the number of operations carried out within one

sampling interval. This analysis is suspended, if the number of samples reviewed in the course of the computation process performed within one sampling interval exceeds (or may exceed in the next step) some threshold value. The analysis of suspended intervals may be performed later (for the successive sampling intervals, in the case of DSDR method), when smaller number of operations is executed, or at the latest, when the measurement is finished (in the case of EF method). Such suspension causes a delay of the computation process, because the computations for the suspended observation intervals must be concluded after the measurement is finished.

The results of the experimental tests of the real-time MTIE computation using DSDR and EF methods with additional procedures were presented in [9, 11]. Application of the modifications proposed – control of computation progress with threshold – has enabled effective protection against exceeding the limit. The results of the tests have proved the ability of the real-time MTIE computation using both methods for the range of 21 observation intervals from 0.1 s till 1000 s performed during time error measurement with sampling interval τ_0=1/30 s. The comparison of the delay time (time of computation performed when the measurement is finished) for both methods is very interesting. Surprisingly enough, the best results were obtained for the EF method, which previously revealed difficulties in the real-time computation [7]. Introduction of the progress control causes the delay of obtaining the final result from some seconds (max 10 s) for modern computer with multi-core microprocessor up to about half a minute for older computer with single-core microprocessor. Application of DSDR method with progress control cause longer delay – from about 20 s using modern computer till almost 12 minutes using older computer. The delay obtained for the EF method is acceptable in comparison with considered time of measurement equal to T=4000 s. Therefore the EF method was implemented for the real measurement and computation process.

In the case of real-time calculation using EF method [7], the computation procedures for each observation interval run independently. Windows' locations (representing the observations intervals) are analyzed after filling out by the samples without waiting for the analysis by the preceding shorter windows. All windows are activated after filling out their first locations by the samples. The number of samples reviewed in the course of the computation process performed within one sampling interval is tracked. If the review of the whole window's location have to be performed for some observation interval (critical case for the EF method), and the number of samples reviewed within this sampling interval will exceed assumed threshold, then the computation for this observation interval is suspended until the end of measurement. The computation for the suspended observation intervals will be completed after the end of measurement. The example of this procedure is presented in Fig. 3 [9]. The extreme sample (8 at the position no. 10) leaves the current location of 10-sample window and the one-sample shift has to be done. Because the new sample coming to the window's location is not "more extreme" than the leaving sample – the review of the whole window at its new location is necessary. Therefore the analysis of the 10-sample window is suspended, because time of this review accumulated with the time of the operations done until now may exceed the length of sampling interval. The analysis of this window will be concluded after the end of time error measurement (Fig. 4) [9]. The algorithm of the real-time MTIE computation using EF methods is presented in Fig. 5.

IV. Implementation of the Real-Time Computation Method

To test the real-time computation of MTIE in a real measurement process, a special time error measurement test module using FPGA technology was made [10]. This device, which allowed for single-channel time error measurements, was created using a Virtex-5 evaluation module. Data storage and real-time computation were performed using a personal computer connected by the USB interface. The real-time assessment of MTIE was performed using the EF method with an additional control of the computation process implemented especially for the test module. The values of MTIE were computed for 21 simultaneously considered observation intervals from the range of 0.1 s to 1000 s. Measurement and computation sessions were performed for independent oscillator configuration (comparison of two independent oscillators) and synchronized oscillator configuration (comparison of two GPS disciplined oscillators). The examples of the working process of the real-time MTIE assessment for independent oscillator measurement are presented in a form of screenshots in Fig. 6-8. Currently computed MTIE values for observation intervals of 0.1 s, 1 s, 10 s, 100 s, and 1000 s are displayed on the screen in the text mode.

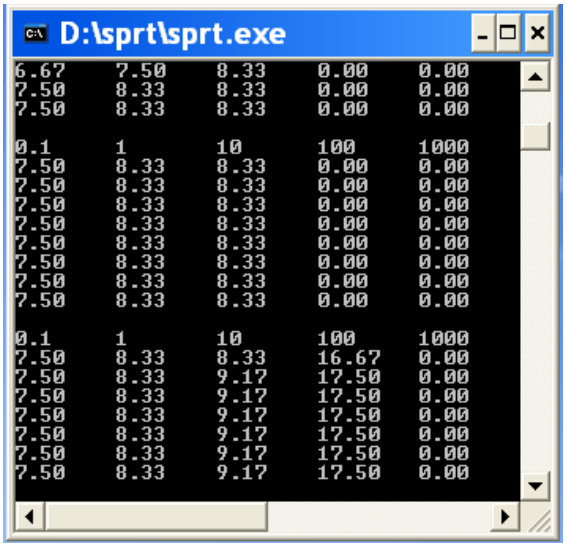

Figure 6. Early stage of the real-time MTIE computation

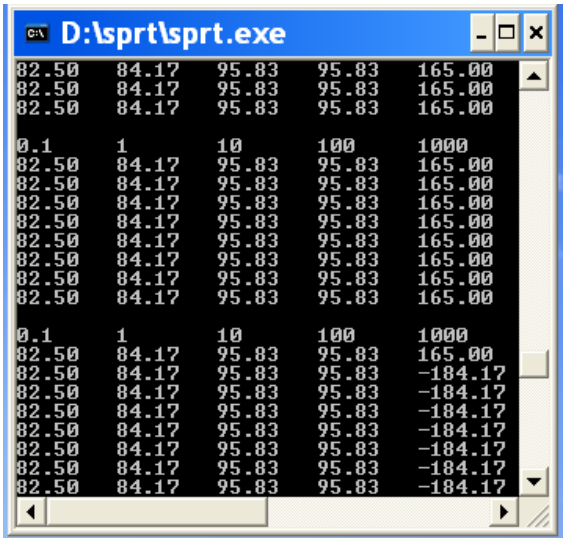

Figure 7. Late stage of the real-time MTIE computation

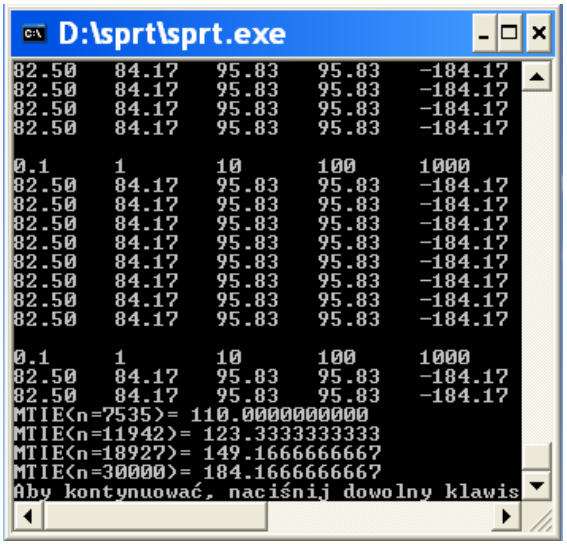

Figure 8. End of real-time MTIE computation

Zero value of MTIE displayed on the screen denotes that the computation for this observation interval does not started yet because of insufficient number of samples measured until now. Negative value of MTIE indicates the suspension of computation for particular observation interval. Threshold value was 12 000 samples. The results of the MTIE assessment successively obtained during the time error measurement process for independent oscillator are presented in the form of three-dimensional plot in Fig. 9. The first segments of the MTIE plot are shorter than the others because the parameters' values for longer observation intervals were not computed for these instants of the time error measurement process. Last segment represents final MTIE curve obtained at the end of the measurement. The results of time error measurement for independent oscillator are presented in Fig. 10. The computations of four observation intervals were suspended during this measurement session (time of measurement T=4000 s).

The examples of the working process of the real-time MTIE assessment for synchronized oscillator measurement are presented in a form of screenshots in Fig. 11-13. The results of the MTIE assessment successively obtained during the time error measurement process for synchronized oscillator are presented in the form of three-dimensional plot in Fig. 14. The results of this time error measurement are presented in Fig. 15. The computations of two observation intervals were suspended during this measurement session (time of measurement T=4000 s).

Figure 15. Time error obtained for synchronized oscillator measurement

V. CONCLUSIONS

The method applied allows to perform the MTIE computation in the real time, during the time error measurement. Application of the modifications proposed enables effective protection against exceeding the limit of computation time. The results of the tests performed have proved the ability of the real-time MTIE computation for the range of observation intervals from 0.1 s till 1000 s performed during time error measurement with sampling interval τ_0=1/30 s. The method applied shows better performance for the time error measurement in the configuration of synchronized oscillator.

In the future the method presented should be implemented in a multifunctional measuring system enabling evaluation of the synchronization signals' quality in the telecommunication network [10]. The implementation of the EF method using multi-task processing and multi-core microprocessor could enable the real-time MTIE assessment without the suspension of computations for particular observation intervals.

***Abstract*—This paper deals with the problem of generation of 1-pps timing signal at the output of computer interface controlled by Network Time Protocol. The methods of synchronization of internal computer clock and transmission of the timing signal to the serial interface are described. The results of the measurement of obtained signals are presented.**

I. INTRODUCTION

In the world facing the technological development, the demand for sources of time signals has been still increasing. Currently, numerous systems which to a high extent meet the needs of the consumers of time signals in every respect are offered. The basic sources of time signal are radio systems, for example DCF-77, information systems, i.e. NTP, and satellite systems like GPS. The offered quality of time signal sources falls into the range of tens of milliseconds for radio sources through hundreds of microseconds for NTP to tens of nanoseconds for satellite systems. It seems that the time signal from the Internet has the broadest application because it is easy to acquire and includes a considerable potential for improving its parameters [5, 6, 8].

The research presented hereby is, therefore, aimed at the application of NTP protocol to generate the timing signal, with a possibility of utilizing the signal outside the Internet network. It was also assumed that the source of signal would be an ordinary computer with an internal quartz clock. This is an important assumption because the utilization of rubidium clock in the NTP receiver would remove a majority of quality problems affecting the acquired time signal, at the expense, however, of a considerable increase in the device price.

Generation of timing signal controlled by NTP could be useful in order to provide some systems with timing signal when we haven't access to good quality timing signal source like atomic clock or GPS controlled oscillator. The authors of this paper have proposed a method of generation of physical timing signal controlled by the NTP [1, 2].

In this paper the method enabling generation of physical timing signal (in the form of 1-pps pulses), controlled by the NTP and brought out using serial port of the computer, is described. The algorithm of control of timing signal using NTP protocol is presented and described. The timing signals obtained were compared with the reference signal controlled by GPS receiver.

II. SOFTWARE AND HARDWARE PLATFORMS OF RESEARCH

The research carried out [1, 2, 3] reveal two basic factors affecting the quality of time acquired from the NTP protocol for which the very NTP system is responsible. These are: the time of servicing a query in the server and the waiting time of the query in the Internet network. Due to the dynamics of phenomena taking place in the network, the compensation of these times by the NTP mechanisms has quality limitations. But when the time signal is led outside computer, the factors resulting from the performance of the computer operating system as well as the factors related to the quality of internal computer clock have an additional influence on the quality of the generated signal. The research carried out proved considerable program difficulties that developed when the MS Windows operating system was utilized to generate the time signal on a computer interface without delays [2]. The computer clock was indeed successfully synchronized by the NTP protocol in time intervals in a range between 2 s and arbitrarily long time intervals. However, difficulties developed in applying the program responsible for transfer the information of time instant from computer internal clock onto 1-pps (NTP second) pulses, which should be transmitted to an external computer interface, like COM or USB. This problem was solved in the Linux operating system. Therefore, in order to generate the timing signal controlled by NTP, this operating system was applied.

The influence of system clock on the parameters of the acquired time signal is significant. Application of a very good clock (with small frequency instability, e.g. rubidium generator) will allow us to refer quite rarely to the synchronizing role of the NTP protocol. Therefore the number of clock adjustments with the potentially occurring noise from the Internet could be smaller. Common oscillators applied in the personal computers feature with frequency inaccuracy and sensitivity to temperature variations. The observations of the performance of computer clocks on different computers

This work was supported by the National Centre for Research and Development in the frame of the project PBZ-MNiSW-02/II/2007 during the years 2007-2011.

indicate that the time error caused by the frequency offset may take the value from 10 μs up to 130 μs for 1 second.

III. GENERATING 1-PPS SIGNAL

A. Setting the computer time from NTP

The "ntpdate" program was applied for setting the NTP time. This is a Linux program operating independently, without any external configuration or system services. The "ntpdate" program is included in a standard NTP packet for time synchronization in the Linux and Windows systems. This application uses a script that makes use of the "ntpdate" command [4] to synchronize the time:

```
#!/bin/bash
interval=$1            # synchronization interval
time_server=$2         # name of server
while :                # infinite loop
do
ntpdate -b $time_server       # synchronize time
with a given server
sleep $interval                # hold script
execution for a given time
done
```

The script call takes the form:

```
./sync.sh vega.cbk.poznan.pl 10
```

The first call parameter is the interval, in seconds, between the instants of time synchronization. The other one is the address of the NTP server. The performance of synchronization script, set for example for a 10-second interval, has the following effect:

```
2 Nov 11:23:18 ntpdate[17247]: step time server
150.254.183.15 offset 0.000030 sec
2 Nov 11:23:28 ntpdate[17253]: step time server
150.254.183.15 offset 0.000024 sec
2 Nov 11:23:38 ntpdate[17264]: step time server
150.254.183.15 offset 0.000034 sec
```

B. Generating 1-pps signal at serial output

Having provided access to a proper, NTP-synchronized time of the system clock, using the "ntpdate" program and assuming the accuracy of synchronization (and its frequency), we applied a Linux program called "OneShot" to transmit the second of computer clock to the serial port output. In this respect, we abandoned the Windows system because it did not ensure as precise control over transmitting the system clock to the COM interface as Linux did it [4]. In this case the DTR signal was applied, "data transfer ready", selected because of easy service of an event from the level of a program written in C language. There is no need to set the port parameters. In this solution there is no transmission of information in the form of ASCII code characters, but the voltage is changed on a selected pin (in this case – pin 4), which represents the 1-pps signal.

The initialized "OneShot" program acquires the system time with resolution 1 μs, and then re-calculates the time till another second. When the time passes, a pulse is sent to the serial port, and then another re-calculation of time is done. The duration of the procedure of sending this pulse is ca 60 μs. Every 1-second re-calculation of time guarantees that the NTP synchronization is taken into account regardless of the assumed synchronization interval. Already in another second, after the system clock is reset, the program can present all variations or inaccuracies resulting from speeding up or slowing down the system clock. Thus the program tries to adjust the pulses, sent every second to the serial port, to the continuously synchronized and variable computer clock. A standard Linux function of C language gettimeofday [4] is applied to acquire the system clock time. This function acquires the current time, given in the form of a packet, from which the time T' that passed from the last full second can be directly acquired. Based on this time, we calculate the time T in which another pulse to the serial port should be sent using the formula:

$$T = 1000000 - T' \quad (1)$$

For this purpose a counter is set up (it can be compared to an alarm), which after given time runs the procedure of sending a pulse onto the serial port. This counter measures the time till another second, based on the Linux setiTimer [4]. This is a function that measures the elapsing real time and generates an alarm after it has passed. The real time measurement means that even when the program is stopped by the system, the counter will still be working and measuring the time till another second. The performance of the "OneShot" program is presented in a diagram in Fig. 1.

IV. MEASUREMENT OF 1-PPS SIGNALS

In order to evaluate the timing signal obtained at the computer interface, two measuring stands were set up. Two computers (with Linux operating systems), connected to the Internet, are supplied with the software described above. 1-pps signal generated at pin no. 4 of PC serial interface is compared with a reference 1-pps signal generated by GPS controlled oscillator. The phase difference between both signals determines the time interval ΔT at the output of a time interval generation module. The interval ΔT is the measure of time error. Next computer (or two computers) is equipped with specialized measuring cards, enabling the measurement and recording of this interval. A block diagram of such measuring system is presented in Fig. 2. The measurement stands applied are presented in Fig. 3.

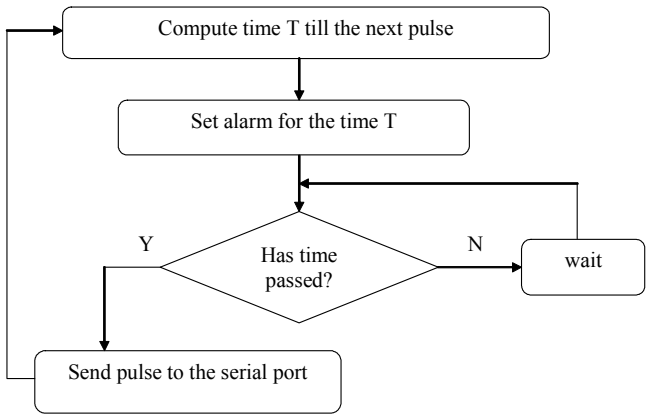

Figure 1. Algorithm of OneShot program performance

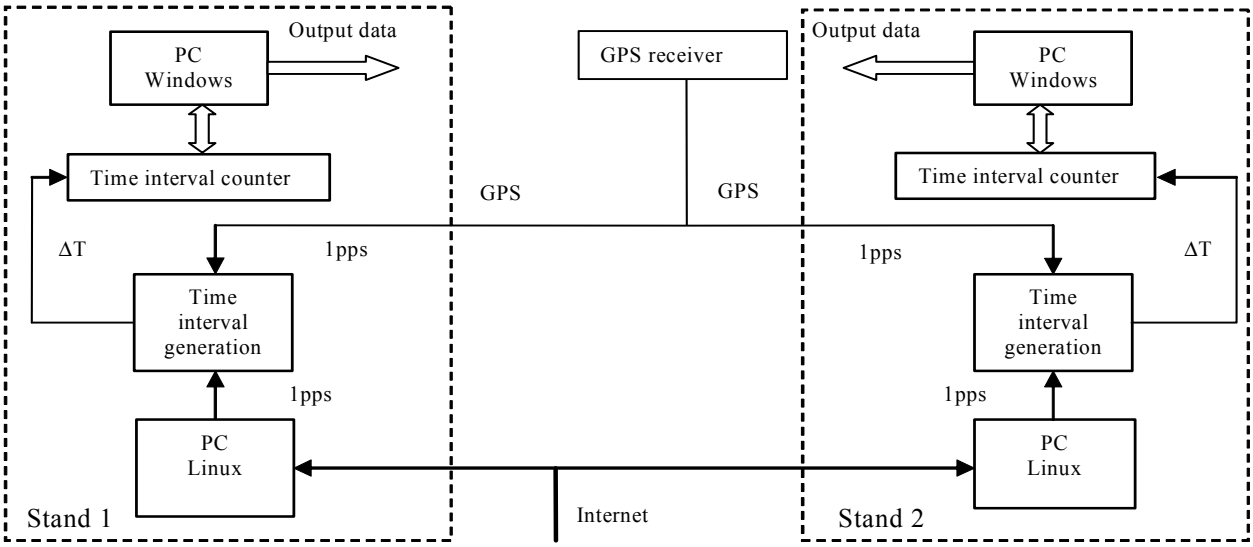

Figure 2. Block diagram of measurement stands

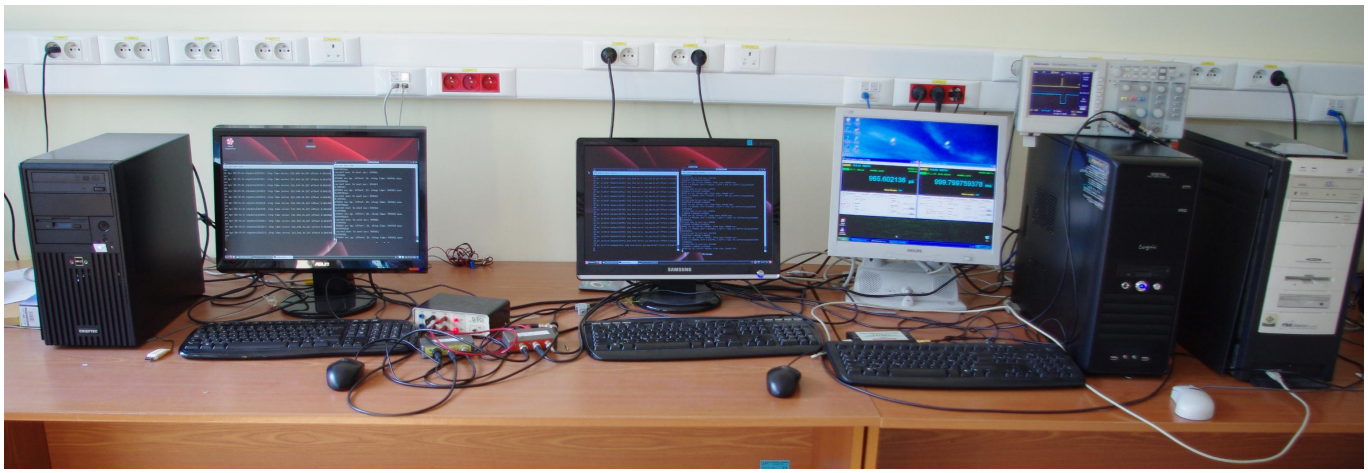

Figure 3. The measurement stands applied

Results of time error measurement of 1-pps signal controlled by NTP server with stratum 1 (tempus1.gum.gov.pl) on both stands simultaneously are presented in Fig. 4. System time of both computers with Linux was synchronized to NTP with 10 s interval.

In the results shown in Fig. 4 a considerable influence of the quality of system clock in computer is visible. The saw-tooth shape of the time error is caused by the frequency offset of the PC internal oscillators. The maximum time error depends on the NTP synchronization interval. Some random peaks of the time error are present in the results. The number and amplitude of these peaks in different results obtained are random. Their amplitudes vary (even up to tens of milliseconds). Similar phenomena were registered in [7].

V. Processing of Controlling Signal

In order to minimize the time difference and the influence of random distortions some additional algorithms controlling the generation of the signal are proposed. The algorithms are working on the values of the time T determining the instants of successively generated pulses.

The methods applied in the algorithms allow averaging or finding a median value of a set of n time intervals T and limiting the changes of the interval T.

In the first case the value T that determines next instant of pulse generation, is average or median value of the set of n last values of interval T. In the second case two thresholds are introduced: threshold t for a maximum value of time T, and threshold c which is an admissible change in the value of time T. The purpose of this threshold algorithm, together with the averaging algorithm, is to limit, and possibly even to eliminate any phase jumps in the time signal, which in the form of peaks can be noticed in Fig. 4.b.

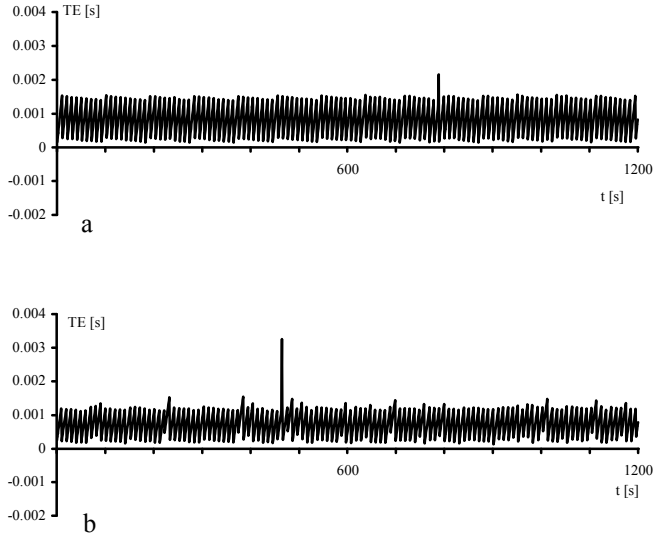

Figure 4. Time error of 1-pps signals controlled by NTP

The algorithm performs in a few steps:

- calculation of the time till another second according to equation (1);
- determining the change in the value of current time in relation to previous time;
- if the absolute value of the change does not exceed the value t, the usual performance of the algorithm is continued;
- otherwise, if a current change does exceed the value t, the difference sign is assumed;
- positive difference means that the time has been elongated, then the previous (last) value increased by c is substituted for a new time T;
- if we put the value c0, then the last value of time T is substituted;
- negative difference means that the time has been shortened, then the previous value, decreased by c, is substituted for a new time T;
- thus calculated new value determines the time till the next second.

The algorithm of determining an admissible threshold in the time signal with value m and the time signal jump to value c for time T is shown in Fig. 5.

Example of execution of the procedure:

```
user@user-desktop ~/time $ timer -m3 -t100 -c100
```

where the parameters are: m3 (or s3) – median (or average) from 3 last values of T; t100 – limit of changes of the value of T set to 100 μs; c100 – fixed change (100 μs) of the value of T, if the limit t is exceeded (for c=0 previous value of the interval T is used).

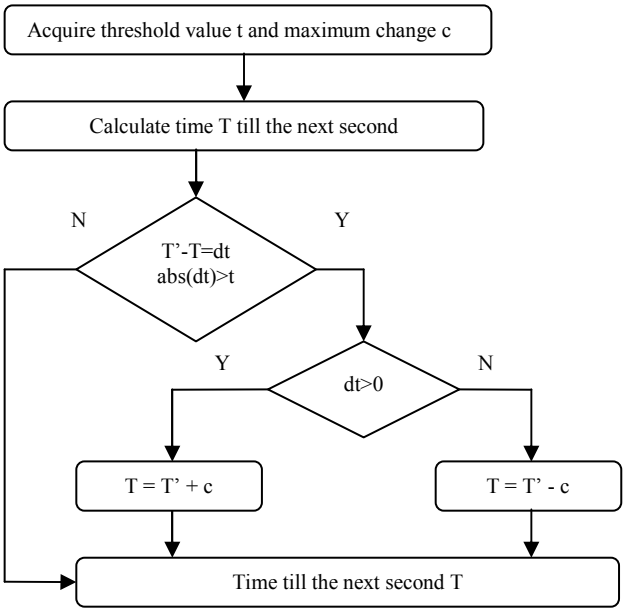

Figure 5. Algorithm for determining threshold t and jump c

VI. MEASUREMENT OF 1-PPS SIGNAL WITH ADDITIONAL CONTROL

In order to evaluate the performance of the proposed algorithms, simultaneous measurements were performed on both measuring stands. Each pair of the measurement results contains one time error series of timing signal obtained without additional procedures and one time error series of timing signal obtained with additional processing. The range of the parameters' values set in the procedures proposed is very wide. Firstly, it is necessary to set properly the number of samples assumed for averaging or calculating the median from successive seconds. Measurements were done for different parameters, and a better stability of the obtained timing signal was confirmed for the median algorithm. The quality of computer clock limits the selection of the number of considered items (values of T) to the value of 10. Still the more difficult is to select the appropriate threshold parameters. Too short intervals of times t and c cause oscillations in the time signal. Setting too long values for those times makes the threshold effect cease. The results of obtained registrations, which illustrate these phenomena, are shown in Fig. 6 and 7.

From the evaluation of results in Fig. 6 and 7 it can be concluded that the peaks in the time error signal were removed by filtering algorithms; whereas the setting of the algorithm in Fig. 6.b is selected inappropriately, which is visible as oscillations in the time signal. The algorithm the performance of which is shown in Fig. 7.b removes peaks and does not introduce oscillations, but it increases the time signal error ca 2 times. The results obtained indicate, however, a perspective for further research; they also prove that it is necessary to optimize the applied algorithms.

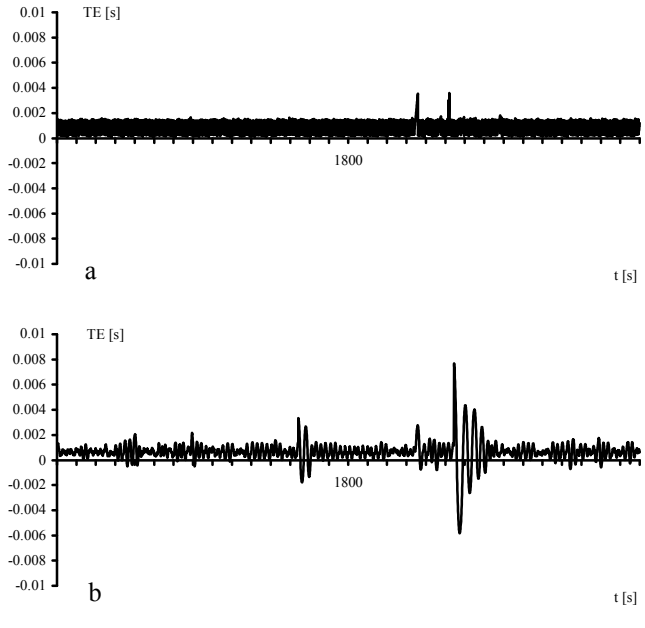

Figure 6. Time error of 1-pps signal without (a) and with additional processing (b) with parameters m3, t100, c100

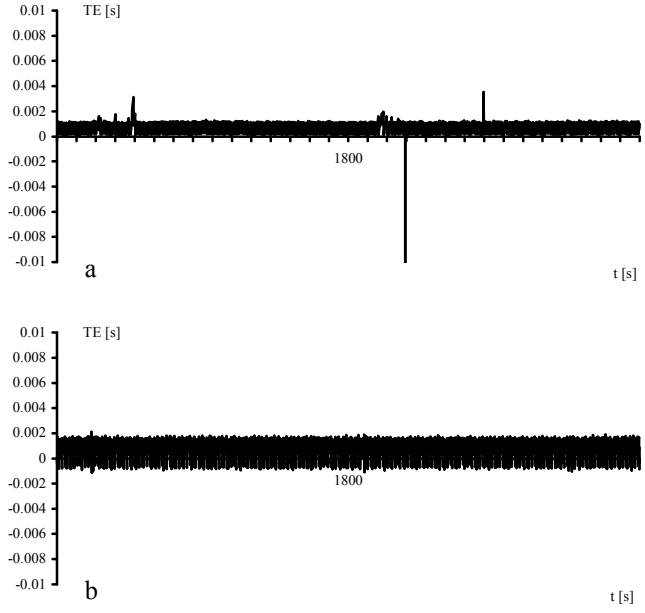

Figure 7. Time error of 1-pps signal without (a) and with additional processing (b) with parameters m3, t7000, c1000

VII. CONCLUSIONS

The technique described in this paper can be utilized for applications different than computer networks at the level of accuracy of the order of several milliseconds. It can be used e.g. for control of the clocks with display in public areas, when the access to the high quality reference is impossible or not necessary. The 1-pps signal controlled by NTP can be applied also in the systems that require the electrical form of the reference signal instead of the data stream.

The quality of the time signal generated on the computer interface depends on the quality of internal computer clock. This quality can be improved by appropriate selection of the parameters of software responsible for cooperation with NTP (intervals of synchronization) and the parameters of software generating the 1-pps signal (control of instants of pulses). Frequent reference to the NTP synchronization procedure makes the time signal more sensitive to the influence of events in the Internet network and may caused other processes simultaneously running on the computer. Rare reference causes increment of the time difference resulting from the frequency inaccuracy of the computer clock.

Some random peaks were observed in the timing signal, which we tried to eliminate using additional algorithms affecting the generated timing signal. The results obtained require, however, the research work to be continued. Further research will make it possible to improve the performance of these algorithms, and to decrease the time error in the obtained signal.

***Abstract*— Short distance fiber based optic distribution of time and frequency is often considered sufficiently stable and therefore, uncompensated one way transfer is used. However, when fiber distances increase to a few km, and a substantial amount of the fiber is installed outdoors or in aisles and attics without temperature control, the delay through the fiber may vary substantially. Since the variations are slow, a microwave frequency modulated on an optical carrier may be assumed to remain sufficiently stable. The time delay through the fiber will nevertheless depend on the extremes of the temperature variation which must be taken into account or compensated for. This study presents the design issues of a real time compensation and some results of an optical compensation technique.**

I. INTRODUCTION

The motivation of this work is to transfer a microwave frequency over a short fiber optic link, with a real time compensation of the delay variations of the fiber. The result will be a fiber link in which the transfer time variations, τ, is actively compensated, in comparison to links with actively compensated frequency transfer, operating on the derivative of transfer time variations $d\tau/dt$.

Previous work on multimode fiber A similar setup using light at 850 nm through multimode fiber has been presented previously [1], as well as a setup based on matched electronic delays [2].

II. THEORY

The delay of an optical single-mode fiber will vary as the temperature of the fiber cable changes. A typical value for standard single-mode fiber is 37 ps/km/K [3]. This variation will occur on outdoor installations, especially when sunlit, but also indoor on non- insulate attics, unheated stairwells and sun heated outer walls. The temperature span of an outdoor installation can exceed 20K over a day and 40K over a year, and in indoor and buried fiber the temperature may change as much as 20K[4] over a year.

If a variable delay is adjusted to counteract the fiber delay variations, the net delay remains constant. This requires two way fiber transmission, and a bidirectional optical delay. Two way fiber transmissions can be achieved in parallel fibers (duplex) or return in same fiber (simplex). Furthermore, the Optical Delay Line (ODL) must have a tuning range exceeding the anticipated fiber delay variations.

III. EXPERIMENT AND RESULTS

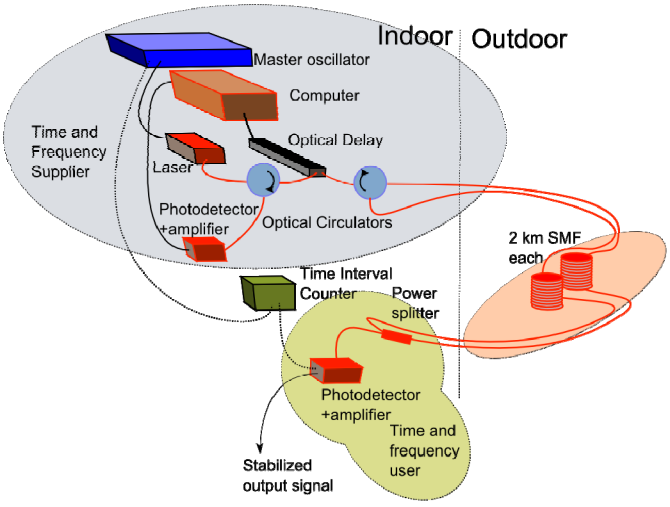

Figure 1. Schematical setup of the experiment.

The experimental setup is schematically described in Fig.1 Two spools of 2 km Standard Single Mode Fiber are installed on the roof. At the user end, 50% of the light is

extracted and 50% returned. Two identical photodetectors are used at both user and supplier end. The returning signal is compared to the transmitted in a double balanced mixer, where the output is detected in a DC-Voltmeter (DCV) set at long integration time. The reading of the DCV is evaluated by a computer that controls the fiber optic delay to keep the voltage constant. The DCV must wait until delay is set at new steady value before starting a new integration of values. This setup is indicated in Fig. 2 below.

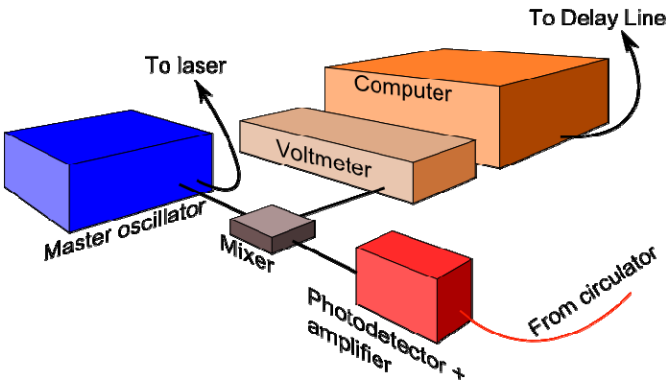

Figure 2. Detailed schematic of return equipment at trensmitter end.

The Time Interval Counter (TIC) is used to evaluate the quality of the fiber system. The Master oscillator is connected to UTC(SP) through an indoor fiber optic link.

A. *Equipment Description*

The laser is a semiconductor laser diode for telecommunication, emitting light at 1550 nm into a single mode fiber. The laser diode is directly modulated by the 10 MHz signal from the Master oscillator.

The photodetectors are semiconductor photodiodes which responds to light at wavelengths of 1300 – 1600 nm, at an electrical bandwidth up to 100 MHz. To increase the electrical signal amplitude, it is amplified before entering the mixer.

The optical circulator will transfer light entering port 1 to exit from port 2. Light entering port 2 will exit from port 3. No light is transferred from port 3 to port 1.

A microwave mixer with identical frequency on both inputs, will emit a DC voltage proportional to the amplitudes of the input signals and *cos(phase),* where *phase* is the phase difference between the two signals. Since there is a fixed relation between *phase* and time, this can be used to estimate the time difference with high resolution.

B. *Experimental Results*

The result of the measurement is shown in the graph in Fig.3. The red dots (left axis) show the time interval measured In the TIC. When outdoor temperature is within 17 – 20°C, the fiber link is stabilized and the transfer time through the fiber link is constant. However, when the temperature decreases below this interval, the ODL reaches its limit, and the transfer time varies with temperature. During test period, outdoor temperature varied between 0 and +20 °C. Furthermore, in active stabilization, a small temperature dependence is still apparent.

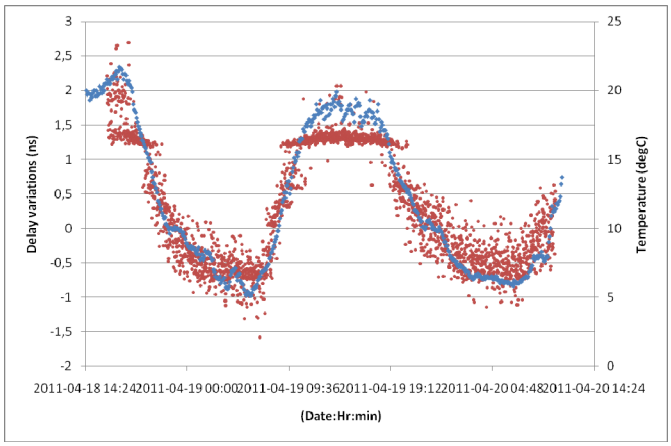

Figure 3. Stabilized output time signal (red, left Y-axis) and outdoor temperature (blur, right y-axis)

IV. CONCLUSIONS

The measurements indicate that the active stabilization of the fiber delay is a feasible method for increased stability on time and frequency transfer over short fiber links. Nevertheless, the ODL must be bidirectional, and its tuning range matched to the fiber link and the installation environment. The commercial ODL used in the experiment have ±100 ps tuning range, which was shown to be insufficient in the present setup. The system regulates the transmitted phase as long as temperature does not change more than a few degrees.

Some remarks on the CCTF CGGTTS format

Jiang Z. and Lewandowski W
Time Department
Bureau International des Poids et Mesures
Pavillon de Breteuil, F-92312, SEVRES CEDEX/France
zjiang@bipm.org

***Abstract*— The CCTF CGGTTS data formats are used worldwide in the applications of various societies from the *UTC*/*TAI* production and scientific studies to all levels of commercial usages. Its design was based on the GPS receiver technique in the 1980s. With the progress of the new GNSS receivers and new T/F transfer techniques, its short points are becoming evident, e.g. the convention that for a tracking arc of 16 minutes only 13 minute data are recorded. In this paper, we discuss the outdate points in the CGGTTS format and how to improve it toward a new CGGTTS convention, namely V03. The new and old versions can co-exist for different applications.**

I. INTRODUCTION

The CCTF GGTTS (version 01) and CGGTTS (version 02) data formats (V01 and V02 hereafter) are used worldwide in the timing community for GNSS time and frequency transfers (T/F). Both are co-exist in the applications of various societies from the *UTC*/*TAI* production and scientific studies to all levels of commercial usages. The designs of the V01 and V02 were based on the state-of-the-art of the receiver manufacture in the 1980s. With the development of the new GNSS receivers and new T/F transfer techniques, some short points, due to the GGTTS convention, become obvious.

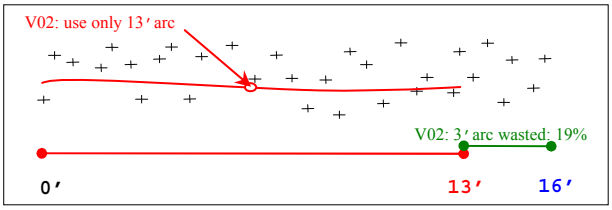

Figure 1. A tracking arc of 16 minutes scheduled by V01 and V02 (among 32 observations of 30 second each, only 26 are recorded)

One of the major defaults in the CGGTTS convention is that for a tracking arc of 16 minutes of measurements only 13 minutes of them are recorded in the CGGTTS (V01 and V02) file. Figure 1 illustrates the case of converting the Rinex observation to CGGTTS. In the earlier days there were only single channel single frequency GPS receivers which followed the BIPM tracking schedule of 16 minutes and for each tracking arc there was a 3 minute's standby for seeking and locking the scheduled satellite. The result is that 3 over 16 (19%) minutes of the raw data rejected this way! This is obviously not reasonable. Theoretically, it is easy to calculate the gain if all the 16 minutes' data will be used: suppose ε is the measurement error of the each 30 seconds' tracking. The error in the average of 13′ is ε/√(26) and that of 16′ ε/√(32). The gain is [ε/√(26)-ε/√(32)]/{ε/√(26)}-1=10%. So nothing but the extra data will have a gain of 10%. As proven below, further improvements will double this gain. Nowadays, dual-frequency multi-channel receivers become popular which allow a continuing satellite locking and data recording. The BIPM tracking schedule and the convention of the 3′ standby become meaningless. This CGGTTS convention is outdating.

The second short-point is that the data are recorded in integer numbers round off at 0.1 ns which accumulates with data processing steps. As we know that in precise and accurate T/F transfers, many corrections, such as the precise orbit, ionosphere and the Earth tides etc. are often less than 0.1ns, i.e. less than the 'round off' errors. In particular, for the future uses of carrier phase, 1 ps recording is necessary.

The third is that the epoch interval of CGGTTS is fixed to 16 minutes. Hence the observation epochs are not the same from one day to next. This is not a convenient practice compared with TW and PPP that are always measured and recorded on integer hours and on the same minute of everyday. The standard MJD of Circular T is on integer hour: 0h. A non-necessary interpolation error is then introduced.

Finally, the recording interval is fixed to 16 minutes. Is it optimal for T/F transfers with modern receivers? Why not varying intervals of 1′, 5′, 10′, 15′, 30′ or 60′ … as options to users according to the specifications of precision and data storing memory required ?

New GNSS systems are coming. To answer the new challenges, we need review the CGGTTS convention. Above we have first investigated the outdating points in CGGTTS and below we will discuss the possibilities to improve the actual version V02 and finally present our considerations toward a new CGGTTS convention, the NEW version, namely V03, is not only for the BIPM *UTC/TAI* computations but also for scientific and commercial purposes. The three, new and old, versions (V01, V02 and V03) can co-exist for different applications in the future.

II. CHARACTERS OF THE CONVENTION: CGGTTS V03

• First the V03 should be as same as possible as the present GGTTS V01 and CGGTTS V02 and compatible to the existing computation programs, e.g. in a Fortran code, it needs only to change the input format from FIX FORMAT to Free FORMAT (*);

• Use and record all the raw data in a tracking arc, i.e. if the

arc is of 16 minutes, all the measurements should be used and converted to the CGGTTS data;

• Optional data collecting intervals for different applications: e.g. 1, 5, 10, 15, 20, 30 and 60 minutes or other user requires. Variable data collecting and recording interval may be interesting for low level or commercial practices. For users interesting only in the long-term stability, a longer recording interval with a less storing memory is a better option. A user can select the best interval according to the specifications of his technical or computer memory etc. Data recording interval is one of the major issues discussed in sections IV, V and VI;

• Optional smoothing methods used in the tracking arcs;

• Allowable, as option, for all the codes, C1, P1, P2 etc.;

• Allowable, as option, for all the GNSS techniques;

• Allowable, as option, for carrier phase information.

III. DATA AND METHOD

A. Data

As numerical examples, we investigate in the paper the P3 data. Hereafter all the analysis is of P3. The standard procedure of Circular T computation is used. In the tables and plots, the solutions are named correspondingly: **V02 13/16** stands for the conventional CGGTTS V02 with tracking arc of 16 minutes of which only 13 minutes are recorded. Similarly, the new solutions are **V03 10/10, 16/16, 20/20, 30/30 and 60/60.** Here the numbers stand for the length of the tracking arcs in minutes, e.g. **20/20** stands for the 20′ arc with all the 20′ data measurements converted to CGGTTS V03. The data sets used are of *UTC* 1001 and *UTC* 1002 (January and February 2010). In order to obtain a reliable statistic result, we analyzed more than 10 short and long baselines coving the continents of Europe, America and Asia. Because the TW links were not very stable since last year, we depend mainly on the comparison with GPS PPP links. We use the Tsoft sub-menu U5 to carry out all the converting computation.

B. Method

The goal is to investigate the relation of the quality of the T/F transfers and the recorded interval length. We use the TW and PPP links as the references which are believed to have a super quality in u_A (uncertainty type A) than the P3 codes. We compare first the standard deviation σ of the Vondrak smoothing residuals in the link computation. Because the computation methods for V02 and V03 are identical and the only difference is the recording intervals, this comparison makes sense. The smaller the σ is, the better the duration of the corresponding interval. Secondly, we compare between the results of V02 and V03 with the TW and PPP. We compute the σ of the differences. It is expected σ2 (V03) < σ1 (V02). We then compute the gain: (σ2-σ1)/σ2. If the gain is bigger than 5%, we consider the gain is significant and the V03 as well as related parameters make sense. We investigate also difference between Comment View and All the View. We present the main statistic results in the plots and tables.

IV. RESULTS AND ANALYSIS

A. Comparison between the arcs 13′/16′ of V02 and V03

We first prove that the Tsoft V03 procedure produces the identical results as V02. Figure 2 illustrates the differences of them. The mean value is 0 ns. The standard deviation σ (of the two raw CGGTTS V02 and V03 without filtering) is ±0.2 ns. Some outliers are up to 2 ns. The differences come from mainly the noises in the raw measurement and how to process them. V03 uses different smoothing and round off at 0.001 ns.

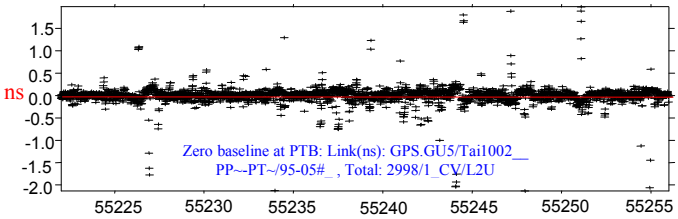

Figure 2. Differences between the V02 13/16 tracking arc link and the V03/U5 13/16 link with σ=±0.2 ns

Figure 3 illustrates the Tdev of an inner-Europe link CH-PTB (640 km). By the Tdev in the figure, we see a significant improve in the short terms until ½ day. Because all the conditions are the same, these gains obtained are thanks to the 19% extra data, i.e. 3 minutes over every 16 minutes.

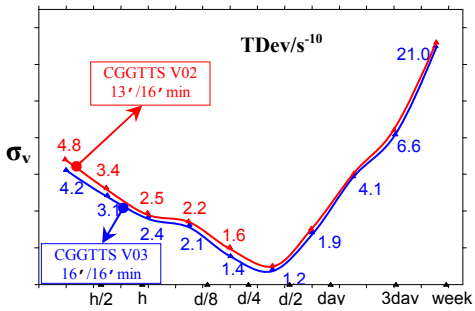

Figure 3. Comparison of Tdev for the link CH-PTB between the V02 13'/16' link (red/up) and the V03 16'/16' link (blue/down)

TABLE I. COMPARISONS OF THE STANDARD DEVIATION OF THE VONDRAK SMOOTHING RESIDUALS BETWEEN THE V02 13′/16′ TRACKING ARC LINKS AND THE V03/U5 16′/16′ LINKS (UNIT IN NS)

Link	Distances km	σ1 V02 13′/16′ /AV epochs	σ2 V03 16/′16′ /AV epochs	Gain (σ1-σ2)/σ1
CH-PTB	640	0.520/2983	0.453/2338	9%
KRIS-PTB	8300	0.629/2840	0.610/2906	3%
NICT-PTB	9100	0.670/3062	0.657/2929	2%
OP-PTB	700	0.764/2124	0.687/2730	10%
OR-PTB	460	0.546/3050	0.516/2933	6%
SP-PTB	1200	0.536/3070	0.501/2943	7%
TL-PTB	9100	0.650/3059	0.607/2939	7%
USNO-PTB	6552	0.611/3080	0.599/2919	2%
KRIS-NICT	1158	0.598/2853	0.548/2916	8%
TL-NICT	2117	0.637/3081	0.575/2995	10%
Average	**3933**	**0.616/2920**	**0.575/2855**	**6.7%**

In the standard *UTC* procedure, we use the Vondrak smoothing to filter the measurement noises. The standard deviation (σ) demonstrates the noises level of a tracking arcs: for V02 the 13′/16′ and for V03 16′/16′. Table I gives the comparisons of the σ for 10 baselines. Most of them are the *UTC* links equipped with HM clocks. For the link CH-PTB, the σ of the residuals is 0.520 and 0.453 ns. We have the gain: (0.520-0.453)/0.520=9%; Similar for TL-PTB (9100 km), we have the σ 0.650 and 0.607 ns. The gain is 7%. Table I shows

that, in all the cases there is a gain, on average 6.7%.

Table II takes the GPS PPP link solution as the reference and gives the results of the comparisons between the V02 and V03 links. Again, in all the cases there is a gain and on average the gain is 6.4%, almost as same as in Table I.

We conclude a gain of 6.6% on average in the V03 format due to the 3 minutes' redundant measurement data.

TABLE II. COMPARISONS OF THE STANDARD DEVIATION OF THE DIFFERENCE BETWEEN THE V02 13′/16′ TRACKING ARC LINKS AND THE V03/U5 16′/16′ LINKS VS. THE PPP LINKS (UNIT IN NS)

Link	Distances km	σ3 V02 13′/16′	σ4 V03 16′/16′	Gain (σ3-σ4)/σ3

Average	**3933**	**0.694**	**0.650**	**6.4%**

B. *Comparison between the arcs of V02 13′/16′ and V03 20′/20′*

The length of the tracking arc of 13′/16′ is outdated. The major receivers now used in practices are of the dual-frequency-multi-channel. By testing the 20′, 30′ and 60′, we try to find an optimal tracking length for precise time transfer. We use the same method as above.

TABLE III. COMPARISONS OF THE STANDARD DEVIATION OF THE VONDRAK SMOOTHING RESIDUALS BETWEEN THE V02 13′/16′ TRACKING ARC LINKS AND THE V03/U5 20′/20′ LINKS (UNIT IN NS)

TL-NICT	2117	0.769	0.684	11%
Average	**3933**	**0.694**	**0.621**	**10.5%**

Table III is the comparisons of the σ between the V02 and V03 links. All the gains are positive, 12.2% on average. Table IV makes the comparisons using GPS PPP as reference. Again, there is a gain in all the cases, 10.5% on average. Increasing the tracking length from 13′/16′ to 20′/20′, a gain of 11% is obtained in u_A. Meanwhile the size of the data file decreases more than 20%.

C. *Comparison between the arcs of V02 13′/16′ and V03 30′/30′*

We continue to increase the length of the tracking arc up to 30 minutes using the same method. Table V presents a gain of 18.7% on average. Table VI makes the comparisons to GPS PPP. Again, there is a gain of 15.9% on average. Increasing the length of tracking arc from 13′/16′ to 30′/30′ makes a gain of 17% in u_A on average. Meanwhile the size of the V03 data file is only half of that of V02.

D. *Comparison between the arcs of V02 13′/16′ and V03 60′/60′*

TABLE VII. COMPARISONS OF THE STANDARD DEVIATION OF THE VONDRAK SMOOTHING RESIDUALS BETWEEN THE V02 13′/16′ TRACKING ARC LINKS AND THE V03/U5 60′/60′ LINKS (UNIT IN NS)

Link	Distances km	σ1 V02 13′/16′ /AV epochs	σ2 V03 60′/60′ /AV epochs	Gain (σ1-σ2)/σ1
CH-PTB	640	0.497/3070	0.321/731	34%
KRIS-PTB	8300	0.629/2840	0.537/579	15%
NICT-PTB	9100	0.670/3062	0.585/736	13%
OP-PTB	700	0.764/2124	0.514/679	33%
OR-PTB	460	0.546/3050	0.419/733	23%
SP-PTB	1200	0.536/3070	0.380/735	29%
TL-PTB	9100	0.650/3059	0.498/738	23%
USNO-PTB	6552	0.611/3080	0.465/718	34%
KRIS-NICT	1158	0.598/2853	0.450/730	25%
TL-NICT	2117	0.637/3081	0.440/739	31%
Average	**3933**	**0.616/2920**	**0.461/712**	**26.6%**

We increase the length of the tracking arc up to 60 minutes. Table VII and VIII show the gains of 26.6% and 18.0% correspondingly. The difference of the gains becomes important. The **σ** in Table VII is a self-smoothing. When the tracking arc increases longer than half hour, this **σ** would become too optimism. On the other side, the PPP is not errorless. The u_A of PPP is about 0.3 ns. So the **σ** in Table VIII would be too conservative. Therefore the real gain should be between the two estimations, i.e. 18.0% and 26.6%. We take the average 22% as the gain of increasing the tracking length from 13′/16′ to 60′/60′. Meanwhile the size of the V03 data file is only a fourth of that of V02. Longer length tracking arcs implies smaller size data collection.

TABLE VIII. COMPARISONS OF THE STANDARD DEVIATION OF THE DIFFERENCE BETWEEN THE V02 13′/16′ TRACKING ARC INKS AND THE V03/U5 60′/60′ LINKS VS. THE PPP LINKS (UNIT IN NS)

Link	Distances km	σ3 V02 13′/16′	σ4 V03 60′/60′	Gain (σ3-σ4)/σ3

Average	**3933**	**0.694**	**0.569**	**18.0%**

E. Gains as a function of length of the tracking arcs

The gain is a function of the tracking length or the recording interval. As the length increases, the gain increases. We make in this section a résumé using the averaged gains in the above tables.

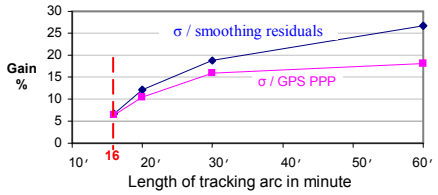

Figure 4. Gains in percentage as a function of the tracking arc length

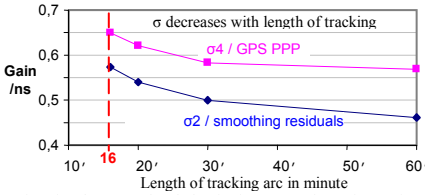

Figure 5. Gains in the standard deviation as a function of tracking length

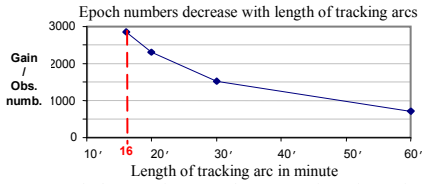

Figure 6. Decrease of observation numbers as a function of tracking length

Figure 4 illustrates the total gains in percentage obtained by increasing the tracking length. From 16′ to 20′, the gain increases more rapid than that between 20′ and 30′. The latter, in turn, increases more rapidly than between 30′ and 60′. Similar phenomena are observed in the Figure 5 where the gains presented with the decrease of the stability of short terms. Meanwhile, as the gain increases, the size of the data decreases by a factor of 4 (Figure 6). However, the tendencies displayed in the figures demonstrate that longer than 1 hour of the tracking arc, the speed of quality improving slows down.

V. TWO REMARKS

A. Comparison with TW

We used also the TW time links as the reference to estimate the gains of V03 against V02. Unfortunately the quality of the European-American TW links degrades since last year. We use then an Asia TW link: KRIS-NICT 1002. The distance is 1158 km. The sigma is only 0.131 ns by the *UTC* standard procedure. The standard deviation of the differences between TW and GPS PPP links is 0.333 ns.

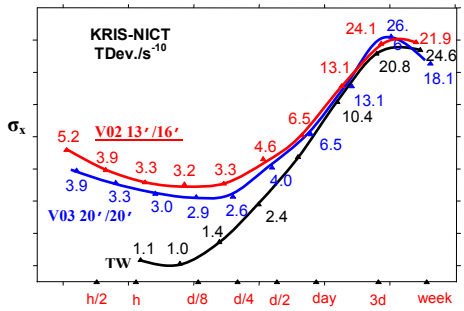

Figure 7. Tdev of the KRIS-NICT baseline: the V02 13′/16′ tracking arc inks and that of the V03 20′/20′ links vs. the TW link

Figure 7 illustrates the time stabilities of the three links: the link of V02 13′/16′, the link of V03 20′/20′ and the TW link. Obviously the TW link is the most stable. The Tdev. of V03 is well below that of the V02 until the averaging time of half day. The three converge after.

We use the same method to compute the gains as did with GPS PPP. The result is listed in Table IX. The total number of the TW measurements is 705. The recording interval is one hour. Therefore for the comparison of V03 60′/60′, it is a point to point comparison. The gains for the lengths of tracking arcs of 16′, 20′, 30′ and 60′ are 7%, 11%, 17% and 21%. The average is 13.9%.

Its comparisons to GPS PPP have been listed in Tables II, IV, VI and VIII. The gains are respectively 8%, 12%, 18% and 14%. The average is 13%. The gains given by the two references of TW and GPS PPP agree with each other.

TABLE IX. COMPARISONS OF STANDARD DEVIATION OF THE DIFFERENCE BETWEEN THE V02 13′/16′ TRACKING ARC KRIS-NICT LINK AND THE V03 16′/16′, 20′/20′, 30′/30′ AND 60′/60′ LINKS VS. THE TW LINK (UNIT IN NS)

σ/V02 13′/16′	σ/V03 16′/16′	σ/V03 20′/20′	σ/V03 30′/30′	σ/V03 60′/60′	Mean.
0.788	0.737	0.701	0.652	0.623	
-	6.5%	11.0%	17.3%	20.9%	13.9%

By conclusion, there is a significant gain in V03 vs. V02, by increase the length of the tracking arc from 20′ to 60′, we have a gain of 14% in u_A on average. However, increasing the recording intervals will decrease the short term details of the

clock behaviors. A user should make the best choices according to the specification of his applications.

B. *Gain with GPS P3 Comment View (CV)*

So far, we discussed only the standard *UTC* AV (All in View) time links. In fact, the CV links used widely in lower level practices have been also analyzed. General speaking, there were gains too: the CV gain is slightly better than that of the AV in short baselines but worse in long baselines.

C. *The reachable uncertainty u_A*

Taking always the P3 as example, the other codes should have the same result. The GPS P3 All in View technique is used for *UTC* time transfer since 2006. The CGGTTS V02 data are used for the computation of the GPS P3 links. The uncertainty type A (u_A) is 0.7 ns as listed in the section 6 of the Circular T.

Above we have theoretically discussed the gain of full use the data 16 minutes is 10%. This implies the u_A(P3) may reduce to 0.63 ns. Taking into account of round off and increasing the tracking length, we can predict the u_A of 0.6 ns for P3 is reachable.

Now we estimate if the V03 is applied, what we can gain. If disregard the lengths of the tracking arcs, the average values of all the σ and gains in the Tables I ~ VIII are listed in Table X. Averagely, the σ(P3/V02)=0.655 ns, knowing that the nominal u_A of GPS P3 is u_A(P3/V02)=0.7 ns; the σ(P3/V03)=0.563 ns. Hence, 0.6 ns is safely reachable in CGGTTS V03 convention. This can be estimated in another way. Because the averaged gain is 14.4% (Table X) and u_A(P3/V02)=0.7 ns, we have u_A(P3/V03)=0.7ns·(1-14.4%)=0.598 ns.

0.6 ns is still a conservative estimation. Because: 1) all the estimations above were based on that the GPS PPP which is errorless; 2) The average gain of 14.4% is average of all the tested lengths of tracking arcs (data recording interval). As suggested to the V03 for *UTC* time transfer, the lengths are 30′ or 60′. The average gain will be 20% and the related stability is 0.529 ns. Same as above, we have therefore the true u_A(P3/V03) equals $\sqrt{[0.529^2 - u_A^2(\text{PPP})]}$. If we use the values 0.3 ns, 0.2 ns and 0.1 ns to replace the term u_A^2(PPP), we will obtain the u_A(P3/V03) becomes respectively 0.432 ns, 0.490 ns and 0.519 ns.

TABLE X. AVERAGE OF THE SIGMA AND GAIN: (UNIT IN NS)

Tables	Distances km	σ /ns V02 13′/16′	σ /ns V03 16′/20′/30′/60′	Gain
I,III,V,IIV	3933	0.616	0.520	16.0%
II,IV,VI,IIIV	3933	0.694	0.606	12.7%
Average		**0.655**	**0.563**	**14.4%**

VI. TOWARD A CCTF CGGTTS VERSION 03 ?

Section II gives the new characters of the suggested CCTF CGGTTS GNSS data recording format convention version 03. The Annex is an example of the version 03. It is the measurement recording of one hour. The options are given in the **COMMENTS** line: the data recording interval is 1200 seconds (20′), the output data are of P3 without carrier phase smoothing. The terms **REFSV, SRSV, SRGPS** and **DSG** are in 0.01 ns but the main term **REFGPS** is in 0.001 ns.

We tested also to change the terms ELV AZTH in 0.01 degree but this made only several ps differences in the REFGPS in the file of LabYYMM.G1I. It seems to makes no sense to record the ELV AZTH in 0.01 degree.

VII. SUMMARY

- We estimated the u_A and the gains obtained using σ of the residuals of Vondrak smoothing (Tables I, III, V, VII) and that of the PPP as reference (Tables II, IV, VI, VIII). Both give almost the same result for intervals shorter than a hour;
- It seems that shorter baselines have bigger gains than longer baselines, e.g. in Table VIII, the average gain of inter-continental baselines (> 6500 km) is 13% while that of the inner-continental baselines (< 2200 km) is 21%; further investigation needed;
- Longer the tracking length, bigger the gains and less the size of storing memory: the gains for 16′, 20′, 30′ and 60′ arcs are respectively 6.6%, 11.4%, 17.3% and 22.3%. For *UTC* time transfer, the data recording interval should not be longer than 1 hour, knowing that the intervals of TW are 1 or 2 hours; It is interesting to notice that a bigger size of data recording would not guaranty a better quality of T/F transfers. The wave length of the filter makes strong influence on the short term uncertainty (< 1 day). However, longer tracking arc implies more tracking data cut off in a passage of satellite. Although the cut off data are of low elevation satellites and it seems this dose not damage the data quality. In fact, this paper proves an improvement of the quality by a reasonable tracking length. Further study should be made on this point;
- The average of total gains is 14.4%. This may be considered as the gain of V03 with respect to V02;
- If V03 (20′/20′) is used in *UTC* computation, the u_A of GPS P3 may be reduced from 0.7 ns to 0.6 ns;
- If V03 is used, the size of the data storing memory will be considerably reduced depending on the length of tracking arc;
- As V02 dose not replace the V01 (we have still V01 data for *UTC* and other applications in T/F transfers). V01 and V02 will co-exist with V03 for as long as needed.

This study concludes:

- The V03 data recording interval may be variable. For *UTC* time transfer, 1800 seconds or 30 minutes is suggested. Increasing properly the data recording interval suggests improving T/F quality and decreasing the size of storing memory. GNSS P code T/F transfers will benefit of a gain of 14.4% on average thanks to this updating;
- It makes sense to convert the tracking data round off 0.001 ns for the related terms;

- As an option, the output C and/or P codes may be smoothed using the carrier phase information;
- Some flexible tolerances or flags may be applicable to allow using more users;
- It is suggested to the CCTF CGGTTS working group to investigate this issue and to pass to the new convention V03.

Finally, it is important to point out that all these suggested modifications are of once for ever with limited software work. Not any investment is required. The gain in uncertainty is based on fully use the potential in the raw measurement data.

***Abstract*— Accurate GNSS (Global Navigation Satellite System) time transfer needs accurate satellite orbit information. Since Nov. 2009, the GLONASS time transfer is introduced in *UTC* generation. The precise and timely GLONASS orbit information is indispensable for Circular T computation. In this paper, we compare the GLONASS orbits produced by different analysis centers. We study the differences of the products, their influences on the common view time transfers and the delays of the availability. The products to investigate are the rapid and final sp3 ephemeredes produced by ESA (Europe Space Agency) and IAC (Information-Analytical Center). IAC belongs to Russia Federal Space Agency. Its primary goal is to analyze the information on the satellite navigation based on the global systems, mainly the GLONASS. The delay of the IAC sp3 rapid products is 24-28 hours. This satisfies the rhythm of the BIPM monthly Circular T computation, of which the deadline of data collection is the 5th of every month. Since Nov. 2010, the BIPM started to use the IAC ephemeredes to compute the GLONASS satellite orbits for *UTC* time transfer. At present the IAC product is the most suitable for the *UTC* GLONASS time link computations.**

I. INTRODUCTION

GLONASS (GLN for short) time transfer was introduced for the first time in *UTC* generation in Nov. 2009 in circular T 267 [1,2,3]. Precise and timely issued GLONASS orbit information is indispensable for the BIPM monthly Circular T computation. There are different GLONASS orbits products supplied by the analysis centers: ESA and IAC (Information-Analytical Center of the Russia Federal Space Agency) [4]. We should make a choice in favor of the *UTC* time transfers.

There are two major indicators for making the choice:

(1) The accuracy and precision of the ephemerid products, including the biases if there are. The quality of the corrections of the on board satellite clocks etc. Their uncertainties in view of the common view (CV) time transfer;

(2) The delay of the issue of these products. Because the BIPM Circular T is a monthly publication, the deadline of data collection is the 5th of a month. The ephemerid products should be available by the deadline. Usually there are the so called rapid and final products. The later is too late for the Circular T computation. However it can be used in this study to estimate the quality of the rapid products.

We study the differences between different SP3 ephemerid products supplied by ESA and IAC.

Most of GNSS users are familiar with the ESA. We give here only a quick introduction on the IAC. More information can be found in its official English web site [4].

IAC belongs to Russia Federal Space Agency. Its primary goal is to analyze the information concerning the satellite navigation based on the global systems GLONASS (Russian Federation), GPS (USA) and GALILEO (European Community). A basis of a web site is the results of its work. It contains the information concerning the GLN and GPS current orbital constellations, Earth maps of the current and daily navigation availabilities, results of the GNSS navigation, fields monitoring in Moscow area in a real-time mode and a number of the other data, cf. Figure 1.

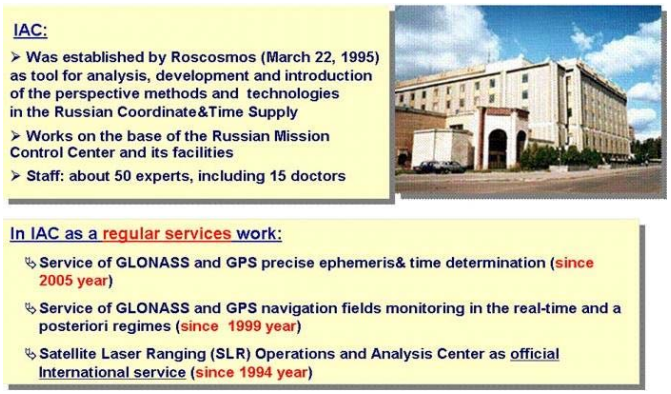

Figure 1. The IAC (Information-Analytical Center) and its missions after http://www.glonass-ianc.rsa.ru/pls/htmldb/f?p=202:1:2253948845654375

IAC supports data archiving and distribution for the Russian and world communities. The main objectives of the archive and FTP-site are to store the GNSS, space geodesy and geodynamics related data and products in a data archive and to disseminate these data and information in a timely manner to Russian and world users.

The IAC archives and distributes the results of the GNSS and SLR data analyzed in IAC and other analysis centers, mainly GLN, GPS and SLR measurements as well as the related products.

The IAC ftp archive consists of 10 head catalogues containing the information about: **MCC**, the results of the IAC work and analysis, including the precise ephemeris and time products for GLN and GPS, daily and monthly bulletins concerning onboard ephemeris and time accuracy, navigation fields quality based on the global network data and others; the **IGS** (International GNSS Service); **IERS** (International Earth Rotation Service); **ILRS** (International Laser Ranging Service); **BIPM** (Bureau International des Poids et Mesures); **NAVCEN**, the official information concerning GPS constellation status from US Coast Guard Navigation Center; **FAF**, the information on indexes of solar and geomagnetic activity; The published official documents, reports and standards of the Russian and international services.

The IAC broadcast navigation information is also indispensable for the precise orbit computations. It can be found in ftp://ftp.glonass-iac.ru/MCC/BRDC/, which however, according to its header, is not an independent product but edited based on all the available IGS broadcast data.

The products supplied by the IAC that we investigated are the rapid and final sp3 ephemerides, which are used to analyze the information on the GLN satellite navigation based on the global systems. The delay of the IAC sp3 rapid products is 24-28 hours vs. a delay of a week by the ESA products.

The timely rapid products of the IAC satisfies the rhythm of the BIPM monthly Circular T production, of which the deadline of the raw data collection of the time links, the clocks and the orbit and ionosphere data is the 5th of every month. As proven in the following sections, the quality of the IAC products is comparable with that of the ESA. Since Nov. 2010, the BIPM started to use the IAC ephemerides to compute the GLN satellite orbits for *UTC* time transfer [2,5,6].

As of this writing, the IAC products are the most suitable for the *UTC* GLN time link computations.

Hereafter are some detailed discussions. In section II, we give the method used in this study and in the sections III-VII we present the results of different numerical tests. Sections VIII and IX are discussion and conclusion.

II. DATA AND METHOD

A. The test data

The main purpose of this paper is to make a comparison in view of *UTC* computation between the products of ESA and IAC:

- different products
- the quality of the products
- availability and rapidity of the products

ESA has not the rapid product but only the final sp3 product. IAC have the both. We have therefore three different products to compare: ESA final sp3, IAC rapid and final sp3. The satellite clock correction is also a topic to study. We can then form four differences:

- between IAC Rapid – IAC Final
- between IAC Rapid – ESA Final
- between IAC Final – ESA Final
- between with and without clock corrections

The time transfer data used is the GLN C/A UTC1009 collected from AOS of Poland, NIS of Egypt, OP of France, PTB of Germany, SU of Russia and UME of Turkey.

Main attention of the numerical analysis is paid at the GLN *UTC* time link SU-PTB. The preliminary conclusion obtained by the baseline SU-PTB was then to be verified with other *UTC* baselines.

B. Method

We use two methods to make the comparisons:

In Method 1, we compare time links computed with the three ephemeredes and we use standard deviation σ of the Vondrak smoothing residuals and Time deviation σ_x of the links as indicators of the quality: smaller the σ and σ_x, the better the ephemeredes. Analysis results are given in sections III-V. In Section VI, we demonstrate the effects of the satellite clock corrections. More results are given in the Annex 1-3 of the reference [5].

In Method 2, we compare the REFSYS values for a single laboratory using different ephemeredes. We estimate how well the quality of the related ephemeredes by computing the σ and σ_x of each difference. This is shown in section VII. Two laboratories in two distant geographic locations are used to provide a variety in geometric configurations: OP in Europe and SG in Asia.

III. TIME LINK COMPARISON USING ESA FINAL AND IAC SP3 FINAL EPHEMEREDES

We first compare the *UTC* time links between SU and PTB and their Tdev obtained using the ESA final (Figure 2) and IAC final (Figure 3) sp3 ephemeredes. Figure 4 illustrates the differences of the two links. The total compared points are 2574 and the σ of the differences is 0.081 ns, which is well below the measurement noise, about 1 ns.

Table I lists the statistics of other 5 baselines. The σ of the differences varies from 0.081 to 0.379 ns. The biggest is the link SG-PTB. SG locates in Singapore. SG-PTB is the longest baseline (6300 km) in this test. The related measurement noise is up to 2 ns. The 4 days' data missing may also explain the big σ. In general, the differences between the GLN time links using the ESA and IAC final sp3 is acceptable vs. their measurement uncertainties.

TABLE I. *UTC* TIME LINK DIFFERENCES USING ESA FINAL AND IAC FINAL SP3 EPHEMEREDES

Baseline	N	σ/ns
AOSPTB	2510	0.200
NISPTB	1264	0.174
OPPTB	2525	0.109
SGPTB	1446	0.379
SUPTB	2574	0.081
UMEPTB	2315	0.148

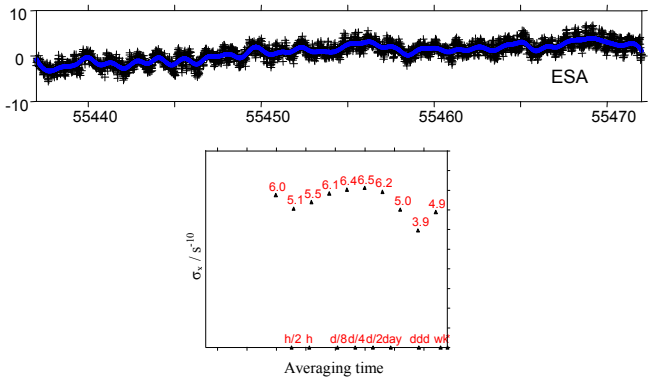

Figure 2. SU-PTB Time link and Tdev using ESA final ephemerid / ns (UTC1009, total CV 3098, smoothing σ 1.068 ns)

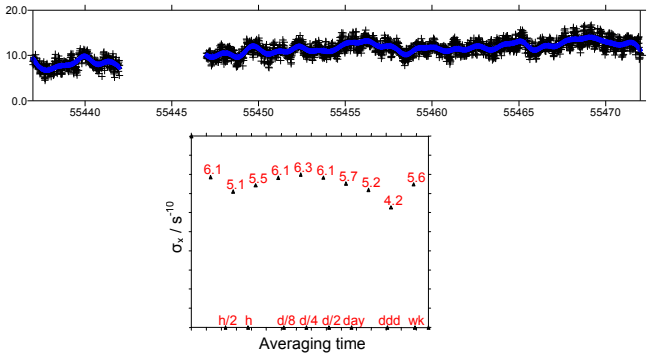

Figure 3. SU-PTB Time link and Tdev using IAC final ephemerid with 4 days' data missing /ns (UTC1009, total CV 2650, smoothing σ 1.055 ns)

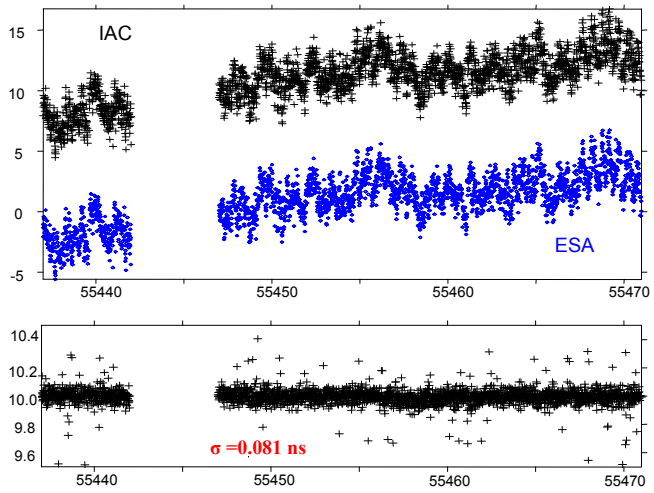

Figure 4. Differences between SU-PTB Time link using ESA and IAC final ephemerid /ns (UTC1009, total points 2574, σ of difference 0.081 ns)

IV. TIME LINK COMPARISON USING ESA FINAL AND IAC RAPID SP3 PRODUCTS

On the 5th every month, we start to compute the Circular T. The final products of either ESA or IAC are too late for the *UTC* computation. Our main concern is then the 2-day delay rapid product of IAC. In this section, comparisons are made between the ESA final and the IAC rapid sp3 ephemeredes. We first compare the *UTC* time links between SU and PTB and their TDev obtained using the ESA final and IAC rapid sp3 (Figure 5) ephemeredes. Figure 6 illustrates the differences of the two results. The total compared points are 3011 and the σ of the differences is 0.089 ns, which is well below the measurement noise and agrees with the statistic result between the final products (Figure 4).

Table II lists the statistics of other 5 baselines. The σ of the differences varies from 0.089 to 0.186 ns. The biggest is still the link SG-PTB due to the long distance. In general, the differences between the GLN time links using the ESA final and IAC rapid sp3 is acceptable vs. their measurement uncertainties. The difference between them is negligible for the purpose of the GLN CV time transfer.

TABLE II. UTC TIME LINK COMPARISON USING ESA FINAL AND IAC RAPID PRODUCTS

Baseline	N	σ/ns
AOSPTB	2942	0.182
NISPTB	1667	0.134
OPPTB	2961	0.125
SGPTB	1676	0.186
SUPTB	3011	0.089
UMEPTB	2734	0.135

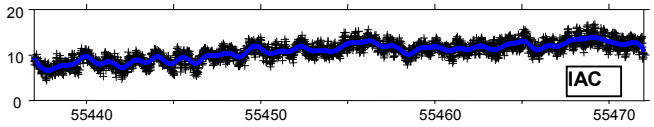

Figure 5. SU-PTB Time link using IAC rapid ephemerid /ns (UTC1009, total CV 3098, smoothing σ 1.066 ns)

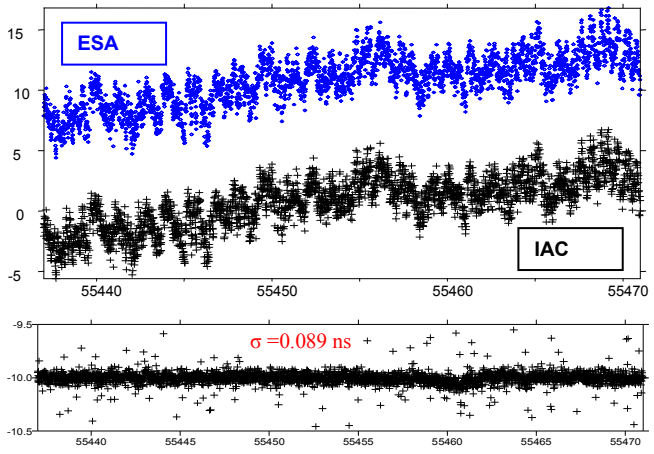

Figure 6. Differences between SU-PTB Time link using ESA final and IAC rapid ephemerid /ns (UTC1009, total points 3011, σ of difference 0.089 ns)

V. TIME LINK COMPARISON USING IAC FINAL AND RAPID

In last section, we conclude the in view of the CV links, the IAC rapid sp3 gives no considerable difference vs. the ESA final one. We now make a comparison within the IAC products between the final and rapid sp3 ephemeredes.

We first compare the *UTC* time links between SU and PTB. Figure 7 illustrates the differences of the two results. The IAC final, as pointed out in Figure 3 and 4, has 4-days hole. The total compared points are 2574 and the σ of the differences is 0.095 ns, which is well below the measurement noise and agrees with the above statistic results.

Table III lists the statistics of other 5 baselines. The σ of the differences varies from 0.095 to 0.377 ns. The biggest is still the link SG-PTB due to the long distance and data missing. In general, the difference is acceptable vs. the measurement uncertainties.

TABLE III. TIME LINK COMPARISON BETWEEN IAC FINAL AND RAPID

Baseline	N	σ/ns
AOSPTB	2510	0.084
NISPTB	1264	0.126
OPPTB	2525	0.100
SGPTB	1446	0.377
SUPTB	2574	0.095
UMEPTB	2315	0.132

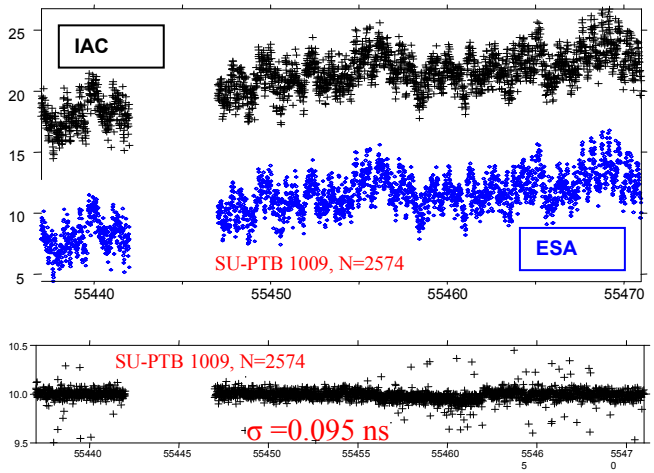

Figure 7. Differences between SU-PTB Time link using IAC rapid and final ephemerid /ns (UTC1009, total points 2574, σ of difference 0.095 ns)

VI. DIFFERENCES BETWEEN ESA AND IAC WITH OR WITHOUT SATELLITE CLOCK CORRECTIONS

In above sections, we did not use the satellite clock corrections given in the sp3 data files. The conclusions drawn from these analysis hold also for the results where the clock corrections are used. This is because, in the CV links, especially for the short or middle baselines, the clock effects are almost cancelled.

Figure 8 illustrates the differences of which the σ is 0.089 ns, as same as the σ obtained among different comparisons in the above sections. The residual influences of the satellite clock corrections are covered by the measurement noises.

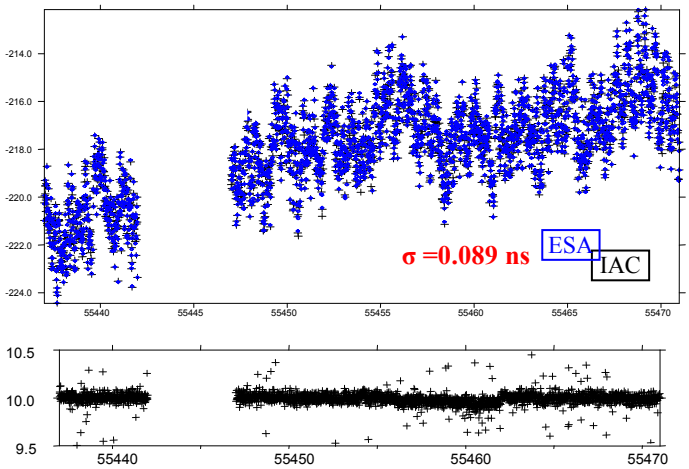

Figure 8. Differences between ESA and IAC final sp3 ephemeredes with or without clock corrections /ns (UTC1009, total points compared 2574, σ of difference 0.089 ns)

VII. COMPARISON OF REFSYS VALUES USING FINAL AND RAPID SP3 EPHEMEREDES FROM ESA AND IAC

In sections III-VI, we analyzed the time links. In this section, we study the influence of the different ephemeredes on the REFSYS values which are the differences between the ground clock and the satellite clock, the satellite time reference system. This is a zero baseline comparison which gives directly the differences between the ephemeredes without the influences of the distance etc.

The comparison results are illustrated in Figures 9, 10 and 11. There are 3 plots. In each figure: the up plot is the difference in ns and down-left plot is the Modified Allan deviation and the down-right the Time deviation.

The comparisons are made between:

- REFSYS differences between ESA and IAC final: Figure 9
- REFSYS differences between ESA and IAC rapid: Figure 10
- REFSYS differences between IAC final and rapid: Figure 11

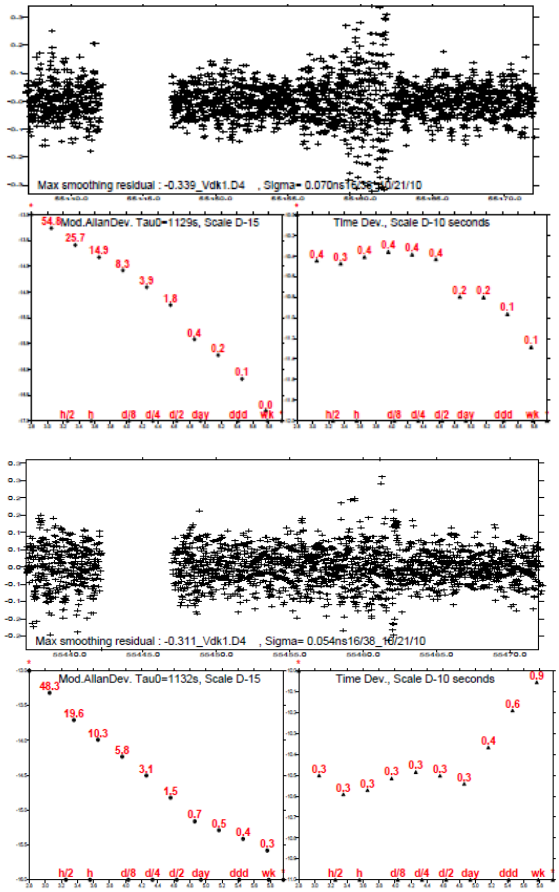

Figure 9. REFSYS differences between ESA and IAC final for SG (up) and OP (down) /ns

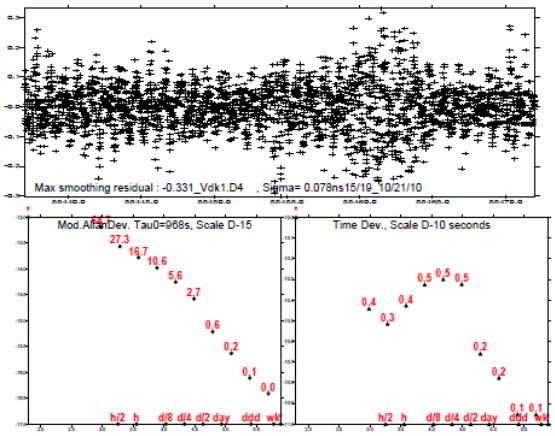

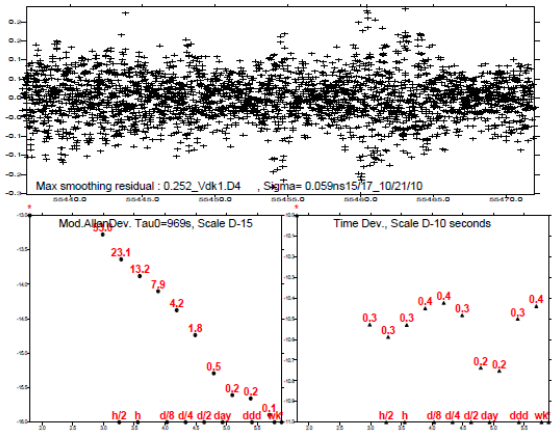

Figure 10. REFSYS differences between ESA and IAC rapid for SG (up) and OP (down) /ns

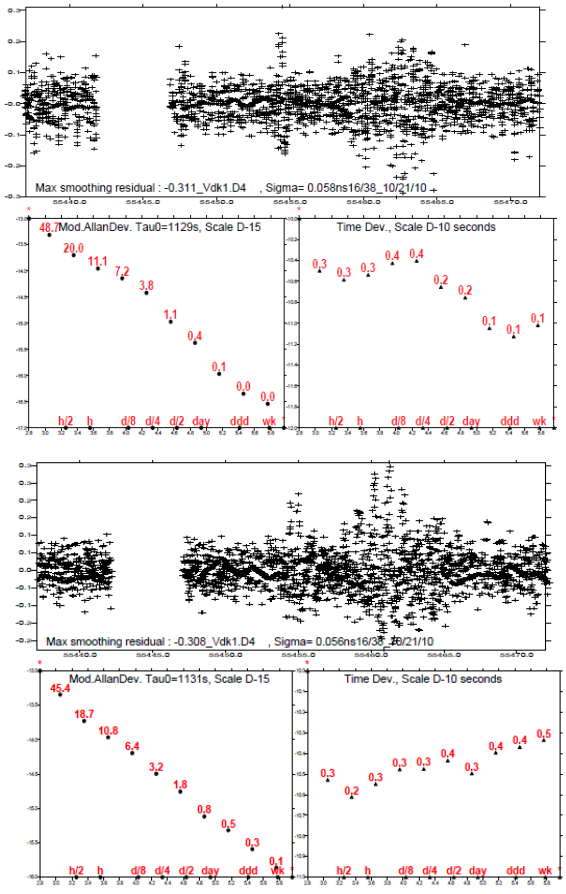

Figure 11. REFSYS differences between IAC final and rapid for SG (up) and OP (down) /ns

TABLE IV. STANDARD DEVIATION OF THE DIFFERENCES OF REFSYS USING ESA/IAC FINAL AND RAPID SP3 EPHEMEREDES

Difference between	SG/ns	OP/ns
ESA final - IAC final	0.070	0.054
EAS final - IAC rapid	0.078	0.059
IAC final – IAC rapid	0.058	0.056

Table IV gathers the statistic results shown in the Figures 9, 10 and 11. The σ varies between 0.05 ns to 0.08 ns. The differences are therefore negligible with respect to the measurement noises.

VIII. DISCUSSION

Method 1 shows that the σ and the first point of Tdev changes very little (1-2%) when using the three different ephemeredes. No significant discrepancies are found between these three products.

Method 2 shows that the three ephemeredes differ from each other less than 0.1 ns in the REFSYS values. In Table IV, the values for the three differences for both laboratories, SG and OP, are similar hence the three ephemeredes are expected to be of similar quality.

The noise level of the GLN C/A code CV time links is about 1 ns [2,6]. The u_A value for CitrT is 1.5 ns. As the difference of the comparisons is very small compared to u_A, we can consider the three products as nearly equivalent. However, we consider that IAC rapid is the best taking into account that it is available more timely than the other ones.

In addition, in Section VI we compared also the CV links with and without clock corrections. The differences due to the clock corrections are less than 0.1 ns. Hardly to say it is a gain by applying the clock corrections. However, we can always use the clock corrections expecting the quality being increased afterwards. Precise clock is the base of the GNSS All in View time transfer. Further study is undertaking at BIPM to use the AV for GLN time transfer.

As the quality of IAC rapid and final are as same as that of ESA, we will use IAC for UTC computation and keep ESA as back up.

IX. CONCLUSION

Since Nov. 2009, the GLONASS time transfer is introduced in *UTC* generation.

Accurate GLN time transfer for *UTC* computation needs accurate satellite orbit information. At present there are available the EAS final and the IAC rapid and final sp3 ephemerid products. Both of the final products are not timely issued for the monthly *UTC* computation. With a 2 day delay, the IAC rapid ephemerid is the only choice.

In this paper, we carefully compared the differences of the IAC rapid products with the final products which are a priori more accurate and precise than the rapid one.

We conclude that, in view of the *UTC* CV time links, the differences between these products and their influences on the CV time transfers are of the order of 0.1 ns which is negligible compared with the measurement noise of 1 ns about.

We should use the IAC rapid sp3 products for *UTC* computation and use the ESA ones as backup.

***Abstract*—In this paper we described the development and the characterization of a 578 nm laser source to be the clock laser for an Ytterbium Lattice Optical clock. Two indipendent laser sources have been realized and the characterization of the stability with a beat note technique is presented.**

I. INTRODUCTION

A yellow laser (λ = 578 nm) to be used for the interrogation of the $^1S_0 \leftarrow {}^3P_0$ clock transition in cold ytterbium atoms [1] was realized and characterized. In Figure 1 we report for convenience the relevant transitions for Ytterbium: the two cooling transitions at 399 nm and 556 nm and the clock transition at 578 nm. The yellow light is generated by frequency sum in a waveguide non-linear crystal of a 1319 nm Nd:YAG laser and a 1030 nm Yb doped fiber laser [2,3]. Two independent, ultrastable lasers are obtained from the same light source in a setup with two Fabry-Pérot cavities.

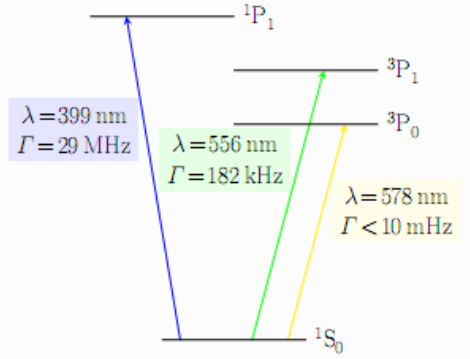

Figure 1. Ytterbium laser cooling and laser clock transitions

II. SUM FREQUENCY GENERATION

The yellow laser is obtained by sum frequency generation of two infrared laser sources (1030 nm and 1319 nm).
The non-linear crystal is a waveguide, magnesium-doped, periodically poled lithium niobate (PPLN) device and works in single pass. Infrared light of both lasers is delivered to the crystal through a polarization-maintaining fiber coupler (y-shaped). The output of the coupler is a bare fiber, aligned very close to the input face of the crystal to couple the light into one of the waveguide channels (the distance is of the order of 1 μm). The crystal is put on a translator to easily align the fiber with the working waveguide channel. In Figure 2 the optical bench scheme for the Sum Frequency Generation is shown.

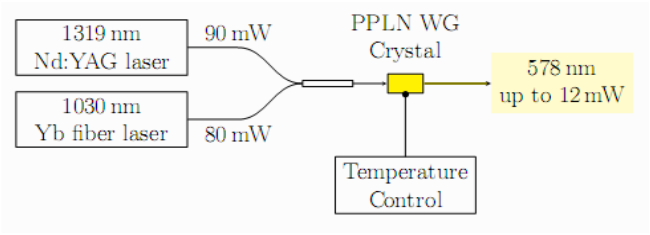

Figure 2. Scheme of the 578 nm laser source Sum Frequency Generation

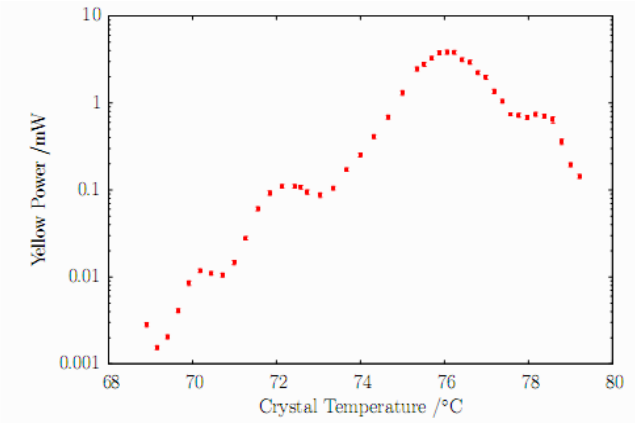

Figure 3. Yellow laser output power vs nonlinear crystal temperature.

The output power is maximized tuning the temperature of the crystal. The power shows a diffraction-like behavior around the phase-matching temperature found at ~76 ◦C, as shown in figure 3. We have generated up to 12 mW of light at 578 nm. Unfortunately the crystal seems to suffer some

This work is supported by Regione Piemonte (YTRO project)

degradation and the maximum power is decreasing slowly. The time instability of the laser intensity is reported in Figure 4. For time intervals up to 100 s, the laser intensity instability is less that 1×10^{-3}.

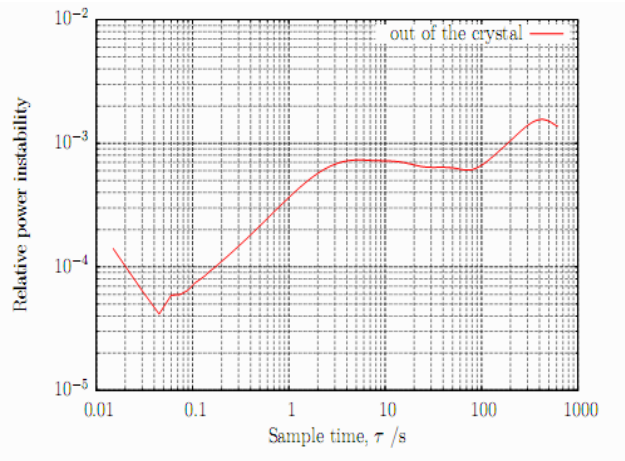

Figure 4. Yellow laser output power temporal stability.

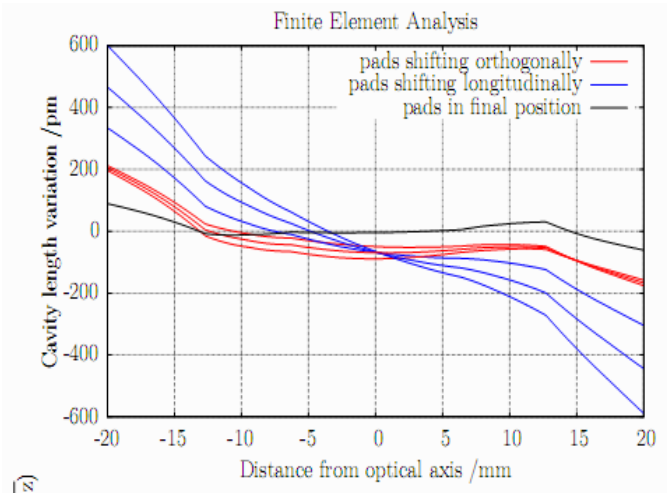

Figure 5. Finite Element Analysis shows a cavity length sensitivity to vibrations of less than 2 pm/g , being g the gravity acceleration.

III. TWO ULTRASTABLE CAVITIES

A couple of ultrastable Fabry-Pérot cavities are used as references to independently stabilize the frequency of the clock lasers. The two cavities are completely made of Corning Ultra Low Expansion Glass (ULE) with a free spectral range of $\Delta\nu_{FSR}$ = 1.5 GHz and a finesse of F1 = 151 000 ± 1000 and F2 = 224 000 ± 4000 respectively, measured with a cavity ring-down experiment.

The ULE spacers are notched, held horizontally and supported by four Viton pads on an aluminum structure. We have performed a finite element analysis to investigate the elastic deformation of the Fabry-Pérot cavity. The final position of the four pads was chosen to minimize the variation of the distance between the two mirrors due to the gravitational acceleration (the cavity is said to be supported at the Airy points).

Each cavity is held in a vacuum chamber (pressure $<2\times10^{-4}$ Pa), placed on top of a passive vibration isolation platform inside an acoustic shielding enclosure.

Finite element analysis shows that the vibration sensitivity of the cavity is less than 2 pm/g , being g the gravity acceleration, that for our cavities (L=10 cm), in terms of relative units means less than 2×10^{-11}s^2/m.

The sensitivity is shown in Figure 5, where we report the cavity length variation when a load of g is applied with respect to distance from the optical axis. Different curves are for different pad positions.

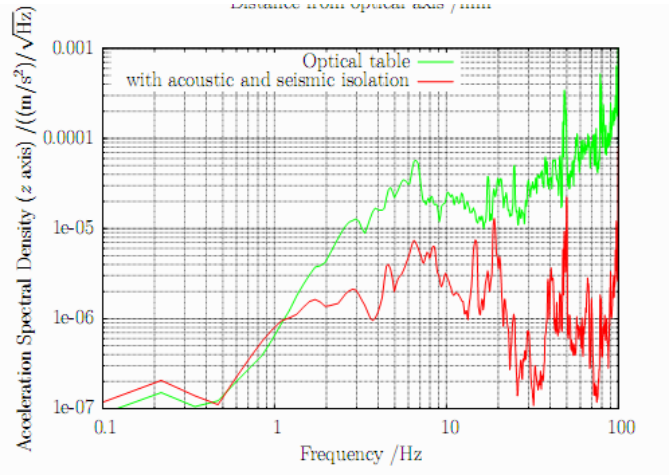

Figure 6. Seismic noise on the acoustic enclosure floor (upper green curve) and on the seismic dumping board (lower red curve).

The noise on the isolation platform was measured with a seismometer. In Figure 6 we report the seismic noise on the acoustic enclosure floor and on the vibration dumping board. The residual seismic noise is compatible with an instability in the laser frequency of 1×10^{-15} @ 1 s when the cavity is held at the Airy points. Thermal isolation is achieved with a copper shield surrounding the cavity. A digital control stabilizes the temperature of the shield, acting on two heaters external to the vacuum chamber. The ULE has a zero in the coefficient of thermal expansion around room temperature. To quickly estimate its value, we give a linear ramp to the temperature of the shield of one of the two cavities, while monitoring the beat note with the other. Aside from an

exponential transient and a time lag, the temperature of the cavity itself should vary linearly. The results are presented in Figure 7. This method allows us to estimate the zero at ~21 ◦C but has some trouble measuring the delay of the cavity temperature (this should translate in a shift of ~0.5 ◦C).

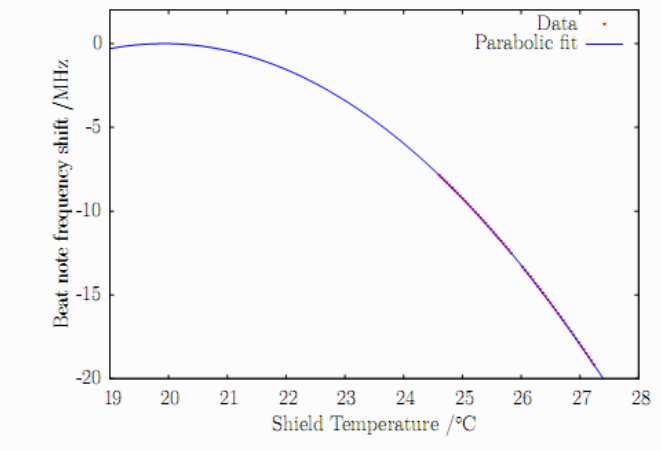

Figure 7. Frequency of the beat note changing one cavity temperature to measure the zero CTE point of the ULE cavity.

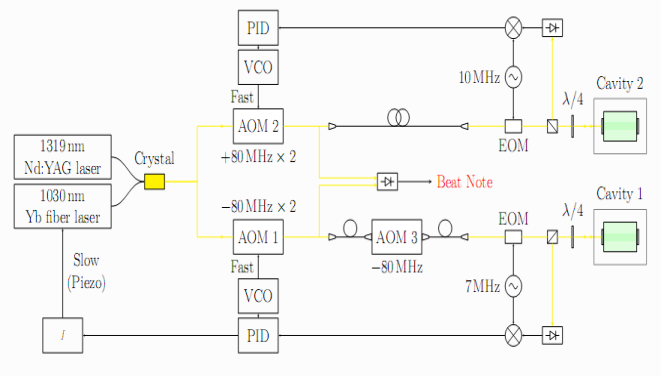

Figure 8. Scheme of the optical bench to lock the lasers on the two ultrastable cavities.

IV. STABILIZATION WITH POUND DREVER HALL TECHNIQUE

The Pound-Drever-Hall technique is used to stabilize the frequency of the yellow laser against the resonances of the cavities. The 578 nm laser at the output of the crystal is split and delivered to the cavities through polarization-maintaining fibers (about 60 µW of laser are impinging on each cavity). Two different beams from the same laser are independently frequency stabilized. In both case an electro-optic modulator (EOM) is used to add sidebands to the carrier of the yellow laser (clearly visible in the transmission). Thus, an optical isolator allows to extract the reflected beam and to obtain the Pound-Drever-Hall error signal.

Two double pass acousto-optic modulators (AOMs) are used for the fast locking of the laser frequency on each cavity. A proportional-integral-derivative (PID) control is used, while a voltage-controlled oscillator (VCO) drives each AOM. The bandwidth of the control is ~ 150 kHz, limited by the delay in the AOMs.

In Figure 8 the optical bench scheme is reported, while Figure 9 shows the transmission signal of the cavity as well as the Pound-Drever-Hall signal.

The Pound-Drever-Hall signal from the first cavity is also used for a slow lock on the piezoelectric actuator of one of the two infrared lasers, in order to correct for the drift. A third AOM is used to bridge the frequency of the two cavities.

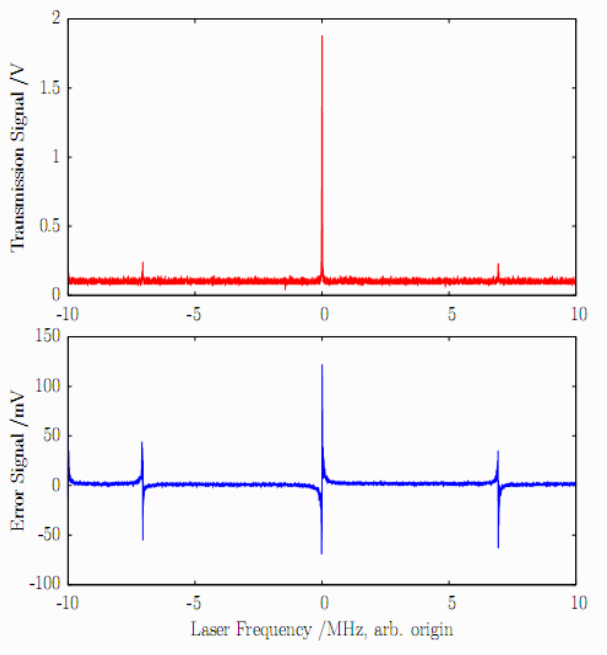

Figure 9. Trasmission and Pound-Drever-Hall signals from the cavities.

V. COMPARISON BETWEEN TWO CAVITIES

The laser beams, stabilized against the two different cavities, are exctracted before the optical fibers delivering them to the anti-acoustic chambers and are superimposed on a fast photodiode. The resulting beat note is then filtered, amplified, down-converted and counted using an hydrogen maser as a

reference. The noise of the two lasers is independent within the bandwidth of the two controls. The noise of the two lasers is independent within the bandwidth of the two controls.

Figure 10 shows the beat note at the spectrum analyzer allowing the measurement of the bandwidth, that is about 150 kHz. Figure 11 presents just the close up scan of the beat note, that allows to estimate a lorentzian linewidth of (3.8 ± 0.1) Hz.

carrier, that has a linewidth of 3.8 Hz (linewidth of the real beat note of the two cavities).

The beat note is then down converted to about 10 MHz and its instability is measured with a phasometer: results are presented in Figure 12. Here, we show the instability of the beat note when the dumping board is not operated (upper green line), showing a large degradation in the short term behavior as expected ($1/\tau$ instability). Then, the red line presents the instability of the lasers when the dumping board is under operation: the short term is much lower than in the previous case, and a linear drift is observed as large as 0.8 Hz/s. The linear drift removal confirms that the frequency noise between 0.5 s and 20 s is mainly flicker.

The frequency flicker floor is at 4×10^{-15}, probably limited by AM to FM noise conversion.

We expect the limit from the thermal noise, dominated by the thermal fluctuation in the ULE mirrors substrate in the cavities to be between 1.5×10^{-15} and 3×10^{-15}.

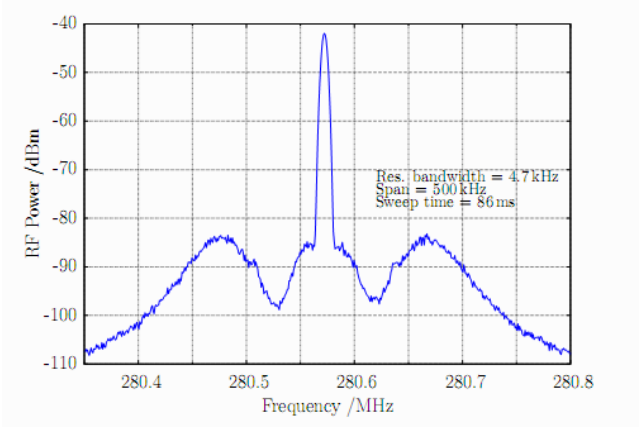

Figure 10. Beat note between the two independent locked lasers, showing the control bandwidth (150 kHz).

VI. CONCLUSIONS

We have realized a laser source at 578 nm for an ytterbium lattice clock capable of 12 mW and a frequency instability $<4 \times 10^{-15}$ corresponding to a lorentzian linewidth <4 Hz. This result is close to the expected thermal limit of the ULE mirror substrate, and we think that the excess of noise is due to AM to PM conversion. Further measurements and the implementation of a power stabilization servo will be useful to reach the thermal noise limit.

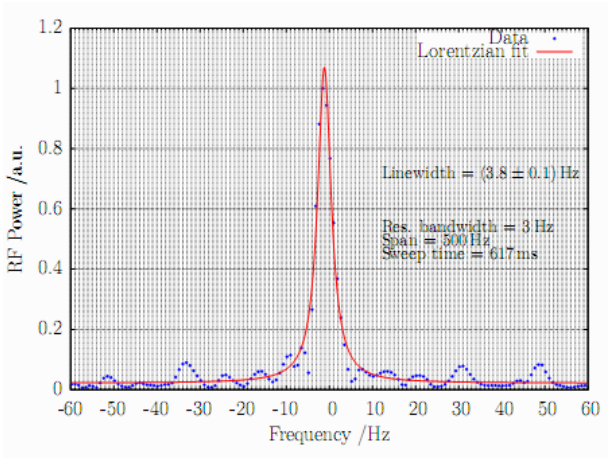

Figure 11. Beat note between the two independent locked lasers, showing a linewidth of 3,8 Hz.

***Abstract*—Ytterbium lattice frequency standard is an outstanding optical clock with a demonstrated relative frequency accuracy of $3.4 \cdot 10^{-16}$, presently limited by the uncertainty on the blackbody radiation (BBR), lattice polarizabilities and cold collisions shifts. In particular the BBR shift is looming as a major component in the uncertainty budget of many optical frequency standards. In fact the uncertainty on BBR systematic shift in Ytterbium atoms is due both to experimental and theoretical limits in the knowledge of the atomic system: presently Ytterbium has the largest theoretical uncertainty on the BBR shift. Then, both for atomic physics and metrology, new measurements of the Ytterbium atomic properties are strongly demanded, such as the determination of transition matrix elements, lifetimes, branching ratios, polarizabilities and hyperfine constants. In this work we present a set of new measurements for the radiative decay and for the cold collisions trap losses in laser-cooled Ytterbium atoms. These data are relevant to the blackbody radiation shift evaluation and to the cold collisions shift theory.**

I. INTRODUCTION

In recent years microwave frequency standard performances based on Cs atoms have been overcome by optical clocks which permit to obtain an "almost" factor 10 of improvements of the metrological properties of the standards. In fact several scientific groups [1-7] have shown fundamental results on the accuracy and the stability of optical clocks based on a set of alkaline-earth and alkaline-earth like atoms.

Among them Yb frequency standards are one of the best candidates for the possible re-definition of the Second, the Time unit in the International System: the astonishing results of the group of Lemke [7], showing a relative accuracy of few parts in 10^{16}, are pushing the scientific community to a more active research on this fields tackling the Yb atoms properties for a better knowledge. A lack in Yb atomic property data limits both evaluation of relative frequency accuracy in Yb optical frequency standards and quantum information experiments. For this reasons more experimental data are needed in order to improve the level of knowledge of this atom.

Thanks to the atomic structure of the Yb atom, the possibility of a deeper comprehension of the Yb atomic level structure can be accomplished by comparison of the different isotope dynamics taking advantages of the laser cooling possibility. In fact Yb can be laser-cooled down to the mK regime with the $^1S_0 \rightarrow {}^1P_1$ (399nm) transition, with the natural linewidth of 29MHz and a Doppler limit temperature of about 690μK.

When the atomic sample reaches the cold regime, a set of interesting parameters, useful for frequency standard applications, can be measured. Among them the measurement of the cold collision coefficient β can clarify the collisional shift theory for Yb optical clocks, improving their accuracy. Moreover the measurements of the so-called D-branching ratio $a_{2,0}$ (which is defined as the de-excitation rate of atoms from the $^1P_1$ state to the ^3P triplet, via the ^3D states) allow to improve the theoretical evaluation of the blackbody radiation shift in Yb optical clocks.

II. EXPERIMENTAL SETUP

In our experimental set up, the Yb source is an effusion oven operating between 360 and 390°C with a nozzle realized with a microchannel bundle, maintained at a temperature of 400°C. The latter is made by 200 microtubes in Monel400 with 100μm of internal diameter, 10mm long, that implies a thermal beam divergence of 17mrad.

The physical structure is maintained under Ultra High Vacuum by two ion pumps which ensure a differential vacuum: the trap region is maintained at a pressure of 10^{-6}Pa while the oven region pressure is 10 times higher. The MOT region is placed about 50cm from the nozzle, where the thermal beam has a diameter of about 20mm. The Zeeman

This work is supported by Regione Piemonte (YTRO project).

slower is not used in order to simplify the structure and avoid any stray magnetic field in the clock implementation. Yb atoms interact with three retro-reflected laser beams in a classical XYZ (0,0,1) configuration.

Each beam has 4mm (1/*e*) diameter and is red detuned of about 30MHz by means of two double-pass acousto-optic modulator systems. The MOT magnetic static gradient is generated by two anti-Helmholtz coils that provide a magnetic field gradient of 0.12T/(m·A). The trapped atom cloud is approximately spherical and has a diameter of 1mm (1/*e*). Atomic fluorescence light is collected by an EMCCD camera placed outside the vacuum chamber, 25cm far from the interaction region.

In order to increase the number of atoms in the trap an additional laser cooling beam has been added, counter-propagating to the Yb atomic beam: this beam works at a fixed frequency, which is 140MHz red detuned from the atomic resonance of the 399nm transition for each isotope.

The laser radiation is provided by the 798nm radiation obtained from a Ti-Sa laser frequency doubled using a 20mm long PPKTP crystal placed in an enhancement ring cavity. Up to 70mW of 399nm radiation have been obtained from a 600mW infrared radiation. The resonant ring cavity is then locked to the Ti-Sa laser using the Hänsch-Couillaud technique. The typical power of each laser beam is about 3mW: about $3\cdot10^4$ atoms of ^{174}Yb are trapped without the pre-cooler.

III. Evaluation of the Two-Body Collision Coefficient

In order to measure the β coefficient, the usual time evolution of the trapped atoms number *N(t)*, described by

$$\frac{dN(t)}{dt} = R - \alpha \cdot N(t) - \beta \iiint n^2(\vec{r},t)d^3\vec{r} \qquad (1)$$

must be analyzed.

In (1), *R* is the atom capture rate, α the linear loss rate of the trap, β the two-body collision coefficient and *n* the spatial density of the trap. If the constant volume regime is assumed and the spatial extension of the MOT is approximated as a sphere with a radius *a*, the atom spatial density is described by $n(r,t)=n_0(t)\cdot\exp(-r^2/a^2)$ and the non-linear second order differential equation is evaluated. The latter is a particular case of the more general class of Riccati differential equations:

$$\begin{cases} \dfrac{dN(t)}{dt} = R - \alpha \cdot N(t) - \dfrac{\beta}{(\sqrt{2\pi}a)^3} \cdot N^2(t) \\ N(0) = N_{in} \end{cases} \qquad (2)$$

Once fixed the boundary condition this equation has only one analytical solution. From (2) we introduce a different and new method for β evaluations, strongly different from methods reported in [8-10]. As in [11], we use a loading/decay technique where both processes are measured in the same experimental setup but, compared to the method developed in [11], without the pre-cooler beam during the acquisition.

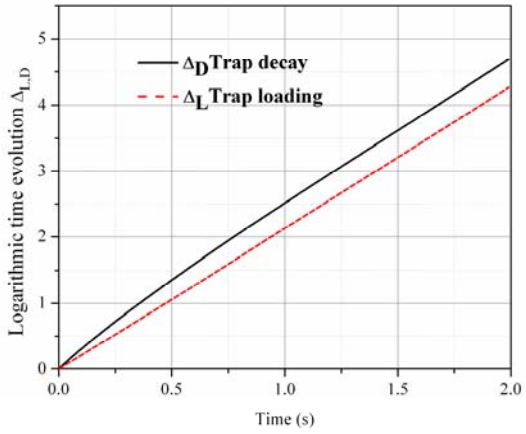

Figure 1. Simulated logarithmic time evolution of the trapped atoms number during trap loading (Δ_L, dashed line) and decay (Δ_D, straight line) assuming $\beta = 4\cdot10^{-15}\mathrm{m^3s^{-1}}$, $a = 0.7$mm, $\alpha = 1\mathrm{s^{-1}}$, $N_{in} = 10^6$ and $R = 10^6\mathrm{s^{-1}}$.

This experimental choice enables us to develop an exact theoretical model reducing the uncertainty on the final result. As a matter of fact we introduce the functions Δ_L and Δ_D defined as:

$$\Delta_{L,D}(t) \equiv -\ln\frac{N_{L,D}(\infty) - N_{L,D}(t)}{N_{L,D}(\infty) - N_{L,D}(0)} \qquad (3)$$

where Δ_L and Δ_D concern the loading and the decay process.

Finally in (3) $N_{L,D}(\infty)$ is the asymptotic value of trapped atoms in the loading/decay processes. As shown in Fig. 1, we generally observe a linear behavior, but close to the beginning of the processes a non linearity enables to distinguish the two situations: this arises because of the different number of atoms, with consequently a different loss rate due to the collisions between the cold atoms.

If we consider the difference $\Delta_{log} = \Delta_L - \Delta_D$, whose behavior is reported in Fig. 2, it is possible to evaluate some important parameters of the atomic sample. The evaluation of the derivative in the arbitrary time origin and the asymptotic value of Δ_{log} leads to a measurement of α and β coefficients using (4). In fact from the solution of (2), it can be easily obtained:

$$\left.\frac{d\Delta_{\log}(t)}{dt}\right|_{t=0} = kN_{Max} \qquad (4)$$

$$\lim_{t\to\infty}\Delta_{\log}(t) = \ln\left(1 + \frac{2kN_{Max}}{a+\varsigma}\right)$$

where $k \equiv \beta/\left(\sqrt{2\pi}a\right)^3$ and $\varsigma \equiv \sqrt{4kR+\alpha^2}$; N_{max} and a are directly measurable using the EMCCD camera imaging, while R is evaluated as the slope in the origin of the solution (4) for N_{in}=0.

IV. Experimental results

The only measurement of the two-body cold collision coefficient β actually available in literature for Yb is accomplished in [12] using ^{174}Yb atoms in the level $^3P_2$ with estimated temperature of 41μK.

In the present work we use laser cooled Yb atoms of different isotopes with a temperature of few mK. While the loading curve is obtained by chopping the six laser beams with a mechanical shutter within closing time lower than 100μs, the decay curve is obtained by switching on-off the RF of the acousto-optic modulator which red detunes the pre-cooler beam of 140 MHz from the atomic resonance and only taking the values of the fluorescence when the RF is off. Each measure is the average of about 30 acquisitions reducing the laser noise.

The image analysis by EMCCD camera signal shows that the spatial density distribution of the atoms in the trap is well described by a gaussian function with a radius of about 0.4mm, depending on the isotope.

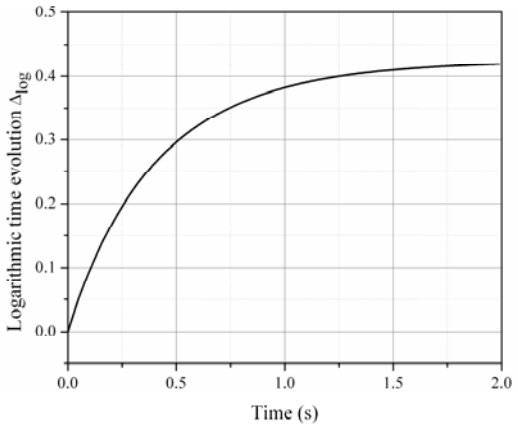

Figure 2. Simulated time evolution of Δ_{log} using the same parameters in the previous figure.

In Figs. 3 and 4 the measurements for ^{174}Yb are shown with a laser trap intensity of 75% of the saturation value. The results for a single run acquisition are reported in Tab. I, where β is obtained solving the equations system (4).
The values of τ_L and τ_D reported in Table I are the loading and decay times of the experimental curves for different isotopes, obtained from an exponential fit of the data. The coefficients reported in the Table I are the first measurement of β for Yb in the mK temperature regime.

V. Branching ratio measurements

In order to estimate the branching ratio $a_{2,0}$, we developed the following simple model: if we neglect the non-linear term in (1), the solution becomes:

$$N(t) = \frac{R}{\alpha}(1-e^{-\alpha t}) \tag{5}$$

This approximation is acceptable if we consider only the loading curve, where the number of the trapped atoms is lower and the non-linear contribution is negligible. In [13-14] the evaluation of $a_{2,0}$ is performed fixing the isotope and changing the laser trap intensity. The latter changes the fraction f of the excited atoms.

The linear loss rate α can factorized in two main contributions as $\alpha = \alpha_b + a_{2,0}\, f$. The first term is the loss due to the collisions between the trapped atoms and the atoms in the thermal beam. The second is the loss due to the atoms decay from the excited state to the metastable ^{3}P triplet.

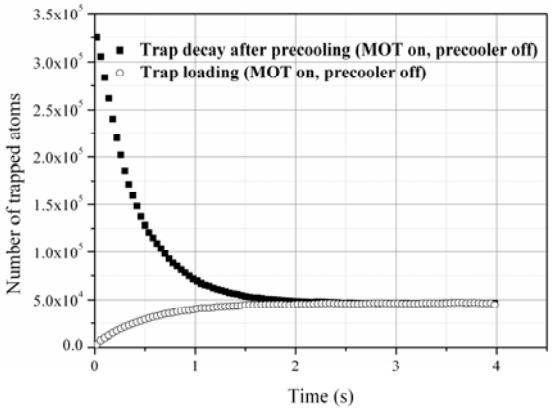

Figure 3. Experimental number of trapped atoms during MOT loading without pre-cooler (empty circles) and during the decay from the pre-cooler switch off to the MOT regime (full squares).

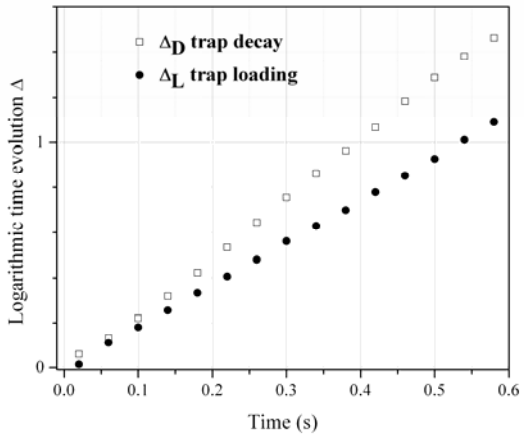

Figure 4. Experimental time evolution of Δ_D (empty squares) and Δ_L (full circles) during trap loading and decay for the ^{174}Yb isotope.

With this assumption $a_{2,0}$ is the D-branching ratio. In this work $a_{2,0}$ is obtained fixing f and comparing couples of loading times of different isotopes to obtain a linear systems with two unknown quantities, L and $a_{2,0}$. This method implies to assume both of the last two parameters constant over all the isotopes and writing α as in the following equation:

$$\alpha_{isot} = \eta_{isot} L + a_{2,0} f \quad (6)$$

where L is a loss term constant over all isotopes, due to collisions between trapped atoms and thermal beam and η is the relative abundance for each isotope. The subscript *isot* denotes quantities that vary for each isotope, while $a_{2,0}$ is assumed to be constant for the whole set of isotopes. The experimental results, in good agreement with [13], are reported in Table II.

VI. CONCLUSIONS

We have developed a new method for the measure of the two-body collision coefficient β and the branching ratio $a_{2,0}$ of Yb atoms in the mK cold collisions regime. These theoretical methods have been then implemented for laboratory experiments allowing us to improve the knowledge of the fundamentals data of the Yb atoms.

***Abstract*—The frequency noise properties of free-running single-mode mid-IR Quantum Cascade Lasers (QCLs) operated near room-temperature in CW mode and emitting at 4.6 µm are presented. The frequency noise level measured in this paper is globally a factor of 100 lower than recently reported for a similar QCL but operated at cryogenic temperature. The results are very promising for the future realization of a QCL-based ultra-stable laser in the mid-IR.**

I. INTRODUCTION

Narrow-linewidth lasers exhibiting a high spectral purity have important applications in various fields, such as high-resolution spectroscopy, coherent optical communications or time and frequency metrology. In the latter field, such lasers can be used as ultra-stable reference for low phase noise microwave generation when frequency-stabilized to a high-finesse optical cavity for linewidth narrowing. Indeed, the relative stability of the ultra-stable optical reference can be transferred to the microwave domain using an optical frequency comb (OFC). Such optical references were demonstrated based on external cavity and fiber lasers in the near-infrared (NIR) [1], but also in the mid-infrared (MIR) with a 3.39-µm HeNe laser stabilized to a CH_4 transition [2]. In this latter case, the relative stability of the HeNe/CH_4 laser was transferred using a MIR comb obtained by difference frequency generation (DFG) between two spectral parts of a NIR comb. As a result of the DFG process, the generated MIR comb has a null carrier-envelope offset (CEO) frequency, independently of the value of the NIR comb CEO. In other words, the translational degree of freedom of the NIR comb can stay free without affecting the generated MIR comb. Therefore, the CEO does not need to be stabilized nor to be measured, which relaxes the need for an octave spanning comb and the associated f-to-2f interferometer.

With the objective to implement a similar optical-to-microwave transfer based on a MIR quantum cascade laser (QCL), we studied the frequency-noise characteristics of QCLs, aiming at assessing their suitability as a potential ultra-stable frequency reference. Indeed, efficient laser linewidth narrowing by frequency-stabilization to a high-finesse cavity with a reasonable feedback-loop bandwidth can be achieved only if the frequency noise of the free-running laser is sufficiently low. An estimate of feedback loop bandwidth required for the realization of an ultra-narrow linewidth QCL will be assessed from our experimental results.

II. EXPERIMENTAL SETUP

We investigated the frequency-noise properties of free-running commercial single-mode DFB-QCLs (Alpes Lasers SA, Switzerland) operated in CW mode near room temperature and emitting at 4.6 µm. The frequency noise measurement was performed by converting the laser frequency fluctuations into intensity fluctuations using the side of a molecular absorption in standard single-pass direct absorption spectroscopy. The emission wavelength of the laser was tuned to the centre of the linear range in the flank of the 250-MHz wide R(14) transition in the fundamental vibration band of carbon-monoxide (CO). The laser was driven (350 mA at 10V) by a home-made ultra-low noise current source (<350pA/Hz$^{1/2}$) and temperature-stabilized with a one-stage Peltier cooler at 277 K. At this operating temperature, the output power was on the order of 5 mW. The beam was collimated with an aspherical ZnSe lens and traversed a 1-cm long absorption gas cell filled with pure CO at a pressure of 20 mbar. The resulting absorption line is shown in Fig 1 and compared to the absorption profile simulated from Hitran

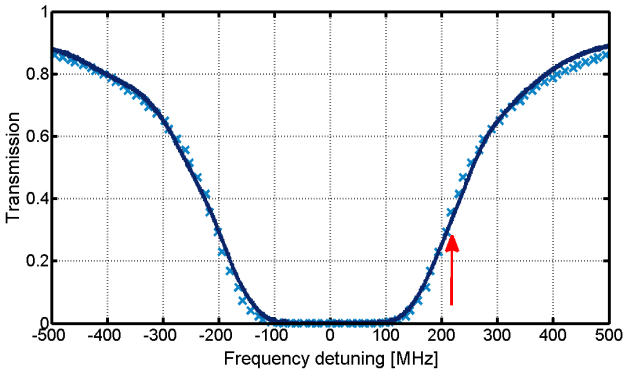

Fig. 1 Carbon-monoxide absorption line used as frequency discriminator (20 mbar, 1-cm pathlength, pure CO). The simulation from HITRAN database is also shown (crosses). The arrow represents the laser frequency operating point.

database [3]. Another ZnSe lens was used to focus the transmitted light onto a low-noise liquid-nitrogen-cooled HgCdTe detector with 20-MHz bandwidth. The detected signal was amplified and measured with a fast Fourier transform analyzer for low Fourier frequencies (up to 100 kHz) and with an electrical spectrum analyzer at higher frequencies.

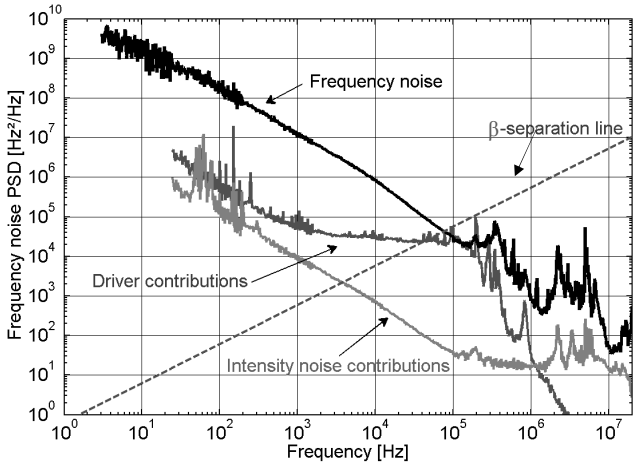

Fig. 2 Frequency noise PSD of the free-running DFB-QCL operated in CW mode near room temperature (T=277 K, I=350 mA, I_{th}=290 mA, U=10 V, P_{op}=6 mW).

III. RESULTS

The measured frequency noise power spectral density (PSD) revealed a 1/f-like behavior, with a noise level of $2x10^8$ Hz^2/Hz at 100 Hz dropping down to a very low level below 100 Hz^2/Hz at 10 MHz (Fig. 2). The contributions of the driver current noise and laser intensity noise are also shown in Fig. 2 and are both well below the measured frequency noise (up to 100 kHz Fourier frequency), which can therefore be attributed to the laser itself. Above 100 kHz, one can observe additional technical noise that deteriorates the measurement, which probably originates from the current driver since similar peaks are observed in the intensity noise spectrum. Despite this technical noise, the frequency noise decreases significantly up to 10 MHz. Moreover, above 10 kHz, it seems to deviate from the 1/f trend observed at low frequency into a steeper slope of $1/f^{3/2}$. However, one cannot exclude that an even steeper behavior is not hidden in that noisy part of the spectrum as previously reported for a cryogenic QCL [5]. As our goal was to assess the required feedback loop bandwidth required for linewidth reduction, the part of the spectrum above 100 kHz is not of prime concern since it lies below the β-separation line also presented in Fig. 2, which is relevant for the determination of the linewidth and thus for the required feedback bandwidth [4]. It is however interesting to note that the white frequency noise level is not reached below 10 MHz and only an upper limit of ~100 Hz^2/Hz can be inferred from our measurement, corresponding to an intrinsic linewidth of ~ 300 Hz. While the intrinsic linewidth is a fundamental limit in a laser, the real observed linewidth is highly broadened by the 1/f noise. The laser FWHM linewidth can be calculated from the frequency noise PSD [4] and depends on the observation time in presence of 1/f noise. Fig. 3a shows the calculated FWHM linewidth of the laser versus the observation time; for instance, a 550-kHz linewidth is obtained for 5 ms observation time. This value agrees very well with the heterodyne beat spectrum linewidth of ~1 MHz measured between two identical QCLs in a complementary experiment (Fig. 3b), since the beat lineshape corresponds to the convoluted lineshapes of the two identical QCLs. Finally, the measured PSD also shows that a feedback loop bandwidth on the order of 100 kHz would be sufficient for a high reduction of the laser linewidth. Because of the low frequency noise measured on this laser, this can be achieved with standard PID servo-controllers.

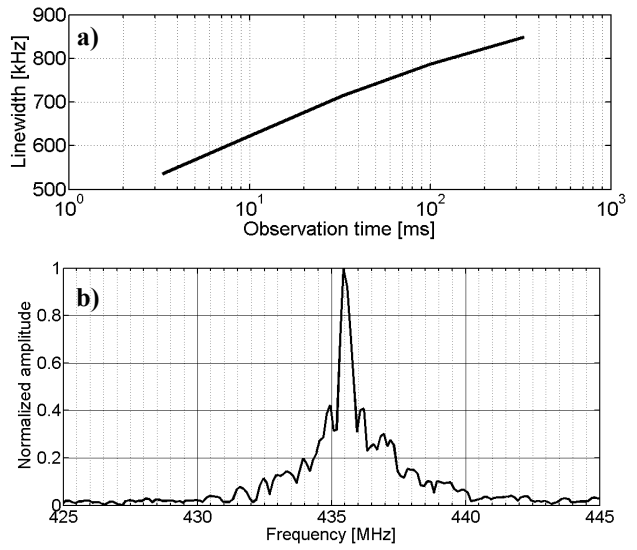

Fig. 3 (a) Laser FWHM linewidth calculated from the frequency noise PSD vs. observation time. (b) Heterodyne beat signal measured between two identical 4.6-µm room temperature QCLs (4 ms sweep time).

Frequency noise properties of QCLs are not widely known and complete PSD characterizations were reported only by a few research groups and only for cryogenic devices so far [5-6]. Interestingly, our results are a factor of 100 lower than data recently reported by Bartalini *et al*. [5] for a similar laser (4.3µm DFB-QCL from Alpes Lasers) but operated at cryogenic temperature. This significantly lower frequency noise is believed to be a consequence of the difference in the laser temperature operation conditions [7], but further investigations are required to fully understand this different behaviour. On the other hand, our results are on the same order of magnitude than what was measured by Myers *et al*. [6], but with a QCL emitting at a considerably longer wavelength of 8.5 µm.

IV. CONCLUSION

We have investigated the frequency noise properties of free-running commercial single-mode DFB QCLs operated at 277 K. The measured frequency noise indicated that ultra-narrow linewidth operation can be achieved by frequency-stabilization with a moderate feedback loop bandwidth on the order of 100 kHz, which is very promising for the future realization of an ultra-stable reference in the mid-IR range, based on a QCL.

V. ACKNOWLEDGMENT

This research is supported by the Swiss National Science Foundation, the Swiss Confederation Program Nano-Tera.ch scientifically evaluated by the SNSF and was initiated by the Gebert-Ruef Foundation in Basel, Switzerland. We would like to thank Prof. Sigrist and M. Gianella from ETHZ for providing the gas cell and Stéphane Blaser (AlpesLasers) for fruitful discussions and information about the lasers.

***Abstract*—We have quantified a short term instability budget for an optical frequency standard based on cold, freely expanding calcium atoms. Such systems are the subject of renewed interest due to their high frequency stability and relative technical simplicity compared to trapped atom optical clocks. By filtering the clock laser light at 657 nm through a high finesse cavity, we observe a slight reduction in the optical Dick effect caused by aliased local oscillator noise. The ultimately limiting technical noise is measured using a technique that does not rely on a second clock or fs-comb.**

I. Introduction

Optical frequency standards based on trapped atoms and ions offer unmatched absolute uncertainties [1], [2]. However, a clock based on cold but untrapped atoms may still offer competitive levels of short term stability while remaining technically simpler and more readily commercialized. Here we discuss limits to the stability of an optical standard featuring cold, freely expanding, Ca atoms [3].

Briefly, atoms are collected in a magneto-optical trap (MOT) by use of the strong ${}^1S_0 \leftrightarrow {}^1P_1$ transition at 423 nm. Though this MOT period lasts only 2.8 ms, many atoms are retrapped between clock cycles, yielding a steady-state atom number of order 10^6. An external cavity diode laser at 657 nm, stabilized to a ULE glass Fabry-Perot cavity (linewidth $\sim$ 9 kHz), is made resonant with the allowed inter-combination transition ${}^1S_0 \leftrightarrow {}^3P_1$. The MOT is shuttered for 0.44 ms, and a sequence of 657 nm pulses forms a Ramsey-Bordé atom interferometer [4] in the freely falling and expanding atoms. Counter-propagating, horizontally aligned pairs of Ramsey pulses suppress residual first-order Doppler shifts, enabling high resolution, and high S/N, spectroscopy [5], [6]. Resonant 423 nm light is used to measure the atoms' ground state population before and after the clock pulse sequence. Dividing these collected fluorescence signals yields a spectroscopic feature normalized against atom number fluctuations with a linewidth (FWHM) of $\sim$ 1 kHz, and signal-to-noise ratio (S/N) of about 50 in 3.3 ms. The clock instability limit implied by these results is about $2 \times 10^{-15}(\tau/1\mathrm{s})^{-1/2}$; which is roughly consistent with the quantum projection noise limit given a coherent fringe contrast of $\sim 10\%$.

We measure the Ca clock instability to be consistently $3 - 4 \times 10^{-15}(\tau/1\mathrm{s})^{-1/2}$ when compared against a superior local optical standard [7] via a fs-comb. We calculate that the optical Dick effect [8], [9] contributes $3.6 \times 10^{-15}(\tau/1\mathrm{s})^{-1/2}$ to this instability. About half of the Dick effect is eliminated by filtering the clock laser through a high-finesse optical cavity to remove high frequency local oscillator noise. We measure a comparable amount of instability, $1.8 \times 10^{-15}(\tau/1\mathrm{s})^{-1/2}$, due to technical sources. In this paper we discuss these contributions and highlight measurement techniques used to quantify them with minimal use of a second clock or fs-comb.

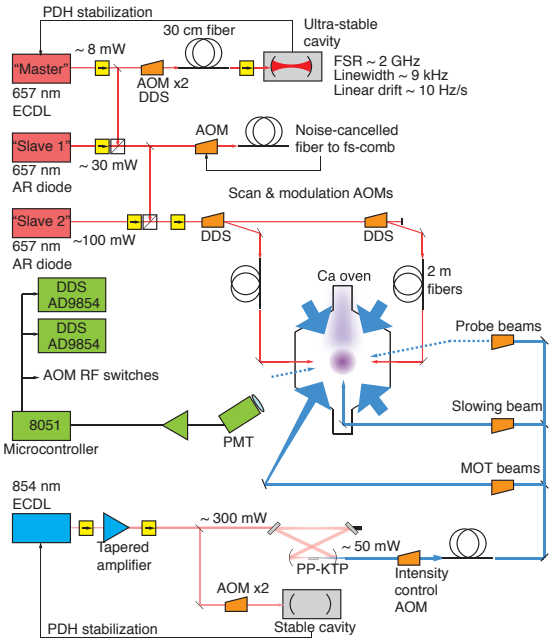

Fig. 1. The free Ca clock is among the simplest optical frequency standards. Slowing, cooling, trapping, and probing radiation at 423 nm is derived from a frequency-doubled external cavity diode laser. A diode laser at 657 nm, AR-coated and placed in a Littman external cavity, is stabilized to an ultra-high finesse optical cavity. Injection-locked 'slave' laser systems boost the 657 nm power to enable very short Ramsey pulses and homogenous broadening of the clock transition up to the residual Doppler linewidth of $\sim$ 2 MHz. A microcontroller triggers the clock sequence every 3.3 ms, acquires fluorescence data, and servos the clock laser on the atomic resonance.

A. A simplified apparatus

Figure 1 shows the current version of the apparatus, which has been optimized for stability and fast cycle rate, rather than accuracy. For instance, the MOT gradient magnetic field

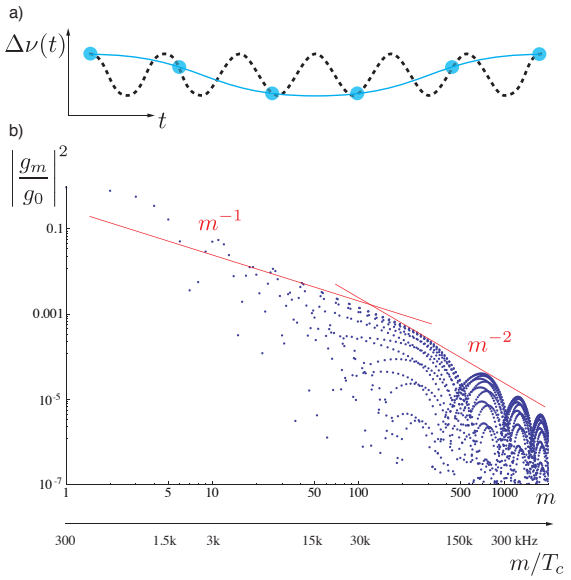

Fig. 2. (a) A cartoon illustrates the optical Dick effect as an aliasing, or downsampling of noise. The dashed line represents a particular Fourier component of laser frequency noise close to the clock measurement repetition rate; the width of each blue circle represents the atomic interrogation period of each clock cycle. Since these interrogation windows are short, it takes many clock cycles to properly average over the noise component. The aliased noise (blue line) is not genuine; if written by a servo onto the local oscillator it can actually increase the short term instability of a clock. (b) Given the Ramsey-Bordé pulse sequence parameters, we calculate sensitivity coefficients g_m/g_0 in Eq. 1 which describe how a local oscillator frequency noise spectrum is aliased into white noise.

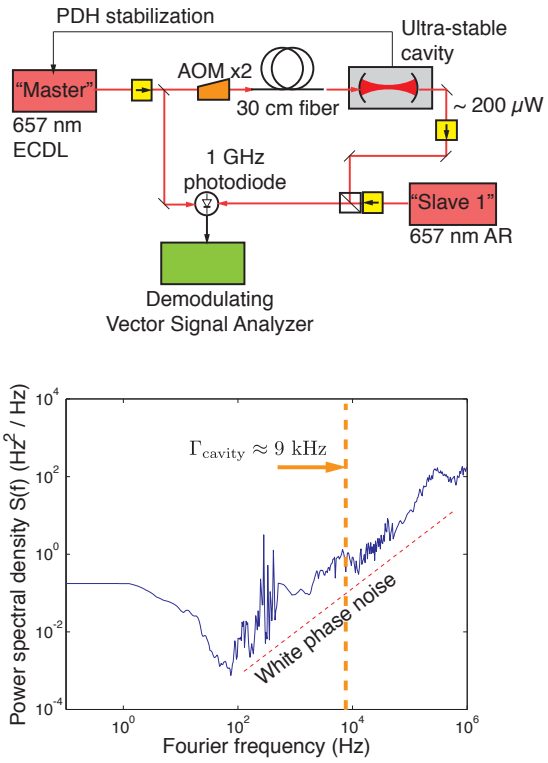

Fig. 3. Fast laser frequency noise is suppressed by filtering through a high-finesse optical cavity; the cavity acts to average out fluctuations faster than the photon ring-down timescale of $\tau = 1/\Gamma_{\text{cavity}} \sim 0.1$ ms. To determine the transfer function of the cavity, we heterodyne laser beams before and after transmission through a high finesse optical cavity used for laser stabilization. The noise added by the injection locking to a second laser is independently evaluated.

remains on permanently, eliminating vibrations that result from rapid toggling [10]. We forgo a quenched second-stage of atom cooling [10] in order to minimize the sequence duration and maximize the atomic interrogation duty cycle. The effusive atomic beam source is located about 15 cm away from the interaction region; no Zeeman slower or chirped slowing beam is employed. Key acousto-optic modulators between the clock laser and the atoms, and between the laser and the stabilization cavity, are driven with maser referenced DDS synthesizers (labeled DDS in Figure 1). The only fiber optics path that is actively noise-cancelled is the long run to the fs-comb.

II. Local Oscillator Noise

A. The optical Dick effect

Since the clock's repetition rate is 300 Hz, a digital servo locking the laser to the atomic resonance should strongly suppress local oscillator noise at 1 s averaging times. However, since the fraction of the clock sequence spent interrogating the atomic resonance—the duty cycle—is small, high frequency fluctuations are not averaged to zero but instead are down-sampled. This process, known as the optical Dick effect, results in extra white noise with a fractional instability:

$$\sigma_d^2(\tau) = \frac{1}{\tau}\sum_{m=1}^{\infty} S_y(m/T_c)\left|\frac{g_m}{g_0}\right|^2. \qquad (1)$$

Local oscillator noise S_y at harmonics m of the cycle rate $1/T_c$ are aliased by the imperfect interrogation. Sensitivity coefficients,

$$g_m \equiv \frac{1}{T_c}\int_0^{T_c} g(t)e^{-2\pi i m t/T_c}\,dt, \quad (m>0), \qquad (2)$$

tend to shrink as the interrogation duty cycle approaches 100% because the sensitivity of the atomic population to oscillator phase $g(t) = 2\,\delta P/\delta\phi|_{\delta_\phi\to 0}$ approaches a constant value. The sensitivity function $g(t)$ for the Ramsey-Bordé pulse sequence is derived elsewhere [8].

Figure 2 illustrates the aliasing effect and shows calculated Dick effect coefficients for our nominal clock cycle having an interrogation duty cycle of 13%. The Ramsey $\pi/2$ pulses last $T_R = 0.75\mu$s. The duration between Ramsey pulses is $T = 215\mu$s. The dead-time between pairs of opposing Ramsey pulses is $T_\nu = 5.8\mu$s. Increasing the two Ramsey dark periods lasting T would increase resolution and the interrogation duty cycle, but would also inflict a loss of signal; the lifetime of the excited clock state is 0.4 ms. Numerical analysis of Eq. 1 with our estimated laser noise spectrum S_y shows that more than 99% of the Dick effect instability is due to harmonics $m < 100$, or laser noise frequency components $f < 30$ kHz.

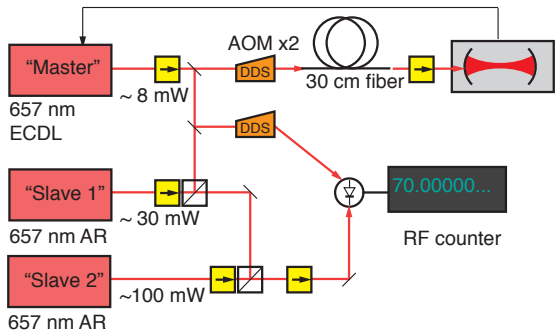

Fig. 4. Illustrated here is a heterodyne between the master external cavity diode laser and an injection-locked 'slave' laser, which is itself seeded by another 'slave' laser. An RF beatnote is created by shifting one of the beams with an acousto-optic modulator (AOM) driven by a maser-referenced synthesizer (labeled DDS). The Allan deviation of maser-referenced RF counter is related to the optical frequency fractional Allan devation relevant to Ca clock operation with $\sigma_y(\tau) = \sigma_\nu(\tau)/f_{\text{optical}}$. Direct counting of a DDS frequency yields a baseline of $\sigma_y(1\text{s}) = 6.0 \times 10^{-18}$. Table I shows the results for several such heterodyne measurements; all instabilities are much lower than the observed clock instability. The noise spectra have not been studied in detail.

TABLE I
INSTABILITY CONTRIBUTIONS DETERMINED BY HETERODYNE MEASUREMENTS.

Heterodyne test	$\sigma_y(\tau = 1\text{s})$
DDS counting baseline	6.0×10^{-18}
Before/after cavity	6.3×10^{-16}
Before/after 1.5m PM fiber	1.3×10^{-16}
Master vs. injection locked 'slave 1'	1.6×10^{-16}
Master vs. injection locked 'slave 2'	1.8×10^{-16}

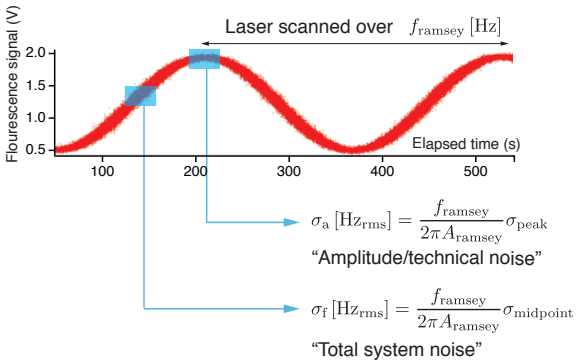

Fig. 5. In the absence of a second local oscillator or atomic reference, one can still derive useful absolute instability of a clock by using the atomic reference as a frequency discriminator. Here, the unlocked clock laser is slowly scanned over a Ramsey-Bordé fringe. Point-to-point rms deviations in the fluorescence signal are larger near the frequency-sensitive nodes. Technical noise, which is presumed to be largely laser frequency independent, is observable at the peaks and troughs of the fringe. The clock's operational parameters can be optimized to minimize each noise level. The technical noise level sets a limit on ultimate system stability even in the absence of local oscillator noise. The noise level at the fringe nodes is quantitatively consistent with the overall clock performance when compared against superior optical standards.

B. Clock laser filtering

We find the instability of the cavity-stabilized clock laser (while unlocked to the atomic resonance) to be 2.5×10^{-15} after 1 second of averaging by comparison to a superior optical reference. This instability is consistent with that derived from the laser's noise spectrum from 1 Hz–1 kHz found by demodulating the laser's beatnote with a referenced fs-comb. Faster laser noise components, perhaps due to residual phase noise not suppressed by the Pound-Drever-Hall stabilization scheme, can be downsampled by the Dick effect. To examine what fast noise might be suppressed by filtering the clock laser, we heterodyne clock laser beams before and after transmission through the high-finesse stabilization cavity. As shown in Figure 3, noise rising as f^2 is observed that contributes directly very little to the local oscillator instability at 1 second; however, through the Dick effect mechanism, the noise above $\Gamma_{\text{cavity}} \approx 9$ kHz is responsible for roughly half of the Dick effect instability. The unfiltered and filtered laser Dick effect instability limits are

$$\sigma_{\text{d,}}(\tau) = 3.6 \times 10^{-15}(\tau/1\text{s})^{-1/2}$$
$$\sigma_{\text{d, filt.}}(\tau) = 2.4 \times 10^{-15}(\tau/1\text{s})^{-1/2}$$

We do not see as large an improvement from clock laser filtering as other groups [11] due to our shorter cycle time and larger interrogation duty cycle.

C. Other noise sources

We performed heterodyne measurements between the master ECDL beam and several derived laser beams—after injection locking, after short fiber optic runs, after acousto-optic modulation (AOM)—to identify other sources of noise that might contribute to the clock instability. An example arrangement is shown in Figure 4. In each heterodyne experiment, AOM frequencies and the RF counter were maser referenced. Table I expresses these noise contributions as fractional Allan deviations of the optical frequency at 1 second.

III. TECHNICAL AND TOTAL NOISE EVALUATION

A. Self-evaluation of instability

Without the benefit of a second, independent clock laser or atomic reference, one can still evaluate some aspects of the absolute instability of a Ca clock apparatus. With a clock laser detuning ν, frequency fluctuations $\delta\nu(t)$, and Ramsey dark period T, the spectroscopy method produces a fluorescence signal [4]:

$$\rho_e(t) \propto A\cos\left(2\pi \times 4T \times (\nu + \delta\nu(t)\right) + \delta\rho_e(t). \quad (3)$$

The laser detuning ν can be slowly scanned over this feature; laser noise $\delta\nu(t)$ is translated into fluctuations in fluorescence proportional to the local slope $\partial\rho_e/\partial\nu$. At the Ramsey fringe nodes, this slope is constant and computable using the Ramsey fringe amplitude A and separation $f_{\text{Ramsey}} = 1/(4T)$. The root-mean-square deviation of successive measurements of ρ_e can be expressed in as a frequency instability by

$$\sigma_\nu(\tau = T_c)[\text{Hz}] = \frac{1}{2\pi A(4T)}\sigma_\rho[V_{\text{rms}}]. \quad (4)$$

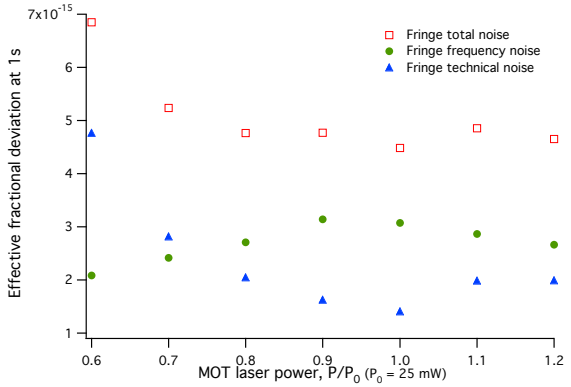

Fig. 6. The instability of the clock system is measured by using the atomic resonance as a frequency discriminator in open loop operation. Noise on the Ramsey fringe peaks and nodes can be related to effective Allan deviations due to technical and frequency-dependent noise, respectively. Here we see how these noises vary as a function of MOT trapping power. An optimum operation condition, the minimum of the total noise, is found without using a second clock or fs-comb.

At the peaks and troughs of the Ramsey fringe we observe technical noise $\delta\rho_e(t)$ which is largely independent of the clock laser frequency but nonetheless contributes noise when the servo is locked to a nodal point. At these lock-points, the technical noise will be equivalent to uncorrelated frequency noise using the same conversion factor $1/(2\pi A4T)$. Several potential sources of technical noise are suppressed by normalizing the signal to atom number, and by dithering the Ramsey-Bordé fringe pattern to remove the incoherent excitation background. The remaining technical noise could include shot-to-shot atom number fluctuations imperfectly accounted for by the normalization pulse, fluctuations in 657 nm pulse power, and frequency noise on the 423 nm probe pulses. Path length, pointing, and wavefront fluctuations between Ramsey pulses in a single clock cycle also appear as excess technical noise, but are dependent on the laser frequency as well. In general, fluctuations in any systematic effect leading to inaccuracy adds instability as well, though dithering of the Ramsey fringe suppresses such effects varying slower than half the cycle rate.

Fourier transforms of recorded $\rho_e(t)$ series at the peaks, toughs, and nodes indicate these noises are largely white from 0.5—150 Hz, and thus have equivalent noise spectra of $S_\nu(f) = \sigma_\nu^2/(f_{\text{rep}})$, where f_{rep} is the clock cycle rate. Effective fractional Allan deviations can be constructed with $\sigma_y^2(\tau) = (S_\nu/2)(1/\tau)(1/f_{\text{optical}})$.

Figure 6 demonstrates the utility of this technique. The MOT laser power is varied around its nominal power of 25 mW, and the effective deviation at 1s implied by the open-loop fringe noise is plotted. Technical and frequency noise (corresponding to peak and node noise levels) are separately plotted, and their sum agrees well with the observed clock instability when the unlocked local oscillator noise is subtracted.

IV. Conclusion

Previous efforts have aggressively pursued an uncertainty budget for the Ca optical frequency standard. In Table II, we present instead an instability budget at 1s of averaging with no account of ultimate accuracy. We conclude that three different methods of evaluating the instability share good agreement: direct measurement against a superior optical standard, a quadrature sum of the calculated optical Dick effect instability and known technical noise sources, and an open loop measurement using the atoms as a frequency discriminator. The latter technique never relies on a second clock or fs-comb, but it is directly sensitive to the open-loop local oscillator noise.

Another important result is that while filtering the clock laser through our high-finesse cavity decreases the Dick effect limit somewhat, it remains comparable to the technical noise that would ultimately limit the system if the local oscillator were significantly improved. Further study must focus on identifying and reducing the principle sources of technical noise. Since this level is thought to be near that of quantum projection noise, an increase in the number of atoms might be necessary for further improvements.

Acknowledgment

The authors would like to thank colleagues T. Fortier and S. Diddams for fs-comb measurements, and A. Ludlow, N. Lemke, R. Fox, and Y. Jiang for comparison measurements with the Yb optical lattice clock and local oscillator. We thank R. Fox, A. Curtis, F. Bondu, G. Wilpers, and Y. LeCoq for their contributions to earlier versions of the Ca apparatus.

***Abstract*— The ultra low expansion cavities play a crucial role in laser stabilization, and they are essential in ion clocks. We present a method to monitor the temperature distance changes in the Fabry-Perot cavity with a spacer from an ultra low expansion material with sub-nanometer resolution. The FPC was placed into a temperature-stabilized stainless steel chamber.**

I. INTRODUCTION

The ultra-low expansion materials are crucial in Fabry-Perot cavities. The laser stabilization to the cavity by Pound-Drever-Hall technique [1] use stable cavities with low expansion material such as Zerodur ceramics [2] and ULE glass [3]. They play a key role in ion clocks [4]. Thermal dilatation on the cavity of length of 20 cm is such as 4 nm per 1 K. The knowledge of the absolute length and dilatation itself is necessary. In this work we present a method of measurement of thermal dilatation of low-expansion materials by the use of a femtosecond frequency comb [5].

The method uses a Fabry-Perot cavity (FPC) itself as tool for length changes measurement. FPC spacer is made from Zerodur. Temperature of the cavity is stabilized and effects of refractive index of air are suppressed by placing into the evacuated chamber. Any fluctuation of FPC length is demonstrated in the change of free-spectral range (FSR) of the cavity while exhibits changes in the selected mode takes effect on the change of tunable laser frequency. Changes of frequency are down-converted from the optical domain by the use of optical frequency comb.

The optical frequency comb stabilized to GPS disciplined oscillator represents a stable source in optical domain and works as a stable frequency rule in optical domain [5-10]. This work is based on evaluation of changes of FPC length by the use of optical frequency comb and tunable DFB laser.

This work was partially supported by European Commission and Ministry of Education, Youth, and Sports of the Czech Republic (project No. CZ.1.05/2.1.00/01.0017). II. METHODOLOGY

A. Stabilized optical frequency comb

The proposed method employs the optical frequency comb is based on the femtosecond laser and FPC. The optical frequency comb produces periodically a train of femtosecond pulses. Optical frequency spectrum of comb lines around the central optical frequency (wavelength) is produced by fs laser. The frequency f_i of a comb spectral component is represented by expression:

$$f_i = f_{ceo} + i \cdot f_{rep} \tag{1}$$

where i is the number of a comb line (typically in the order of 10^6) and f_{rep}, and f_{ceo} are frequencies typically set in radio frequency (RF) domain, called repetition and offset frequency, respectively. The repetition frequency f_{rep} is indirectly proportional to the period of the train pulses and the offset frequency f_{ceo} is caused by phase-shifts between envelope of the pulses and their carrier wavelength [11]. The offset frequency has to be retrieved from comb spectrum by self-referencing method called as the f-2f interferometric technique [5]. The offset frequency f_{ceo} is as well as the repetition frequency f_{rep} phase locked to the stable oscillator or atomic clocks RF signal by a servo-loop. The result is the optical comb frequency spectrum with relative stability of all of frequency components coupled to the relative stability of the RF oscillator or atomic clocks (thus more than 10^{-14}).

B. Fabry-Perot cavity

The optical resonator FPC consists of two mirrors separated by the geometrical distance L_{cav}. This length is represented by the spacer made from the low-expansion material. It transfers only optical frequency ν fulfilling the relation:

$$f_m = m\nu_{FSR} = \frac{mc}{4nL_{cav}}. \tag{2}$$

where ν_{FSR} is FSR of FPC, *m*-th is a longitudinal mode of the FPC in confocal geometry with mirrors separated by L_{cav}, *c* is speed of the light, *n* is the refractive index of air inside the cavity.

C. Measurement of cavity length

The comb spectrum is transmitted through FPC if some of optical frequency spectral lines f_i (1) meet the resonance frequency from (2). Reasonable number of lines transmit only than FRS of the FPC is an integer multiple of f_{rep} thus: $\nu_{FSR} = x \cdot f_{rep}$ [12]. The optical signal at the output of the FPC depends on the distance between mirrors in FPC. Then the optical output of the FPC contains number of separated resonance lines [13]. Otherwise the optical output from FPC represents the similar signal to the white light continuum and the signal doesn't contain any resonance peaks. These problems can be solved by The use of a single-mode stable laser has one resonance peak per FSR of the cavity. The use of tunable laser source is advantageous for monitor of small changes of length. Optical frequency of the closest optical frequency comb line is used as a precise frequency reference to the tunable laser source. The optical frequency of the tunable laser referenced to optical comb line (1):

$$\nu_{opt} = f_{ceo} + i \cdot f_{rep} \pm f_{beat} \tag{3}$$

where f_{beat} is the beat frequency between the closest optical comb spectral line and the tunable laser locked to the FPC. The beat frequency polarity can be easily evaluated from the nature of temperature length variations with respect to the beat frequency f_{beat}. Let us equal f_m (2) to ν_{opt} (3), then:

$$\nu_{opt} = f_m = f_{ceo} + i \cdot f_{rep} \pm f_{beat} = \frac{mc}{4nL_{cav}} \tag{4}$$

Extracting the exact length of the FPC from (4) then:

$$L_{cav} = \frac{mc}{4n\,(f_{ceo} + i \cdot f_{rep} \pm f_{beat})} \tag{5}$$

Because *i* and *m* are integer constants and *c* is exact speed of the light in vacuum, the exact length L_{cav} of FPC is determined by frequencies f_{ceo}, f_{rep} and f_{beat} . Repetition and offset frequencies are controlled by RF reference by f-to-2f stabilization. The influence of refractive index of air on the result is suppressed by placing the FPC into the vacuum chamber where refractive index equals 1:

$$L_{cav} = \frac{mc}{4(f_{ceo} + i \cdot f_{rep} \pm f_{beat})}. \tag{6}$$

The FPC mirror distance is defined by f_{beat} frequency between optical frequency comb and the tunable laser.

FPC of initial length L_{cav0} at temperature t_0 is enlarged to length L_{cav1} at temperature t_1 characterized by CTE - α:

$$L_{cav1}(t_1) = [1 + \alpha \cdot (t_1 - t_0)] \cdot L_{cav0}(t_0) \tag{7}$$

Relative changes of cavity length caused by temperature (7):

$$\alpha(\Delta t) = \frac{\Delta L_{cav}}{\Delta t} = \frac{\Delta f_{beat}}{\Delta t \cdot (f_{ceo} + i \cdot f_{rep} \pm f_{beat})} \tag{8}$$

CTE of low-expansion materials reaches values down to $0.01 \cdot 10^{-6} K^{-1}$ [2,3]. Precision of the RF stabilized oscillator 10^{-12} is equivalent to temperature change in order of 0.1 mK. So temperature instabilities are easily detected.

Next, the integer number *i* (the number of the comb line components) is last unknown variable that has to be defined for evaluation of α.To determine the *i* integer of the comb line has to be measured by "the ruler" with better resolution than by ν_{opt} / f_{rep} . The number *i* characterizing the closest component to the tunable laser frequency is evaluated by tuning the laser frequency f_{cw} (Fig. 1):

$$\Delta f = f_{cw} - (f_{ceo} + i \cdot f_{rep}). \tag{9}$$

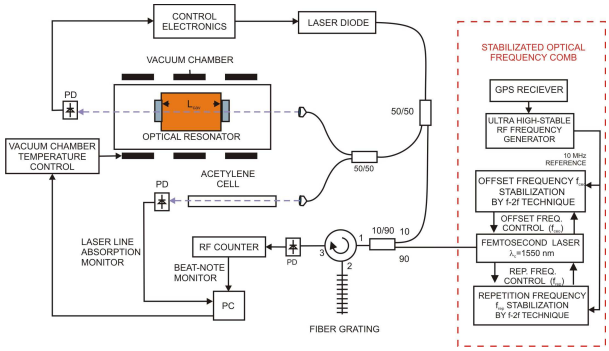

Figure 1. Scheme of the optical setup for measurement of expansion coefficient of Zerodur material represented by optical resonator using stabilized optical frequency comb and additional laser diode and acetylene cell for exact length evaluation.

The number of frequency comb component *i* can be extracted by tuning at center of absorption lines f_{ac1}, f_{ac2}, f_{ac3}, etc. (*j*=1,2,3,…) of absorption gas (for ex. Acetylene):

$$\Delta f_{acj} = f_{acj} - (f_{ceo} + k \cdot f_{rep}) \tag{10}$$

With known repetition and offset frequency of the frequency comb and measuring the beat frequency between the laser diode and the frequency comb we can easily evaluate CTE of the FPC spacer from (8).

III. Experimental Set-up

Method was verified on Zerodur ceramics tube used as spacer in confocal FPC of 400 MHz FSR. Finesse of the cavity was 339 and mirrors were deposited on the 10 mm thick fused silica substrates are optically connected to the Zerodur spacer of 187.5 mm length. The FPC was placed on four points holder in the axis of temperature stabilized stainless steel vacuum chamber evacuated down to 10^{-4} Pa. Temperature stabilization of the vacuum chamber was done by two resistance wires surrounding the chamber and controlled to 0.5 K. The temperature was measured outside the vacuum chamber as well as around the Zerodur spacer by four

temperature sensors. The temperature at the FPC surface was stable down to 0.5 mK for a period of tens of minute.

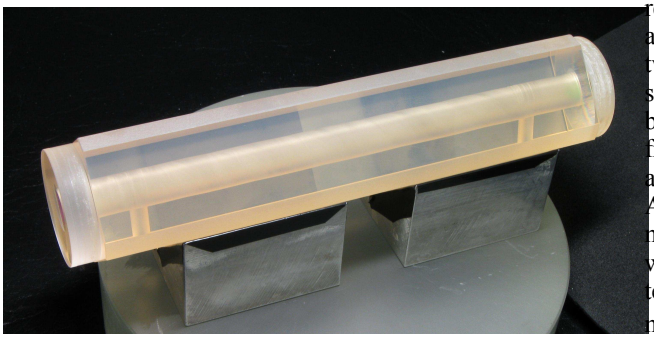

Figure 2. Photo of Fabry-Perot cavity tube with Zerodur spacer and fused silica mirror substrates.

The DFB laser diode works at central wavelength of 1542.14 nm (194.40 THz) and can be tuned by the operating temperature control for more than 2 nm (250 GHz). Another temperature control within the range from -10°C to 80°C was used to increase SNR and the FBG's central filtering wavelength was tuned within the same interval as DFB laser diode. The FBG had 0.186 nm FWHM bandwidth. Optical frequency comb was Er:doped stabilized femtosecond mode-locked laser with 100 MHz repetition frequency and central wavelength at 1550 nm and the fiber spectral output 1500-1600 nm was used. The optical frequencies of the femtosecond mode-locked laser were stabilized by f-2f interferometry [8] to 10 MHz RF reference represented by the temperature stabilized quartz oscillator disciplined by GPS receiver to Cs clock in long term.

The light from the DFB laser diode is mixed with the optical frequency comb fiber output and the beat signal is through the fiber circulator backreflected on the FBG with 0.186 nm (FWHM). Beat frequency between the closest comb components and the DFB laser diode were detected by infrared fast photodetector (PD), counted by a RF counter and recorded by the computer.

Second part of the DFB laser diode output was splitted in 50/50 coupler to the acetylene cell and to the FPC. Infrared PDs monitor absorption at the acetylene cell and the output resonance mode spectrum of the FPC. The absorption cell with the help from optical frequency comb and FPC resonance help to determinate the exact absolute value of the optical frequency of the DFB laser. The DFB tuning range covers the range from P(13) to P(11) $^{13}C_2H_2$ absorption lines [14].

Exact number of a spectral component of the frequency comb closest to the DFB frequency is determined by tuning DFB while monitoring the absorption of acetylene cell and counting repeating beat signal (10).

IV. RESULTS

Our measurement was carried out in temperature stabilized vacuum chamber at 20-30°C. The temperature range was chosen because it is close to the lowest CTE of prefabricated Zerodur material. Signals from PD's are presented in Fig. 3. Intensity of the DFB laser light transmitted through the FPC cavity is represented by the red curve. The data represents detuning of the DFB laser diode frequency from one resonance transmission peak to the closest acetylene absorption line P(11) represented by the green line to another two absorption lines P(12) and P(13) while detune over several resonance mode of FPC (red line). The beat signal between DFB laser diode frequency and the closest optical frequency comb was measured in the same time (blue line) and used for calculation of DFB frequency detuning change. After such evaluation of the k component (10) the long-term measurement at fixed FPC resonance transmission peak FPC was done. Similar measurement was done at various temperatures. Relative length changes of FPC spacer in the measurement temperature range were from $0.8\cdot10^{-7}$ to $5.8\cdot10^{-7}$ and the standard deviation for the data was $2\cdot10^{-9}$. It corresponds to absolute change of 15 to 464 nm in the case of 187.5 mm long FPC with the standard deviation of 0.4 nm. The factory CTE of the Zerodur [2] spacer was $(0.028\pm0.005)\cdot10^{-6}K^{-1}$ at 23°C. Measured CTE within the temperature range was always higher than this value in the range from $0.03\cdot10^{-6}K^{-1}$ even to $0.1\cdot10^{-6}K^{-1}$. According to [15,16] measurement of CTE of Zerodur in this temperature range could have either positive or negative value with zero crossing between 22.5-30°C. Even that the standard deviation of data may seem to be high the resolution of the method is in the order of resolution of the beat frequency counter 1 [Hz] to the optical frequency of the DFB laser - 194.40 [THz] or by the stability of the reference whichever apply first. For FPC with 187.5 mm long spacer it reaches the resolution down to 1 fm.

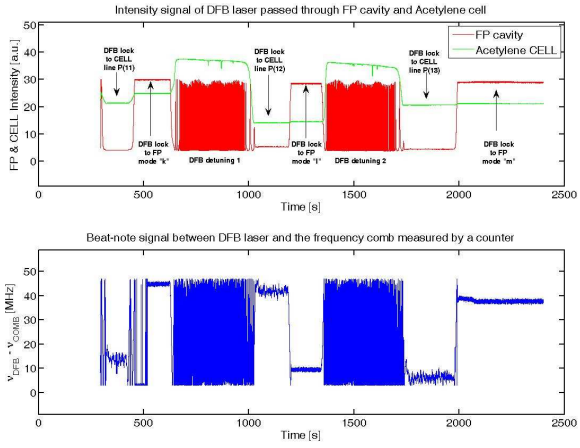

Figure 3. Measurement of DFB laser frequency detuning with from Fabry-Perot cavity mode to P(11), P(12) and P(13) acetylene absorbtion line. Fabry-Perot cavity modes (red line), absorption in acetylene cell (green line). Beat signal between optical frequency comb and DFB frequency.

V. CONCLUSION

We experimentally demonstrated the method to monitor the cavity length changes and expansion coefficient of an

ultra-low expansion material with DFB laser. Optical frequency comb was used as a frequency "ruler" reference. Acetylene cell was used as the coarse reference for finding of the optical comb component.

***Abstract*— We developed a theoretical method within the framework of relativistic many-body theory to accurately treat correlation corrections in atoms with few valence electrons, and applied it to calculate polarizabilities and the blackbody radiation (BBR) shifts of atomic frequency standards. We have performed the calculations of the BBR shifts in B^+, Al^+, and In^+ that allowed to reduce the ultimate uncertainties due to this effect at room temperature to 10^{-18} level for B^+ and In^+ and to 4×10^{-19} for Al^+. These uncertainties approach recent estimates of the feasible precision of currently proposed optical atomic clocks.**

I. Introduction

Recent advances in atomic and optical physics led to unprecedented improvements in the accuracy of the optical frequency standards. In 2010, the construction of optical clock with a fractional frequency inaccuracy of 8.6×10^{-18}, based on quantum logic spectroscopy of an Al+ ion, was reported [1]. Development of more precise frequency standards will open ways to more sensitive quantum-based standards for applications such as measurements of the fundamental constants and testing of physics postulates, inertial navigation, magnetometry, and tracking of deep-space probes.

The operation of atomic clocks is generally carried out at room temperature, whereas the definition of the second refers to the clock transition in an atom at absolute zero. This implies that the clock transition frequency should be corrected in practice for the effect of finite temperature of which the leading contributor is the blackbody radiation (BBR) shift. Experimental measurements of the BBR shifts are difficult.

While the BBR shift in Al^+ frequency standards is anomalously small, its contribution becomes significant at the current level of precision. The BBR frequency shift of the clock transition can be related to the difference of the static electric-dipole polarizabilities between the final and initial clock states. Owing to severe (98%) cancellation between the static polarizabilities of the two clock states in this frequency standard, accurate calculation of the BBR shift in Al^+ is very difficult and required development of new all-order methodology. We developed a theoretical method within the framework of relativistic many-body theory to accurately treat correlation corrections in atoms with a few valence electrons [2]. This method combines the all-order approach currently used in precision calculations of properties of monovalent atoms with the configuration-interaction (CI) approach that is applicable for many-electron systems. In this work, we have extended this method to accurate calculation of the ground and excited state polarizabilities of divalent ions. The resulting polarizabilities are used to evaluate the BBR shifts at 300K in the $ns^2 - nsnp\ ^3P_0$ clock transitions in Al^+, B^+, and In^+. Frequency-dependent corrections are also evaluated and found to be negligible in all three cases.

II. Calculation of polarizabilities

The BBR frequency shift of the clock transition can be related to the difference of the static electric-dipole polarizabilities between the clock states, $\Delta\alpha_0$, by [3]

$$\delta\nu = -\frac{1}{2}(831.9\ \mathrm{V/m})^2 \left(\frac{T(K)}{300}\right)^4 \Delta\alpha_0(1+\eta), \quad (1)$$

where η is a small dynamic correction due to the frequency distribution and only the electric-dipole transition part of the contribution is considered. The magnetic-dipole contributions are suppressed by a factor of α^2 [3]. We estimated that the contribution to the Al^+ BBR shift due to the $^3P_0 - ^3P_1$ M1 transition is below 10^{-5} Hz and is negligible at the present level of accuracy. The evaluation of the dynamic correction η requires the knowledge of the electric-dipole matrix for transitions giving the dominant contributions to the polarizabilities.

In the combined CI + all-order approach used in the present work, core excitations are incorporated in the CI method by constructing an effective Hamiltonian using fully converged all-order excitation coefficients. This approach is described in detail in [2]. Its application to the polarizability calculations is described in [4]. The valence part of the polarizability is determined by solving the inhomogeneous equation of perturbation theory in the valence space [5]. The ionic core part of the polarizability is calculated separately in the random-phase approximation (RPA). The small valence-core (VC) term that corrects the ionic core polarizability for the presence of the valence electrons is also calculated in the RPA. DHF calculations are carried out as well for both of these contributions to evaluate the uncertainty associated with this term.

We note that the ionic core contribution is the same for both clock states and so it does not contribute to the BBR shift. On the other hand, the VC contribution is different for the two clock states. It is negligible for B^+. It is the largest for the

$^3P_0$ polarizability of In^+ to which it contributes only 0.5%. However, its contribution to the BBR shift is much larger, 1.8% and 5% in Al^+ and In^+, respectively, owing to the large degree of cancelation between $^1S_0$ and $^3P_0$ polarizabilities. We estimate the dominant uncertainty in this term as the difference of the DHF and RPA values, and assume that all other uncertainties do not exceed this dominant uncertainty. Adding these two uncertainties in quadrature, we estimate that VC term leads to the 0.6% and 2% uncertainties in the BBR shifts for Al^+ and In^+.

In order to establish the accuracy of our approach to the calculation of valence polarizability, we also perform the CI and CI+MBPT [6] calculations carried out with the same parameters (configuration space, basis set, number of partial waves, etc.). No core excitations are added in the pure divalent CI approach. Comparison of the CI, CI+MBPT, and CI+all-order values allows us to evaluate the importance of the various correlation corrections, therefore establishing the upper bound on the uncertainty of our calculations. Unless stated otherwise, we use atomic units (a.u.) for all matrix elements and polarizabilities throughout this paper.

Tables I and II presents the comparison of the experimental energies of Al^+, B^+, and In^+ with those calculated in the CI, CI+MBPT, and CI+all-order approximations. Relative differences of the B^+, Al^+, and In^+ calculated energy levels and NIST data (in %) are presented. CI, CI+MBPT, and CI+all-order data are listed in columns labeled "CI", "CI+MBPT", and "CI+All", respectively. Experimental energy levels are listed for reference in cm^{-1}. Two-electron binding energy is listed in the first row. All other levels are counted from the ground state. Significant improvement of the energy values is observed for Al^+ and In^+ with the CI+all-order method as expected owing to the more complete inclusion of the correlation corrections in comparison with the CI and CI+MBPT approaches. The CI+all-order energies are within a few cm^{-1} of the experimental values for B^+ and Al^+ for most of the levels. The accuracy of the In^+ energy levels is sufficient for the purposes of the present work, i.e. replacing our theoretical energies by the experimental values in the dominant polarizability contributions leads to only 1% change in the value of the BBR shift. The accuracy of the CI+MBPT method for B^+ is already at the level of our numerical precision for most of the transitions.

The breakdown of the contributions to the $ns^2\ ^1S_0$ and $nsnp\ ^3P_0$ polarizabilities α of B^+ ($n = 2$), Al^+ ($n = 3$), and In^+ ($n = 5$) is given in Table III. Absolute values of the corresponding reduced electric-dipole matrix elements

are listed in column labeled "D" in a_0e. The ionic core polarizability and VC term that corrects it for the presence of the valence electrons are listed in rows labeled "Core" and "VC". Final polarizability values are listed in rows labeled "Total". We subtract the values of the terms listed separately in Table III from our total valence polarizability values to obtain the remaining contributions that are listed in the rows labeled "Other". Our dominant contributions for Al^+ are in excellent agreement with CI calculations with a semi-empirical core potential (CICP) of Mitroy *et al.* [7].

The oscillator strengths f_{gn} can be obtained from the reduced matrix elements by using

$$f_{gn} = \frac{2D_{gn}^2 \Delta E_{ng}}{3(2J_g+1)}, \tag{2}$$

where $\Delta E_{ng} = E_n - E_g$ and $J_g = 0$ for the present clock states.

We investigate the uncertainty due to the inclusion of the core excitations by comparing the difference $\Delta\alpha_0$ calculated in the CI, CI+MBPT, CI+all-order approximations. These results are summarized in Table III. We find that the entire contribution of core excitations to the BBR shift, estimated as the difference of the $\Delta\alpha_0$ CI+all-order and CI values is only 3%, 5%, and 16% for B^+, Al^+, and In^+, respectively. The difference between CI+MBPT and CI+all-order values is 0.4% for B^+ and Al^+, and 1.7% for In^+. Therefore, we place an upper bound on the uncertainty of our BBR values at 10% for all three cases.

III. BBR SHIFTS

Our final results are summarized in Table IV [4], where we list the polarizability difference $\Delta\alpha_0$, BBR shift at $T = 300K$, relative BBR shift $\Delta\nu_{\rm BBR}/\nu_0$, and the uncertainty in the relative BBR shift for B^+, Al^+, and In^+. We find that dynamic corrections are very small for both states and nearly cancel each other contributions. Their contributions to BBR shift are negligible for all three ions. Our BBR shift value in Al^+ $\Delta\nu_{\rm BBR} = -0.00426(43)$ Hz is in agreement with CICP value of Mitroy *et al.* [7] and recent coupled-cluster calculation [8]. It is also consistent with experimental measurement $\Delta\nu_{\rm BBR} = -0.008(3)$ Hz from Ref. [9]. The values of η for Al^+ are in agreement with [7].

TABLE IV

BBR SHIFTS AT $T = 300K$ IN B^+, Al^+, AND In^+. $\Delta\alpha_0$ IS GIVEN IN a_3^0; THE BBR SHIFTS $\Delta\nu_{\rm BBR}$ ARE GIVEN IN HZ.

Ion	$\Delta\alpha_0$	$\Delta\nu_{\rm BBR}$ (Hz)	$\lvert\Delta\nu_{\rm BBR}/\nu_0\rvert$	Uncertainty
B^+	-1.851	0.0159(16)	1.42×10^{-17}	1×10^{-18}
Al^+	0.495	-0.00426(43)	3.8×10^{-18}	4×10^{-19}
In^+	2.01	-0.0173(17)	1.36×10^{-17}	1×10^{-18}

IV. CONCLUSION

In summary, we have performed the calculations of the BBR shifts in B^+, Al^+, and In^+ that allowed to reduce the ultimate uncertainties due to this effect at room temperature to 10^{-18} level for B^+ and In^+ and to 4×10^{-19} for Al^+. These uncertainties approach recent estimates of the feasible precision of currently proposed optical atomic clocks [10]. This work demonstrated the success of the CI+all-order method in accurate determination of the polarizabilities and BBR shifts.

***Abstract*—This paper presents recent work on ferroelectric-piezoelectric lead zirconate titanate (PZT) RF MEMS resonators. Several research topics are introduced including design modifications that improve out-of-band rejection by 35dB, a demonstration of a high rejection (~117dB) parallel resonant mode with DC bias tunable rejection, a MEMS support design for the mitigation of anchor loss, and a numerical electrode shaping design technique that permits the excitation of arbitrary modes in arbitrary geometries.**

I. Introduction

Piezoelectric transduction via PZT offers a number of unique advantages for RF MEMS applications. It offers extremely low power consumption and low voltage device operation [1]. CMOS compatible voltages in RF MEMS switches have been previously demonstrated [2]. Due to the strong piezoelectric effect in PZT, actuators are capable of very large force generation and or large displacements. This provides advantages in devices like RF MEMS switches where large forces lead to low contact resistance/insertion loss and improved lifetime and large displacements lead to improved high frequency isolation. These actuation capabilities are a consequence of the large electromechanical coupling factors and piezoelectric coefficients of the material. PZT has coefficients that are generally an order of magnitude larger than those of AlN or ZnO [3]. PZT is not only a piezoelectric material but also possesses ferroelectric properties. The high electric field response in ferroelectrics permits the tuning of the dielectric, elastic, piezoelectric, and coupling factors of PZT [4]. This permits the advantageous DC-bias tuning of frequency and motional impedance in RF MEMS resonators based on ferroelectrics like PZT [5].

Thin film piezoelectrics tend to have much higher breakdown strengths than their bulk counterparts. This permits the safe application of actuation or bias fields that are well in excess of the coercive field of the PZT. Consequently, significant high electric field nonlinearity and hysteresis are observed in thin films that are rarely encountered in bulk PZT actuator applications. At these high electric fields, PZT exhibits the traditional ferroelectric hysteresis loop relating electric polarization and field. The dielectric and piezoelectric coefficients display a similar nonlinear response [6]. The combination of the piezoelectric and dielectric nonlinearity leads to tuning of the various quasi-static electromechanical coupling factors; such that high DC biasing provides significant improvements in electromechanical coupling.

Despite the long and successful history of bulk PZT resonators [7]; drawbacks to PZT, particularly at higher frequency operation, have discouraged the exploitation of this strong piezoelectric in thin films and MEMS. PZT does have high mechanical and dielectric loss and the temperature stability of the dielectric, ferroelectric, and piezoelectric properties can pose challenges. Despite these challenges, there exist several key and unique advantages for utilizing PZT in RF MEMS resonator applications. The strong piezoelectric coefficients and material coupling factors permit wide-bandwidth and low motional resistances in filters and high efficiency and voltage gain in electromechanical MEMS power transformers [8]. The high field ferroelectric response permits interesting opportunities to tune and/or trim resonators with DC bias. High levels of device integration have also been demonstrated in PZT RF MEMS, including one of the first demonstrations of monolithically integrated switches and filters [9]. Previous work demonstrated the advantages of integrating thin film PZT with high mechanical quality factor single crystal silicon, or PZT-on-Si resonator technology, to create an effective thin film composite piezoelectric material [5]. By utilizing the PZT as the transducer and the silicon as the primary resonator structure, favorable tradeoffs exist between the mechanical quality factor of the silicon and the effective coupling factor of the resonators. Despite the reduced effective coupling, the improvements in quality factor generally lead to not only higher Q but also to reduced motional resistance.

The remainder of the paper introduces some recent research in PZT-based RF MEMS resonators. Section II addresses the improvement of out-of-band rejection in two-port PZT resonators. Section III presents the demonstration of a high rejection (~117dB) and tunable parallel resonant mode. Section VI introduces a novel MEMS support design technique for the mitigation of anchor loss. Section V introduces a numerical electrode shaping design technique that permits the excitation of arbitrary modes in arbitrary geometries and Section VI concludes the paper.

II. Improving Out-of-Band Rejection

Improving out-of-band rejection in resonant filters is necessary for reducing the interference from unwanted signals. An illustration of a previously designed length extensional mode, PZT-on-silicon resonator design is shown in Fig. 1(a). A high isolation device type is also illustrated where the drive

978-1-61284-110-6/11/$26.00 ©2011 IEEE

and sense common bottom electrode is etched with the fabrication process previously developed [10]. This PZT/Pt etch feature is illustrated in Fig. 1(b). Equivalent circuit models, including the device parasitics, are shown in Fig. 2(a-b). These correspond to the illustrations in Fig. 1(a-b), respectively. The resistance, R_g, arising from the routing of the bottom platinum in the tethers to the ground plane is proportional to the tether length/width. It is important to note that this resistance has a significant effect on the stop-band performance of the resonant device. This R_g value is particularly important to consider with the high dielectric constant of PZT. At high frequencies, current can flow out of node A through the sense capacitance, due to the low impedance of C_{sense}, manifesting itself as "feed-through" current in the frequency response.

Three fabricated device types are under consideration. The first (type-I) is a high feed-through device with R_g = 1.7 Ω, the second (type-II) is a high feed-through device with R_g = 15 Ω, and the third (type-III) is a low feed-through, high isolation device with R_g = 1.7Ω. The length, L_{elec}, width, w_{elec}, of both devices' top electrodes (Fig. 1(b)), and gap in the PZT and platinum, w_{gap}, are 196 µm, 14 µm, and 4 µm, respectively. The device length, L_{tot}, and width, w_{tot}, are 200 µm and 40 µm, respectively. The platinum thickness is 100 nm, the device silicon is 10 µm, and the PZT is 0.5 µm. The measured S-parameter (S_{21}) frequency responses for the device types in the 1-200MHz range are shown in Fig. 3. The devices have been de-poled to illustrate the purely electrical feed-through. An improvement of 35dB (type-I versus type-III) in the stop-band is measured at 200MHz. A 16 dB degradation in the stop-band rejection, consistent with theory, results for the device with larger R_g (15 Ω versus 1.7 Ω). This confirms the importance of this parasitic as a relevant device parameter. Further minimizing this parasitic may be achieved through modified tether design (Section IV) and fabrication steps to improve both resonator insertion loss as well as high frequency stop-band rejection.

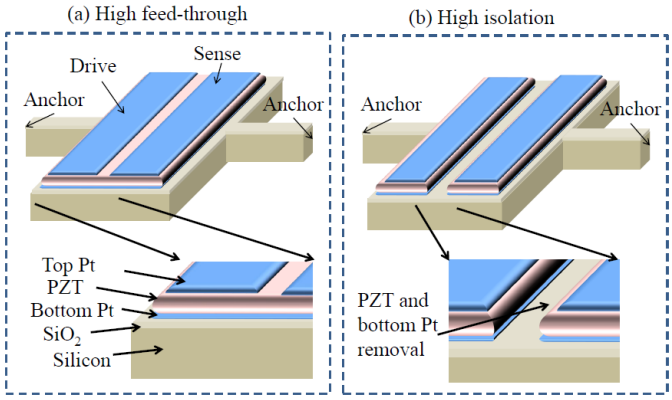

Figure 1: (a) 3D illustration of high feed-through, low isolation resonator device fabricated through a PZT-on-silicon process [10]. (b) Illustration of the high isolation device where PZT and the bottom platinum are etched in the region between the drive and sense electrode.

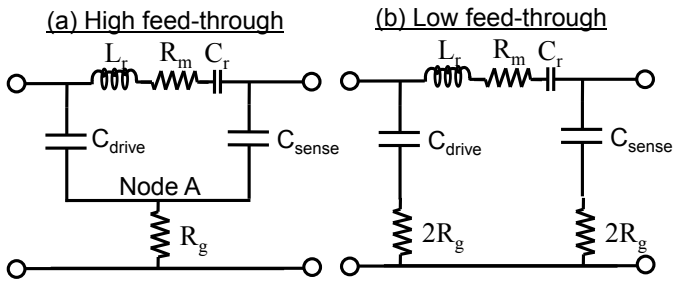

Figure 2: (a) Equivalent circuit of the two port resonant device of Fig.1(a) including the routing parasitics and electrically equivalent representation of R_m, C_r and L_r of the mechanical response (b) equivalent circuit of device with etch feature as illustrated in Fig. 1(b).

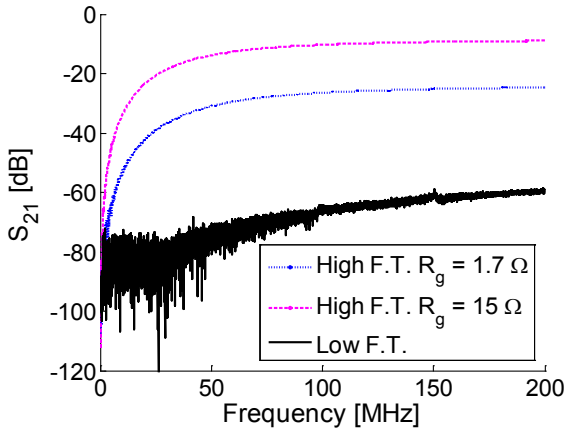

Figure 3: Frequency response of device with (low F.T.) and without (high F.T.) the PZT/Pt cut on the resonator.

III. High Q Parallel Resonances

In addition to the utility of RF MEMS resonators for band-pass filter applications; they may also be used as high rejection, parallel resonators, in band-stop or notch filter applications. The following illustrates that the existence of high rejection, parallel resonances are a consequence of the cancellation of motional and feed-through currents. For the current analysis, the following frequency dependent impedances will be used: $Z_r(s)$, the motional impedance of the resonator, $Z_d(s)$, the impedance of the drive capacitance, $Z_s(s)$, the impedance of the sense capacitance, and $Z_L(s)$ the load impedance of the measurement instrument (50 Ω). The drive and sense capacitances are illustrated in Fig. 1(a). The complex variable, s, is represented by $j\omega$, where ω is the frequency in [rad / sec]. Assuming $Z_r(s) >> Z_L(s)$, the ratio of the motional current, $i_r(s)$, to feed-through current, $i_f(s)$, current is

$$\frac{i_r(s)}{i_f(s)} \approx \frac{1}{Z_r(s)}\left(Z_d(s)\left(1+\frac{Z_s(s)+Z_L(s)}{R_g}\right)+1\right) \quad (1)$$

The conditions for parallel resonance are achieved with +/- 180° phase and unity magnitude for the above expression which leads to current cancellation of the motional with the feed-through current.

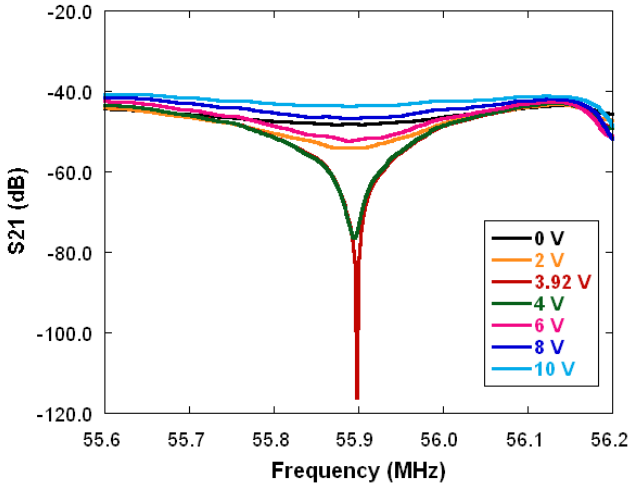

Figure 4: Frequency response of device with a high feed-through design under various DC bias conditions. High rejection parallel resonance is observed when the resonator motional exactly cancels the feed-through current.

For a device similar to that described above in Fig. 1(a), a high rejection parallel resonance mode was identified. The measured frequency response is shown in Fig. 4. A DC bias is superimposed on the AC signal at both the input and output ports using bias-tees. A high isolation of 117 dB is measured with a 3.92V DC bias at 55.9 MHz. The pass-band insertion loss is measured as 45dB at 55.6 MHz. Through DC bias tuning of the ferroelectric PZT properties, a quasi-infinite isolation can be achieved through proper design of the resonator motional impedance and the finite resistance to ground, R_g, which was introduced in Section II.

IV. Anchor Loss Reduction

Anchor loss has long been known to be a potential limiting mechanical loss mechanism. Integration of PZT with single crystal silicon enables dramatically higher quality factors than are achievable with PZT alone and anchor loss may eventually limit resonator quality factors. The common solution in MEMS resonators and older wire supported quartz and ceramic resonators is quarter-wave acoustic matched support design [11]. Quarter-wave support design views the support structure as a mechanical impedance transformer [12]. The support should accommodate some velocity at the attachment location between the tether and the resonator (drive point) and provide a large mechanical impedance at the attachment location with the substrate (anchor point). However, in an actual continuous elastic structure, there is always the potential for stress concentration at the anchor point. Therefore anchor loss can be further reduced by minimizing the amount of strain energy present near the anchor point that could potentially radiate into the substrate.

A conservative estimate of the anchor loss quality factor (anchor Q) may be obtained by assuming all of the strain energy present at the anchor point will be completely radiated during a given vibration cycle. This implies that no acoustic energy is reflected back into the resonator due to scattering of

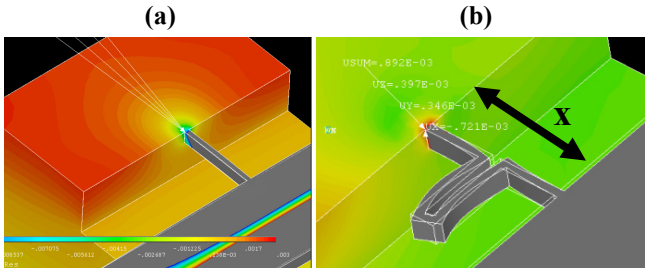

Figure 5: (a) Displacement modal analysis of a 200μm x 40μm free-free beam resonator operating at the fundamental length extensional mode (23.1 MHz). The resonator is supported by a straight 20μm long x 2μm wide tether. (b) Modal analysis of the same resonator as in (a) but with an alternative tether design. The beam resonator is visible in the lower right of both figures. The plotting contours highlight the response in the substrate.

acoustic waves radiated during prior vibration cycles. This assumption will result in predicting a lower bound to the quality factor. The anchor Q is merely the ratio of 2π times the stored mechanical energy in the resonator to the acoustic energy radiated into the substrate per period. As strain energy is proportional to the square of the strain, the conservative estimate for the anchor Q is proportional to the inverse of the square of the strain at the anchor point.

In contrast to modeling anchor loss via harmonic analysis [13], modal analysis is far less computationally demanding for the same physical model but only provides relative kinematic and dynamic data. However dissimilar support designs can be compared if the modal data of the two designs are scaled with a consistent normalization scheme; for example by normalizing both modeshapes to unity. The ratio of the squares of the modal strains of the two designs will be equal to the ratio of their anchor Qs (lower bound).

Fig. 5(a) illustrates a typical MEMS straight tether support, and Fig. 5(b) illustrates a potentially more compliant support. The results are from an ANSYS 12.0 FEA modal analysis of the same resonator at its fundamental length extensional mode of 23.1 MHz. As can be seen in Fig.s 5(a-b), the different tethers are experiencing different "local" vibrations, at the identical resonator mode, which provide different anchor loss conditions. The tether in Fig. 5(b) actually has an average absolute value of the relative Von Mises stress at the surface between the tether and the substrate that is 89% lower than that of the straight tether design in Fig. 5(a).

This difference in these tether responses can be understood by considering the frequency response and modal data of the isolated tether. The tether structure behaves essentially as its own resonator with dynamics, partly determined by the boundary conditions imposed by the substrate and resonator, and excitation imposed by the motion of the resonator at the drive point. At a given frequency, the motion of the tether will be some linear combination of the "local" tether modes of vibration. Tether modes with low mechanical impedances at the drive point, subjected to large relevant forces by the motion of the resonator, will be the dominant tether modes governing the dynamics of the tethers, at any given frequency. The goal of any design approach is to determine

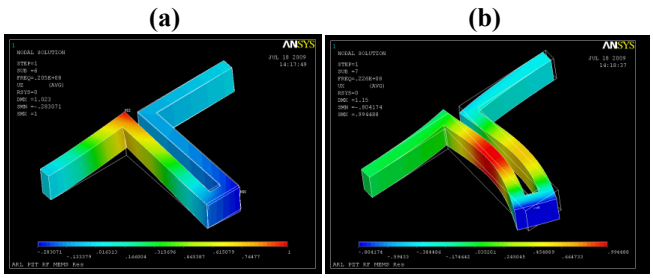

Figure 6: Modal analysis of isolated tether under boundary conditions consistent with substrate and resonator attachments impedances. The plotted response is the vector-sum of displacements (unity normalized).(a) 21.2 MHz tether mode (b) 22.6 MHz tether mode.

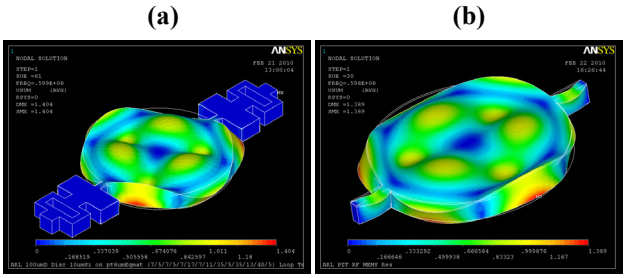

Figure 7: Modal analysis of 100µm diameter PZT-on-Si disc resonator operating at 60 MHz high order disc flexure mode. (a) New transformer design (b) 20µm long x 5µm wide straight tether design.

what tether modes will dominant the dynamics of the tethers at the desired resonator operating frequency. Generally, the supports can be designed by considering the isolated tether clamped at the anchor point and then by defining mechanical boundary conditions at the drive point that are compatible with the relevant mechanical impedances presented by the resonator.

For example, the drive point of the length extensional mode free-free beam resonator of Fig.s 5(a-b), present x-direction finite displacements to the tethers. Consequently, the relevant mechanical impedance is that of the ratio of the x-direction translational velocity to axial forces in the same direction. The isolated tether was simulated with a clamped boundary condition at the anchor point and the drive point was constrained to only permit x-direction displacements.

Fig. 6(a) and Fig. 6(b) illustrate two modeshapes of the tether from Fig. 5(b) that have resonant frequencies within a few MHz of the main free-free resonator frequency (23.1 MHz). The mode in Fig. 6(a) displays a much higher mechanical impedance (less motion at the drive point – right side of tethers in Fig. 6) than the mode in Fig. 6(b). Comparison of Fig. 6(b) with Fig. 5(b) reveals that the 22.6 MHz isolated tether mode is the dominant "local" tether mode present in the tether at the resonators resonant length extensional mode of 23.1 MHz.

Utilizing this approach for design involves determining a desired resonator geometry and mode, determining the relevant mechanical impedances of the tether attachment locations, and simulating a given tether design with the appropriate boundary conditions. The average values of the stresses on the surface between the substrate and the tether (anchor surface) are calculated and compared for the various tether modes. Once a low average stress mode is selected, the tether dimensions are resized so that it is the dominant local tether mode at the desired resonator frequency.

This technique was used to design the resonator support seen in Fig. 7(a). To compare this design with a typical MEMS straight tether design, a 20µm x 5µm straight tether (Fig. 7(b)) was simulated with a 100µm diameter silicon disc resonator with a similarly sized new mechanical impedance transformer design. The tether dimensions were fixed without constantly matching for each resonator mode to assess the bandwidth sensitivity of the designs. The average

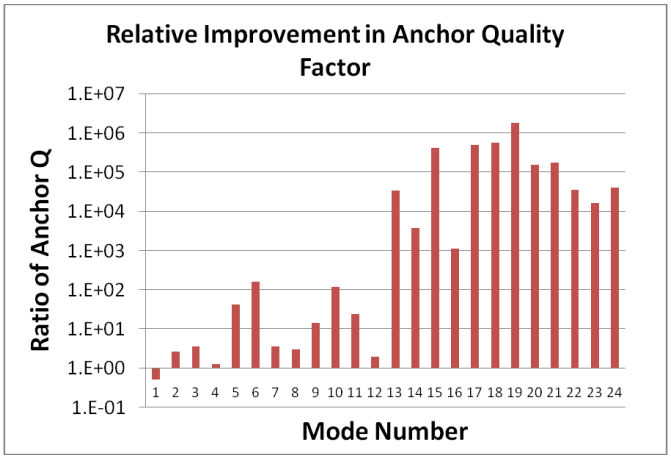

Figure 8: Plot of anchor Q ratio (mechanical transformer design Q / straight tether design Q) for the first 24 disc modes. The anchor Q ratio is the ratio of the squares of the average anchor surface stresses.

of the absolute value of the Von Mises stress on the anchor surface was calculated for each mode in each case. Fig. 8 plots the ratio of the anchor Q (lower bound) for the straight and transformer tether designs for the first 24 disc modes. In all but the first case, there are multiple order of magnitude improvements in the anchor Qs between the two designs, particularly for higher frequency modes. Fig. 7(a-b) plots the modal displacements for an example 60 MHz disc mode. The improved theoretical performance of the transformer tether design is apparent between Fig. 7(a) and 7(b) where the transformer tether exhibits virtually no displacements. Nearly all of the disc modes from about 15 MHz through ~200 MHz (upper frequency limit of simulation) display similar anchor performance as Fig. 7(a). The predicted performance difference suggests that the transformer based design dramatically reduces the anchor loss, is less sensitive to the matching requirements of quarter-wave designs (superior performance over a wide range of frequencies without resizing), and permits larger geometries that can reduce the tether parasitics described in Section II.

V. ELECTRODE SHAPING

The drive to achieve insertion losses and quality factors consistent with commercializing MEMS resonator technologies have led to a research focus on minimizing motional resistances and maximizing quality factors. In addition to achieving further improvements in these metrics, there remains a need to improve the suppression of spurious vibrational modes, increase resonant frequencies, improve power handling and linearity, and achieve wider bandwidth resonators for band select filter applications. The proper design of the resonator electrodes to selectively excite and detect desired modes, or "electrode-shaping", can provide improvements in these performance metrics. There has been an extensive body of research in electrode-shaped transducers, particularly for applications in active vibration control of structures [14].

Optimal excitation and detection electrodes may be analytically derived for simple one-dimensional modes by utilizing the orthogonality property of the vibrational modeshapes [15]. However, extending this technique to more complicated modes is difficult but extending the theory to higher dimensional modes, such as those existing in discs, poses considerable complications. In addition, to determine electrode-shapes in arbitrary cases, numerical techniques are required to treat issues such as nontrivial geometries, modes not conveniently described by analytical models, deformation coupling effects in asymmetric composites, anisotropic material properties, and the influence of non-optimal tether conditions on the modeshapes.

An alternative to the traditional approach is to determine the local suitability of placing an electrode on the resonator. The electrode shapes are then ascertained from maps of this local determination of electrode placement. For excitation, maximizing the local strain leads to maximizing the local contribution to the lumped equivalent excitation force, or modal force. Therefore, we may determine the local suitability of electrode placement by considering strain compatibility between the excited piezoelectric and the desired mode at each location on the resonator. The mode is excited locally when the piezoelectrically induced stresses are consistent with the modal stresses; for example when the piezoelectric material is assumed to be in compression, it will excite regions of the resonator for modes where that location is also simultaneously in a state of compression.

This technique does not necessarily maximally excite the desired mode or maximally suppress unwanted modes, but rather determines electrode shapes that ensure the desired mode is excited and detected. For this scenario, the excitation electrode shape for a particular mode may be determined by finding those locations where the e_{31} and e_{32} piezoelectric stress constants both excite or inhibit the mode. For PZT, these are the locations where the two modal principle stress components have the same sign. For locations where the two modal principle stress components have dissimilar signs, some degree of force cancellation occurs and these locations are neglected. The determination of the detection electrode shape consists of solving the constitutive equation for the direct piezoelectric effect locally for the differential of the induced charge.

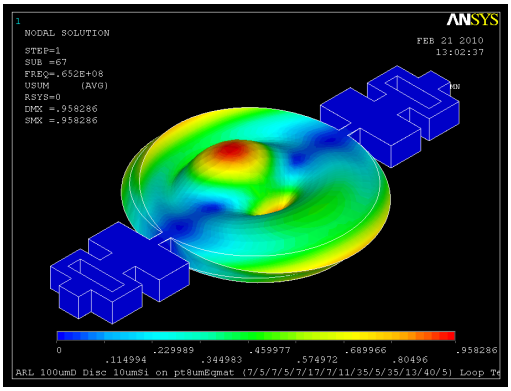

Figure 9: FEA modal analysis of an example electrode-shaped device, a high order flexure disc mode (100μm diameter). The plotted response is the vector-sum of displacements (unity normalized).

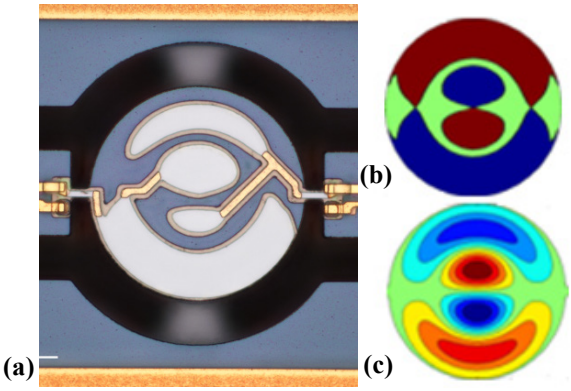

Figure 10: (a) Micrograph of the fabricated two-port PZT-on-Si disc resonator electrode-shaped for the mode illustrated in Fig. 9. The intended excitation port is on the left side of the image (b) Model result for excitation electrode shape. (c) Model result for detection electrode shape.

This technique was implemented with numerical modal analysis in ANSYS 12.0, MATLAB data processing and scripted automatic CAD generation. To validate the technique, sixteen different disc modes were designed as two-port devices and characterized. The device fabrication and layer thicknesses were previously described in Section II. The fabricated resonators were tested in an RF probe station at atmospheric pressure. Full S-parameter matrices were extracted for each resonator using a Rohde & Schwarz ZVB vector network analyzer.

Fig. 9 illustrates the modeshape of an example device, a high order flexure mode. Fig. 10(a) is a micrograph of the fabricated device; Fig. 10(b) displays the results of the electrode-shaping technique for the excitation electrode; and Fig. 10(c) displays the results of the technique for the detection electrode for the two-port devices. The red and blue regions of Fig. 10(b) correspond to the two possible excitation electrode locations. These locations correspond to either tensile or compression regions of the modal analysis simulation and either location may be chosen. The red and blue graded regions visible in Fig. 10(c) display the locations for the detection electrode. These locations correspond to either positive or negative charge regions of the modal analysis simulation and again, either may be chosen. However, in both the excitation and detection cases, electrodes

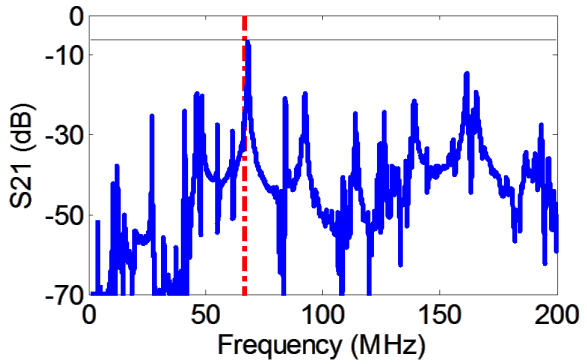

Figure 11: Experimental results for the transmission frequency response of the device shown in Fig. 10(a). The dashed red line identifies the design frequency.

that overlap the two different regions will experience some degree of force or charge cancellation, respectively. Fig. 11 displays the frequency response of the measured forward transmission coefficient S_{21} for the device shown in Fig. 10(a), displaying an unmatched (50Ω terminated) insertion loss of 6.6 dB. The dashed red line indicates the design resonant frequency for the intended mode at 68 MHz. The proximity of the lowest loss mode to the design frequency suggests the electrode shape is successfully exciting the desired mode.

To more fully characterize the electrode-shaped resonators, the measured S_{21} peak values within ±4% of *each* design frequency were determined for *each* resonator. The difference between the peak S_{21} of a given design and the average of all of the other resonators, within the same ±4% search window, provides a measure of the how well a particular electrode-shape is performing. Fig. 12 is a stem plot of this difference for each of the 16 different electrode designs for the disc resonators. The average across the different disc designs yields an average improvement in S_{21} for the shaped designs of 18.1 dB and a maximum improvement of 44.3 dB.

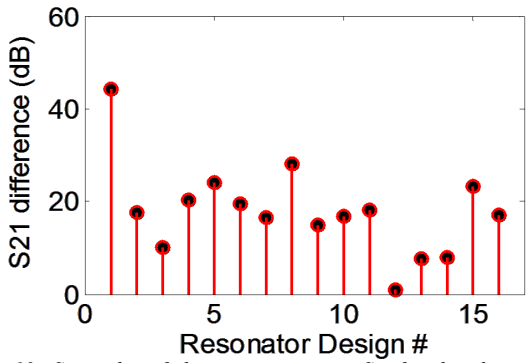

Figure 12: Stem plot of the improvement in S_{21} for the electrode-shaped designs, relative to all other electrode designs (same resonator geometry). Each value represents the improvement in insertion loss of that mode relative to the average of the other designs within ±4% of the design frequency.

VI. Conclusions

In summary, this paper introduced several research topics related to piezoelectric-ferroelectric PZT RF MEMS resonators. Significant improvements in out-of-band rejection (>35 dB), consistent with theory, were demonstrated by isolating the bottom electrodes of the excitation and detection transducers of two-port piezoelectric resonators. A high rejection (~117dB) parallel resonant mode was demonstrated with the benefit of the tunable ferroelectric properties of PZT-on-silicon resonators via high field DC bias. A MEMS support design technique, utilizing modal analysis, for the mitigation of anchor loss was presented. A theoretical comparison illustrated mechanical transformer-based tether designs derived from this technique, can provide orders of magnitude lower anchor loss than a more traditional MEMS straight support design. A numerical electrode shaping design technique was demonstrated to permit the excitation of arbitrary modes in disc geometries. The average improvement in S_{21} for the electrode-shaped designs was 18.1 dB relative to all other electrode designs for the same resonator geometry and a maximum improvement of 44.3 dB were demonstrated.

Ultra High Frequency Air/Aluminum Nitride Fractal Phononic Crystals

Nai-Kuei Kuo, Gianluca Piazza

***Abstract*—This paper presents the first design and experimental demonstration of a fractal phononic band gap (PBG) structure in air/aluminum nitride (AlN). The PBG exhibits two frequency band gaps for symmetric Lamb waves centered around 900 MHz and 1.10 GHz, respectively with bandwidths of 11.1% and 9.09% and attenuation as high as 40 dB. The unit cell of the fractal design consists of a center square air scatterer with four scaled-down side squares repeating at its corners. The presence of the side squares effectively shortens the scattering distance between each unit cell and permits the opening of band gaps for higher vibration modes, *i.e.* higher frequencies, for a given minimum feature size. AlN Lamb wave transducers were integrated with the PBG in order to launch acoustic waves into the structure and characterize its performance. This demonstration not only offers the evidence that it is possible to synthesize GHz PBG structures with relatively large feature sizes, but also shows that these devices can be integrated with more established radio frequency microelectromechanical systems (RF MEMS) and ultimately lead to novel all-acoustic signal processors.**

I. INTRODUCTION

Phononic crystals (PnCs) have recently become a very interesting research topic because of the possibility to synthesize novel acoustic functionalities (*e.g.* acoustic isolation and acoustic multiplexing) in a small form factor. Additionally, the use of microfabrication techniques for the making of PnCs has enabled the substantial miniaturization and mass manufacturability of these structures [1,2]. Nonetheless, the goal of utilizing these devices for the synthesis of compact radio frequency (RF) signal processors eventually capable of on-chip acoustic multiplexing and channel selection requires noteworthy advancement of the state-of-the-art. Some PBG-based acoustic devices such as acoustic cavities [3, 4, 5] waveguiding, and focusing [6] have been demonstrated, but very few have been extended to the ultra high frequency range (UHF). Operation in this region of the frequency spectrum is required in order to devise PBG structures applicable to RF systems. Although UHF PBG structures have been previously demonstrated [5], these solutions require extremely small features (< 500 nm), which challenge the reproducible synthesis of high frequency PBGs.

The fractal unit cell design is introduced in this work in an AlN/air structure to address this challenge. A fractal structure is a geometry that repeats its original shape with a scaling factor in a specific pattern. Because of the particular arrangement of the repeating elements, it is possible to reduce the scattering length between adjacent unit cells and effectively attain operation at higher frequency for a larger feature size than a conventional circular PBG topology. In this paper, the operation of an AlN/air fractal PBG around 1 GHz is demonstrated experimentally with a minimum lithographically defined feature size of 700 nm.

II. DESIGN OF THE FRACTAL PBG STRUCTURE

A. *Principle of Operation of the Fractal PBG*

Fig. 1 shows the example of a conventional "T-square" fractal structure and its pattern formation (up to 3 repetitions).

Figure 1. The patterns of a conventional T-square fractal with side square extension up to 3 times.

In this work, the T-square fractal design is employed for the implementation of the PBG structure. However, in order to attain a sufficiently wide frequency band gap, the area of each repeating square is not kept constant, but the center square is made smaller than the conventional T-square design (area scaling of 0.16 instead of 0.25) and the corner squares are scaled to each occupy 0.09 of the unit cell area (the largest square). Only the first pattern repetition is implemented experimentally, since further extension would require the definition of very small features. The PBG structure array is defined in aluminum nitride (AlN), so that direct in-plane

This work was funded by the DARPA CSSA program.

integration with piezoelectric Lamb wave transducers is possible.

In the conventional PBG structure design, the frequency of operation of the band gap is determined by the acoustic wavelength associated with the phonon scattering within the periodic array and is proportional to the unit cell lattice constant, a (Fig. 2). Differently, the presence of the side squares in the fractal PBG structure essentially forms sub-scatterers in each unit cell, which decrease the acoustic wavelength of phonon scattering (Fig. 2).

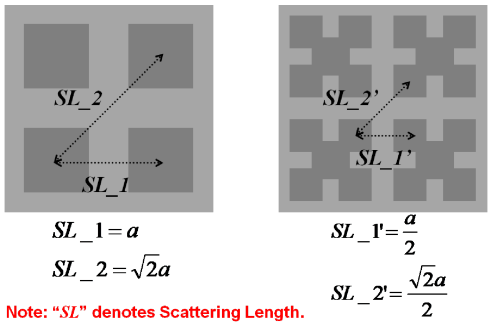

Figure 2. Comparison between the scattering length of a conventional square lattice PBG structure and that of a fractal PBG structure.

Thus, phonon scattering occurs for higher vibrational modes and results in higher frequency band gaps. Because of the extended side squares, the design space of the fractal PBG structure is more complex than then one of a simple circle and it is set by the following parameters: the lattice constant, a, the center square length, c, the side square length, s, and the film thickness, d (Fig. 3).

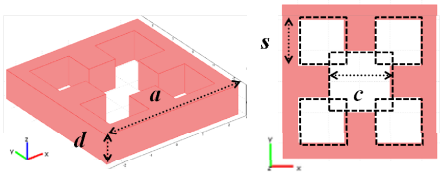

Figure 3. Unit cell of a fractal PBG structure. The main physical parameters that characterize the unit cell are: the lattice constant, a, the center square length, c, the side square length, s, and the thickness, d.

In order to understand the dependence of the fractal PBG on these various parameters, COMSOL® finite element method (FEM) simulation software is utilized to derive the operating frequency and bandwidth of the PBG [7]. The FEM solver is used to derive the eigenfrequencies of the PBG along the first symmetric Brillouin zone of the desired unit cell design. By applying periodic boundary conditions to the unit cell design, it is possible to construct a dispersion relation between the vibration modes and the reciprocal space, which further effectively reveals where frequency band gaps exist (no vibration modes present). An example of such analysis is given in Fig. 4, where the frequency dispersion plot of a conventional square lattice and a fractal PBG structure in AlN with the same periodicity (5 µm) are compared. In Fig. 4, the conventional square lattice with a circular scatterer PBG structure opens a frequency band gap centered about 3,700 m/s and bounded by the 6th and 7th vibration modes. In contrast, the fractal PBG structure operates between the 16th and 17th modes and exhibits a complete frequency band gap at approximately 5,300 m/s, which is almost 1.4 times higher than what extracted for the square lattice. This comparison confirms that the fractal design has the ability to operate at higher frequencies than a conventional circular design for a given lattice size.

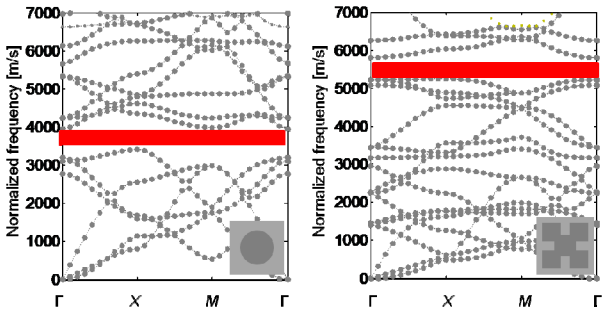

Figure 4. Comparison between the dispersion relationship of a square lattice PBG and a fractal PBG having the same lattice size. The red highlighted area is the complete frequency band gap.

In addition, in the minimum feature size associated with this PBG operating at higher frequency is much larger than the one required by the circular geometry (800 vs. 500 nm). This preliminary analysis clearly shows that the fractal design is beneficial in alleviating the manufacturing challenges generally associated with high frequency PBGs.

B. Frequency Band Gap Design and Dependence on Geometrical Parameters

For operation at 1 GHz, the lattice constant is set to be 5 µm (λ ~ 10 um in the AlN/air compound). The center square length, c, also plays an important role in the definition of the center frequency (Fig. 5). When varying the c-to-a ratio from 0.3 to 0.5, a general increase in the center frequency of the band gap is observed. Many frequency gaps are present (Fig. 5), but several are available around 1 GHz (5,000 m/s in terms of the normalized frequency) for a c/a of 0.4. For this reason, the center square length is set to be 2 µm.

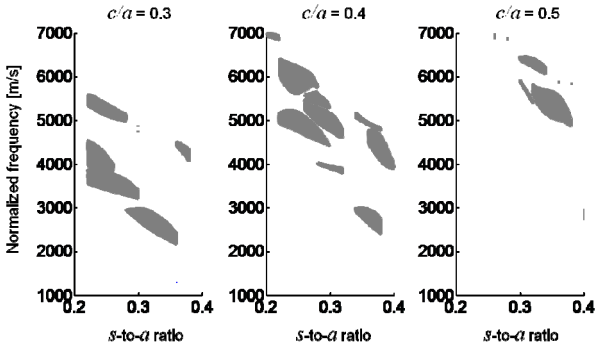

Figure 5. Map of frequency band gaps with respect to the s-to-a ratio for various center square length (c/a varying from 0.3 to 0.5). d/a is fixed at 0.2.

Moreover, to attain sufficient frequency band gaps without extreme miniaturization, the side square length, s, is defined to be 1.5 μm (s/a = 0.3), so that the minimum feature on the mask is kept at approximately 700 nm (the diagonal distance between the two neighboring cantilevers where center and side squares overlap), which is also the minimum feature that our lithography equipment allows us to define.

Furthermore, the frequency band gap sensitivity with respect to changes in the minimum feature size was also investigated. Fig. 6 is a clear evidence of the insensitivity of the band gap width to small variations in the s-to-a ratio. When the side square length decreases by 5% of the original value of 1.5 μm, the frequency band gap width shifts from 8.64% to 8.4%. On the other hand, when the side square length increases by 5%, the frequency band gap changes from 8.64% to 8.12%. Therefore, these variations in the minimum feature size are tolerable.

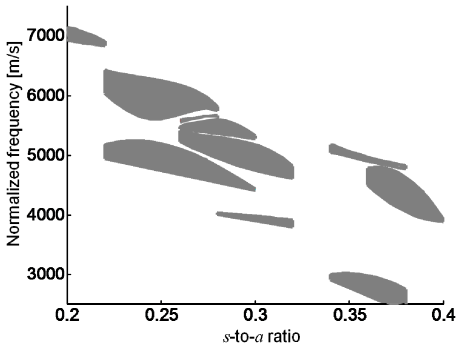

Figure 6. Map of frequency band gaps with respect to the variation in the s-to-a ratio from 0.2 to 0.4.

Finally, the film thickness is primarily fixed by the need of integration of the PBG with the AlN Lamb wave transducers. In order to attain an efficient electromechanical coupling (k_t^2) at 1 GHz, the AlN film thickness is set at 1 μm [8].

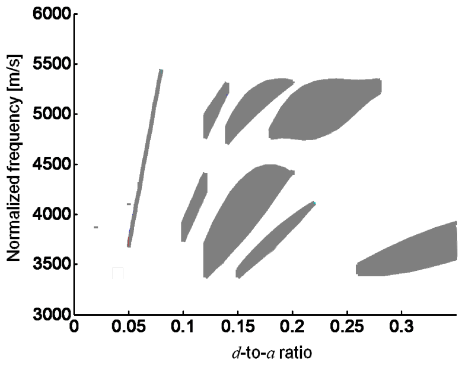

Figure 7. Map of frequency band gaps with respect to variations in the d-to-a ratio from 0 to 0.35.

Fig. 7 shows the behavior of the frequency band gaps with respect to the change in the film thickness while all other parameters are kept constant. The analysis shows that for the d/a ratio < 0.2, the frequency band gaps defined by the lower modes tend to widen. Nonetheless, small variations of d/a from 0.2 result in acceptable (almost negligible) changes in the PBG bandwidth. For example, if the thickness increases by 1% of the original value of 1 μm, the bandwidth of the stop band changes from 8.64% to 8.71%; on the other hand, if the thickness decreases by 1%, the bandwidth changes from 8.64% to 7.8%. These data clearly indicates that small variations in thickness will not have a dramatic impact on the desired frequency band gap.

Therefore, the desired fractal PBG structure of this work is defined by the following parameters: a = 5 μm, c = 2μm, s = 1.5 μm, and d = 1 μm. This PBG exhibits two complete frequency band gaps: one from 960 MHz to 1.03 GHz, another from 1.05 GHz to 1.07 GHz (Fig. 8).

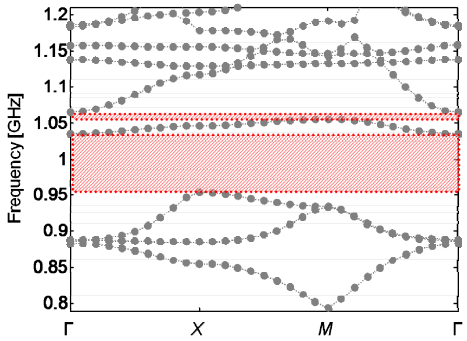

Figure 8. Dispersion relationship for the designed fractal PBG structure with physical key parameters: a = 5 μm, c = 2μm, s = 1.5 μm, and d = 1 μm. The red shaded areas are the regions where the complete frequency band gaps exist

III. EXPERIMENTAL RESULTS AND DISCUSSION

The designed fractal PBG structure was microfabricated in a four mask process. Fig. 9 presents the scanning electron microscope (SEM) images of the fabricated structure and devices.

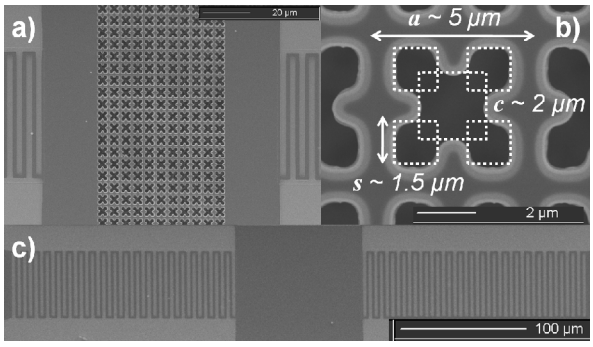

Figure 9. SEM images of the micro-fabricated a) fractal PBG array sandwiched by the Lamb wave transducers with b) the zoomed-in view of the fractal unit cell with key parameters labeled. c) The piezoelectric acoustic delay-line device used as the acoustic transmission reference.

In order to verify the PBG performance over a large frequency range (0.8 to 1.2 GHz), 14 sets of AlN piezoelectric transducers centered at various frequencies were integrated with the fractal PBG. Along with the PBG devices, 14 sets of the piezoelectric acoustic delay lines (Fig. 9c) matching the frequencies of the PBGs were fabricated simultaneously and served as a reference to which the PBG acoustic transmission was normalized. Approximately 4-5% bandwidth of the center

frequency of each of the 14 transducers was taken and summed up to realize the response over the entire frequency range. Each response was normalized to the corresponding acoustic transmission line to report the pure PBG response (independent of electrical and acoustic mismatches between the transducers and the delay line element).

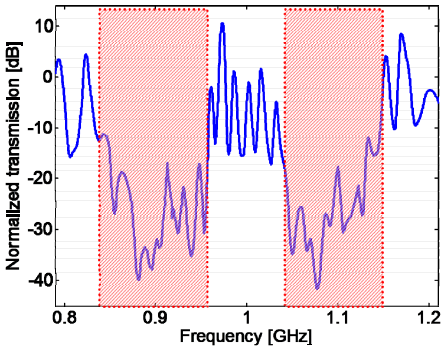

Figure 10. Experimental frequency response of the microfabricated fractal PBG device. The two main frequency band gaps are highlighted in red.

The experimental result indicates that there are two frequency stop bands: one from 850 to 950 MHz (with 11.1% gap-to-midgap ratio); and another from 1.05 to 1.15 GHz (9.09% gap-to-midgap ratio) with maximum attenuation of 40 dB. Although two frequency stop bands around 1GHz were attained, these are not the two complete band gaps for which the PBG was designed. According to the simulation (Fig. 11), the designed band gaps have shifted to higher frequencies because of fabrication imperfections that resulted in side squares with rounded edges.

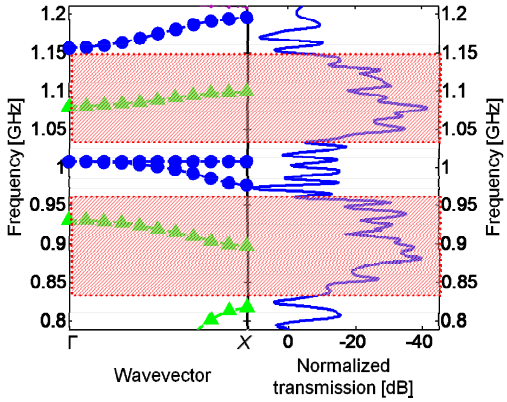

Figure 11. Dispersion curve obtained from COMSOL® simulations (blue dots represent the symmetric Lamb waves; and the green triangles represent the Asymmetric Lamb waves) are compared the the experimental data. The effect of rounded edges in the unit cell have been taken into account and justify the shift in frequency of the acoustic band gaps with respect to the design values.

The rounded edges (Fig. 9b) effectively change the acoustic velocity of each mode, and cause an upper shift in the frequency of operation of the PBG. Nonetheless, the fabricated PBG exhibits two large band gaps because the AlN lamb wave transducers mainly launch symmetric modes in the Γ-*X* direction and exclude the propagation of asymmetric modes. Although a non-complete frequency band gap was demonstrated, the experiment shows that the integration of the fractal design with same-plane AlN transducers can yield wide regions of little acoustic transmission. Edge rounding appear to have a more pronounced effect on the center frequency of operation of the PBG than the regular dimensional scaling that was accounted for in the design section. Future efforts will be devoted to eliminate the design sensitivity to edge rounding.

IV. Conclusion

In this paper, a novel fractal PBG design in AlN has been studied via FEM analysis and experimentally demonstrated to work in the UHF range when integrated in the same plane with AlN lamb-wave transducers. This work is a clear evidence that GHz operation in PCs can be achieved without drastic PBG miniaturization (minimum feature of 700 nm). As GHz operation was attained, it is now possible to consider utilizing these PBG structures for the making of radio frequency (RF) devices such as resonators or filters. Simultaneously, modified fractal designs will be explored in order to relax the dependence of the PC acoustic characteristics on manufacturing variations.

Abstract: We propose a new acoustic resonator concept based on a periodically poled transducer (PPT) in a piezoelectric substrate ($LiNbO_3$ or $LiTaO_3$), embedded between two guiding substrates in order to create an acoustic waveguide. A resonator operating at 131MHz have been successfully fabricated and used in order to stabilize an oscillator. However the fabricated resonator presents a significant thermal sensitivity. The following experiments have consisted in studying a Si/thinned PPT layer/Si in order to reduce the thermal sensitivity.

I. INTRODUCTION

Surface Acoustic Waves resonators are usually used for the frequency stabilization of electrical oscillators in the range of 50 MHz to 2 GHz. We have developed an isolated wave guide allowing for the propagation of acoustic waves within a PPT plate ($LiNbO_3$ or $LiTaO_3$) in between two silicon guiding substrates, yielding advanced packaging opportunities. In the first part, we present the simulation, the fabrication and the characterization of a PPT-based resonator operating at 131 MHz with a Silicon(380µm)/$LiNbO_3$ PPT(500µm)/Silicon(380µm) structure. We present the resonator oscillation characteristics, more particularly the phase noise and the frequency stability. In a second part, we exhibit the advantages of thinning down the piezoelectric transducer in showing the dispersion properties analysis. We describe the fabrication process and the characterization of resonators based on thinned PPLN or PPLT layers. The phase noise of an oscillator using a Si/PPLN/Si resonator, exhibiting a 50µm period and a 500µm thick piezoelectric layer, has pointed out the concept feasibility and answers to scope statement. In fact, these resonators, with low insertion losses and a phase noise at 100 kHz of the carrier wave controlled, less than 160dBc/Hz, are well-suited for radar applications. Moreover, for each PPT period, the dispersion properties analysis has shown an optimum thickness of the piezoelectric plate, corresponding to the maximum electromechanical coupling coefficient. Si/PPT/Si test vehicles, exhibiting a 50µm period and a thick piezoelectric layer around 30µm, have pointed out the existence of an isolated mode operating at frequencies near 110MHz for a $LiNbO_3$ PPT and near 90MHz with $LiTaO_3$ PPT with low thermal sensitivities.

II. BASIC PRINCIPLES OF THE PPT-BASED RESONATOR

We propose a new guiding concept using interface ultrasonic waves. We suggest a compact structure based on poled ferroelectric layer bonded between two guiding substrates (fig.1). An acoustic wave is excited by a periodically poled transducer, and the waves then are trapped within a buried guiding structure. $LiNbO_3$ or $LiTaO_3$ as piezoelectric and ferroelectric materials are exploited to fabricate the PPT's [1] and silicon substrates are used to guide the acoustic wave and allow for a low cost packaging [2]. These components have to operate at high frequencies (RF until X band domain) and need spectral purity, short-term stability, low phase noise around the carrier wave and thermal insensitivity notably for radar applications. PPTs have been investigated recently as an alternative to standard periodic inter-digital

978-1-61284-110-6/11/$26.00 ©2011 IEEE

transducers (IDTs) for the excitation and detection of guided acoustic waves [2] and consist of a periodic alternation of oppositely poled ferroelectric domains included between two electrodes. The main advantages of PPTs compared to standard IDTs are the robustness of the excitation versus defects or surface contamination, the opportunity to excite fundamental waves exhibiting an operating frequency twice higher and the possibility to excite several waves at the same time.

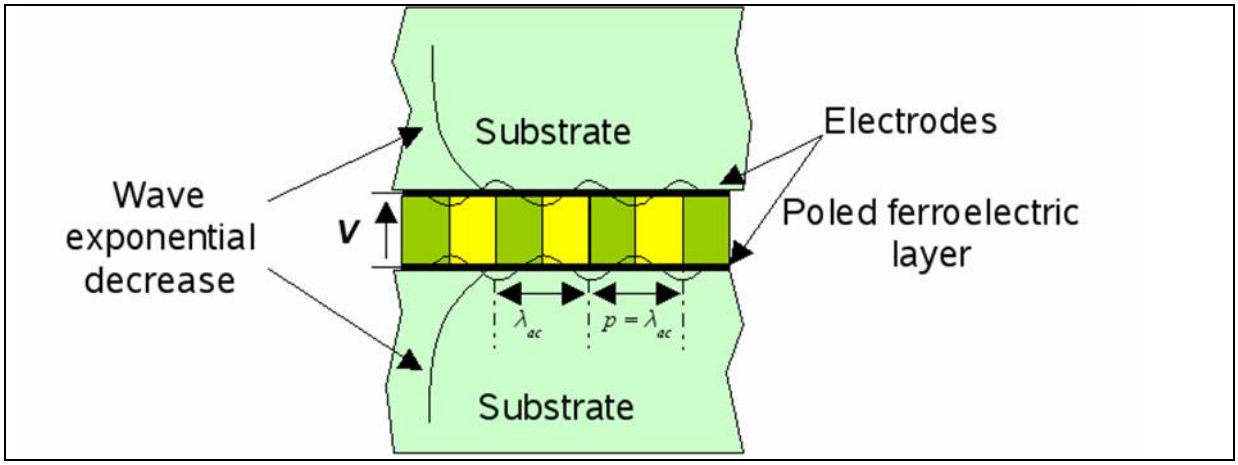

Fig. 1. Principle of the PPT isolated wave transducer

III. Si/thick PPT/Si- BASED WAVEGUIDE, RESONATOR AND OSCILLATOR

The fabrication of acoustic waveguides based on PPTs consists in bonding a silicon wafer on each side of the periodically poled wafer. $LiNbO_3$ or $LiTaO_3$ as piezoelectric and ferroelectric materials are good candidates for the fabrication of the PPTs. In fact, these materials have a spontaneous polarization which can be inverted by applying high voltage thanks to our home-made poling technique [3]. The voltage needed to invert the domains is around 11kV for a 500µm-thick wafer. The different steps of fabrication are detailed in fig. 2 and reported in reference [4].

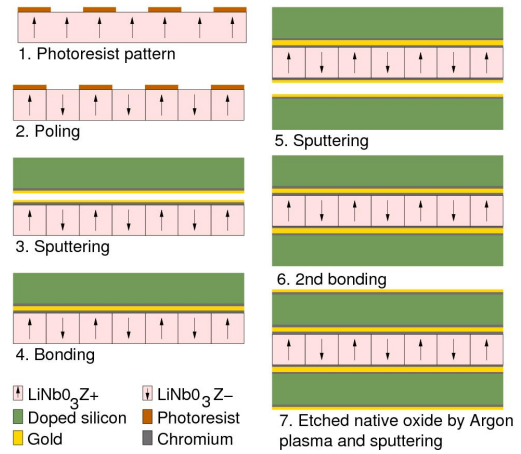

Fig.2. Flow-chart of fabrication

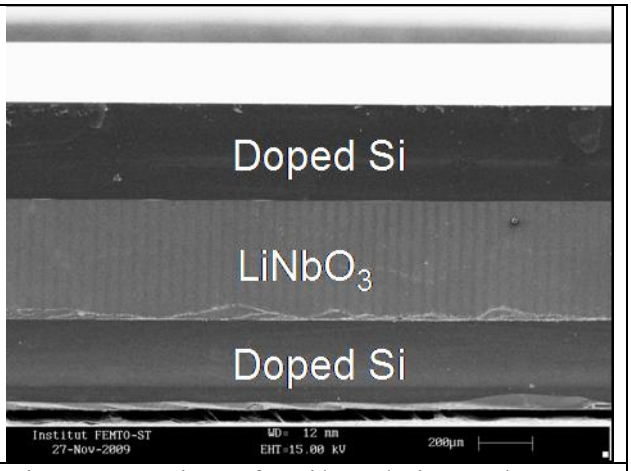

Fig.3. SEM view of a Si/PPT/ Si transducer

On figure 3, we can see a SEM observation of poled domains after HF wet etching for a 50µm period of this Si/500µm PPT/Si structure. The different domains confined between the 2 doped silicon layers are clearly observed. Operational test vehicles with a 50µm period have been achieved using doped silicon wafers in order to ease the electrical contact and tested by means of a spectrum analyzer yielding Si/PPT/Si devices responses.

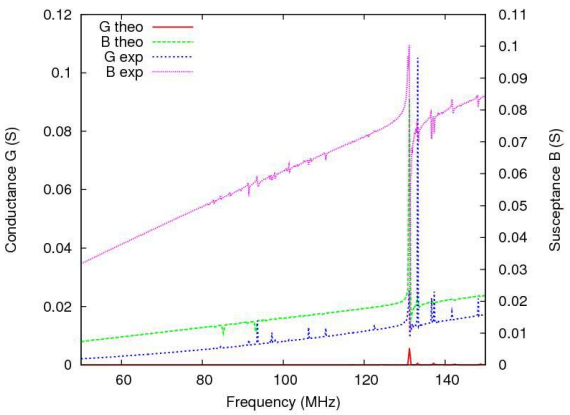

Fig.4. Theoretical and experimental admittances of a Si/$LiNbO_3$(500µm)/Si structure

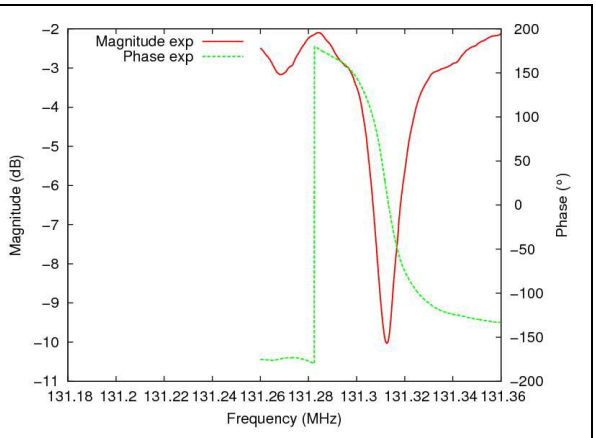

Fig.5. Evolution of the dynamic of the coefficient S_{11} and the phase rotation versus frequency for the longitudinal mode

Theoretical and measured electrical admittances agree well and allow for identifying a main contribution corresponding to a guided longitudinal mode at 131 MHz (fig.4). The corresponding phase velocity is very close to the one of the PPT alone (i.e 6500 $m.s^{-1}$) [3].
This resonator operating near 131MHz exhibits a quality factor of 13000 and an electromechanical coupling ks^2 equal to 0.25% (twice higher than a SAW quartz resonator). The corresponding phase rotation (320°) and the dynamic of its electrical reflection coefficient S_{11} equal to -8dB reveal compatible with oscillator applications (fig.5).

A specific printed circuit has been implemented for the phase noise tests with our Si/500µm PPT/Si resonator and the Colpitts oscillator (fig.6). The phase noise of the oscillator at 100kHz from the carrier shows a value less than -160dBc/Hz (fig.7), which can be honestly compared with other acoustic wave oscillators at such frequency, accounting for the fact that the device was excited with a quite low signal level (-6dBm). Therefore, increasing the excitation should allow for a significant reduction of the noise floor and then advantageously compete with standard solutions.

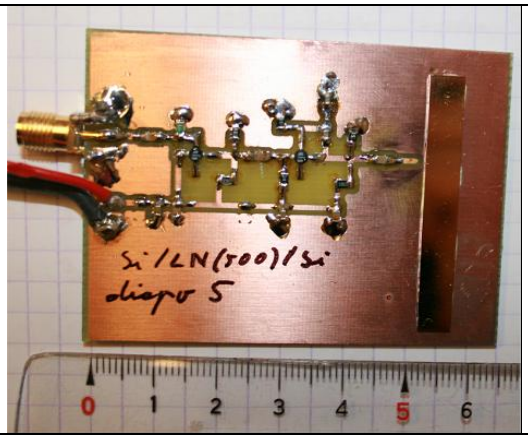

Fig.6. The oscillator board implemented for phase noise tests

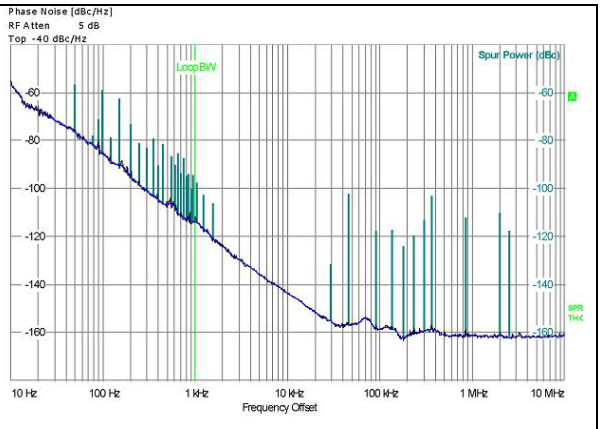

Fig.7. Phase noise of the 131 MHz oscillator stabilized

We have also studied the stability of this 131MHz oscillator, and we have obtained a frequency stability equal to 10^{-9} at less than 1s (fig.8). This experiment has been made at room temperature without any thermal compensation.

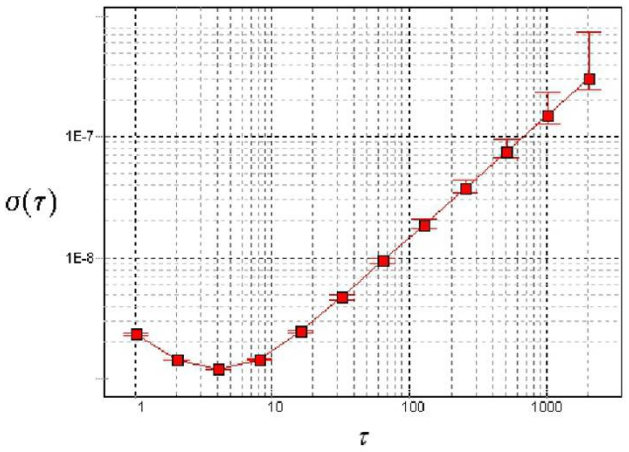

Fig.8. Frequency stability curve of 131 MHz oscillator

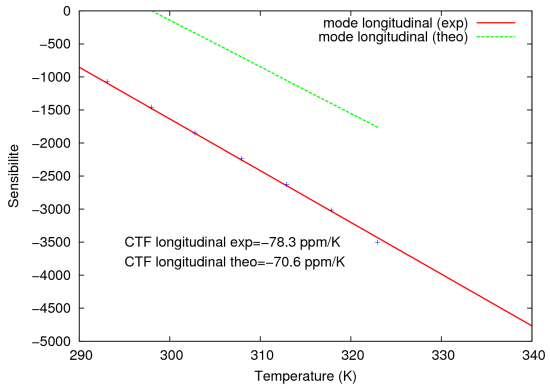

Fig.9. Frequency drift versus temperature for the longitudinal mode

The frequency drift of this longitudinal mode at 131MHz versus the temperature is reported in fig.9. We have found frequency variations of -78ppm/K for the longitudinal mode for a thick $LiNbO_3$ layer bonded between two Silicon layers. This value is sensibly the same than the one of isolated $LiNbO_3$ devices. We can conclude that we obtain a significant thermal sensitivity for Si/thick $LiNbO_3$ layer/Si and this value depends essentially of the material used for the PPT layer and cannot be reduced by the two guiding substrates. The further experiments consists in studying a Si/thinned PPT layer/Si in order to obtain a monomode acoustic wave device with an isolated mode with a low thermal sensitivity.

IV. Si/thinned PPT/Si- BASED WAVEGUIDES

The study of the dispersion properties enables to define a specific configuration using a thinned PPT layer [4]. Interesting guidance properties have been obtained for a ratio between the thickness of the layer and the period of inverted domains lower than 1 and as a result the maximum of the electromechanical coupling is obtained for a 25-35µm thick $LiNbO_3$/$LiTaO_3$ layer for a 50µm period. The global flow-chart to fabricate Si/thinned PPT layer/Si acoustic waveguides is approximately the same than the process used for Si/thick PPT/Si (fig.2). The supplementary step consists in lapping and polishing the PPT layer in order to obtain a thinned PPT layer of about 25-35µm, thanks to our lapping machine (fig.10). Finally this material stack is bonded on a second doped silicon wafer in order to define the aimed compact structure Si/PPT/Si. On figure 11, we can see a SEM observation obtained for a 25µm thick $LiNbO_3$ layer confined between the two silicon substrates for a 50µm period.

Fig.10. Photograph of the equipment used for lapping/polishing operations

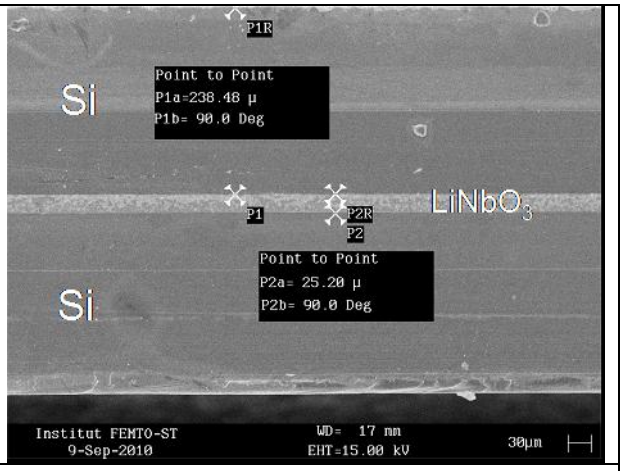

Fig.11. SEM view of a Si/thinned PPT/Si transducer

Operational test vehicles have been achieved using $LiNbO_3$ and $LiTaO_3$ wafers as poled ferroelectric layer. Experimental results of the Si/thinned PPT layer/Si devices with a 50µm period are reported in fig.12. For the two materials, only one contribution is obtained: at 110MHz for a 25µm thick $LiNbO_3$ layer and at 88MHz for a 35µm thick $LiTaO_3$ layer. Unfortunately, these monomode acoustic devices, due to a non homogenous thickness of the PPT layer along the several millimeter long ferroelectric gratings, don't exhibit properties compatible with oscillator applications.

(b)

Fig.12. Theory/experitment assessment for a Si/thinned PPT/Si device with 50µm of poling period built on a Z-cut $LiNbO_3$ plate (25µm) (a) and a Z-cut $LiTaO_3$ plate (35µm) (b)

We have also studied the frequency drift of the isolated mode versus the temperature for a 50µm period structure (fig.13). We have found frequency variations of -33ppm/K for the isolated mode for a 25µm thick $LiNbO_3$ layer and of -31ppm/K for a 35µm thick $LiTaO_3$ layer. So we can conclude that bonding onto two silicon wafers and lapping/polishing the $LiNbO_3$ layer have compensated this frequency drift versus temperature by a factor 2. Moreover the temperature coefficient of frequency (TCF) value of the compact structure is close to the TCF value of the silicon guiding substrate. So we can conclude that if we choose an appropriate insensitive material as guiding substrate, we can obtain an insensitive resonator versus temperature.

V. CONCLUSION

We have proposed a new acoustic resonator concept based on a periodically poled transducer in a piezoelectric substrate ($LiNbO_3$ or $LiTaO_3$) embedded between two silicon guiding substrates in order to create an acoustic waveguide. A resonator operating at 131MHz have been successfully fabricated. This resonator presents the required properties to stabilize an oscillator at this frequency but however the developed resonator presents a significant thermal sensitivity (depending mainly on PPT substrate used). The following experiments have consisted in studying a Si/thinned PPT layer/Si: monomode acoustic wave devices with an isolated mode have been successfully fabricated with a low thermal sensitivity. A thermal insensitivity is possible with an appropriate choice of guiding susbtrate. However these monomode devices don't exhibit properties compatible with oscillator requirements due mainly to technological limits to be solved. Future works consist in improving the lapping process in order to obtain a homogeneous thickness for the compact structure, studying the possibility to reduce the noise floor of the oscillator with increasing the input power of the resonator at 131MHz and trying to invert micrometric periods in order to achieve a 2GHz frequency resonator.

***Abstract*— Electrostrictive acoustic resonators have been widely investigated during the last 8 years. Despite their interesting dc-controlled electromechanical coupling and switchable properties, the main drawback remains their poor quality factor. Here we show that HBAR LiNbO3 single crystals can be useful to act as high quality factor switchable resonators thanks to their electrostrictive properties and to their intrinsic low acoustic losses. For a resonance frequency at 1.95GHz, HBAR Q reaches 9000. This outstanding behaviour could be of interest for RF applications.**

I. INTRODUCTION

Since 2003, several groups have been working on electrostrictive acoustic resonators (EARs) as an alternative to the well-established piezoelectric resonator [1,2,3]. The latter is used as the building block for RF filters for telecom purpose [4,5]. Although the commercial success of these devices is huge, it is highly desired to add controllable abilities to resonators in order to simplify RF architectures [6]. A solution would be using electrostrictive materials instead of piezoelectric ones. The best identified materials belong to the perovskite family, including $SrTiO_3$ (STO), $Pb(Zr,Ti)O_3$ (PZT) and $(Ba,Sr)TiO_3$ (BST), the last being the most studied one. Indeed, using such materials gives the opportunity 1) to switch on/off the resonator as desired simply by adding a dc voltage superimposed to the RF signal as pointed out by Volatier et al. [7] 2) to tune the resonance frequencies by adjusting the dc voltage due to linear and non linear electrostriction as described by Vendik in 2008 [2]. Although such properties might deeply change future RF systems architectures, the main EARs drawback today is their low resonance quality factor Q, which is a figure of merit of the resonance and antiresonance peak sharpness. The majority of the papers dealing with EAR reports Q values between 50 and 150 [1,2,3,7], ten times lower than the required values for filtering devices, fulfilled with AlN resonators for which quality factors reach 1000 or even 2000 [4]. To be attractive, EARs need to overcome this issue. The physical explanation of the low Q factor of EARs is manifold. The global material quality is obviously involved as for BST and STO films we are far from the AlN thin films quality in terms of density, orientation control and phase purity. Recently, Gevorgian's team published Q values reaching 350 for hot sputtered BST thin films which is a significant breakthrough [8], even though still far from the targeted value exhibited by pure piezoelectric thin films. Besides, the domain wall boundaries motion in lead based materials like PZT is an intrinsic reason for the limited Q factors [9]. Identified some years ago by Arlt [10] it was pointed out more recently by Muralt's team [11]. Avoiding domains is why people are keener in developing non ferroelectric materials as STO and BST instead of PZT. Another possible reason is the film roughness, which is related to the material quality as well [13]. To overcome these three main drawbacks, we propose hereafter to use single crystals $LiNbO_3$ (LNO) thin films. Indeed, LNO belongs to the ilmenite family and exhibits only one possibility for the polarization direction, avoiding non-180° domains and consequently energy dissipation due to domain wall motion. Moreover, single crystals exhibit a prefect structure, without any grains boundaries and misorientation. Single crystals thin films can be obtained by using a transfer process based on ion implantation / molecular bonding on host substrate / blistering by heating. This technique, called Smart Cut™ has been recently adapted from Silicon On Insulator (SOI) purposes to LNO thin films onto LNO carrier substrate in collaboration with SOITEC [12]. Another specificity of this study is that the carrier substrate is kept during all experiments. Indeed, one should consider this study as a first step towards the released single crystal LNO thin film which represents a tremendous technological challenge. . Therefore, in the following, we will focused on the dc-controlled High overtone Bulk Acoustic Resonator (so-called HBAR) behavior of LNO single crystals thin films transferred on LNO substrate.

II. EXPERIMENT

A. *Technology*

The technology used to perform the sample is described elsewhere [12]. Both thin films and substrate are X-Cut LNO. The transferred film is 800nm thick. Handle and donor wafers are both full 3-inch LNO wafers. The bottom electrode (Pt 100nm) was sputtered on the handle wafer. Bonding was achieved between two SiO_2 layers deposited respectively on the metallic layer and the handle wafer. The 100nm-thick sputtered top electrode is made of Pt and patterned by lift off technique. The LNO transferred layer is indeed a single crystal exhibiting an electromechanical coupling coefficient due to piezoelectricity as high as 40%, which is equivalent to bulk values [12].

B. *Characterization*

The device under test corresponds to a Metal Insulator Metal (MIM) configuration. RF characterization is performed by using a Vector Network Analyser (VNA) in the 2GHz range. A dc field is superimposed to rf signal.

III. RESULTS

Figure 1 shows the real part of the MIM capacitance impedance as obtained versus different dc voltages between 1942 and 1958MHz. One can observe two types of resonances: P (piezoelectric) and E (Electrostrictive). On one hand, the highest peaks (P) are related to the piezoelectric shear waves always appearing whatever the dc voltage applied. Interestingly, on the other hand, another peaks type (E) appears only when dc is on, as zoomed on inset b), Figure 1. Its height depends on the dc voltage amplitude. Peaks repetition is due to the substrate. They correspond to harmonics of the fundamental substrate longitudinal thickness mode of vibration. Although the nature of the P peaks is well identified (shear wave in X-LNO), E type is not common. The frequency distance between two substrate peaks (Δf) is related to the sound velocity v and the substrate thickness t_s by $v=2 t_s \Delta f$.

Therefore, if one assumes the wave propagation and the resonance frequencies are mainly influenced by the substrate, v_E extracted from E type gives $v_E=6550 m.s^{-1}$.

As $v = \sqrt{c^D / \rho}$ (with c^D the stiffness coefficient and ρ the density (4630 kg/m^3 for LNO)), one deduces $c^D=1.99.\ 10^{11}$ N/m^2. This value corresponds to $c_{33}{}^D$ in X-cut. Therefore, this sound velocity is the evidence that dc voltage in LNO induces a longitudinal acoustic wave which is not coupled in X-cut while its corresponding piezoelectric constant is zero. The longitudinal coupling is possible here as dc voltage is combined to the second order electromechanical coupling called electrostriction.

Figure 2 is a zoomed part of Figure 1 focusing on one electrostrictive peak. One can clearly observe that at 0V dc, no resonance is visible. As soon as dc voltage is applied, resonance (ReY) and antiresonance (ReZ) peaks appear. The frequency positions of these peaks depend on the dc voltage value, which is typical for electrostriction. It is essential noting that the quality factor Q of the highest peak reaches 9000 at 1955MHz, inducing Qf factor reaching 1.7 10^{13} Hz.

One should bear in mind that this very high Q is mainly influenced by the LNO substrate which exhibits lower acoustic losses than silicon. As the acoustic wave spend much more time in the substrate than in the thin film, its influence on Q is huge. It is also interesting to compare this Q with the one exhibited by the shear wave resonance named *P* (as Piezoelectric) as observed in Figure 1. Indeed, this last reaches 45,000 as already reported [13]. This is 5 times higher than the *E* resonance. The first reason is that shear waves are always less lossy than longitudinal waves. Moreover, one should consider the accuracy a of the applied dc voltage which is typically 0.02% as given by the supplier. If one consider that the corresponding quality factor Q_S of this voltage supply is roughly $1/a$, than $Q_S=5000$. Therefore, it is likely that the resonator Q is not intrinsically limited by electrostriction on the current characterization.

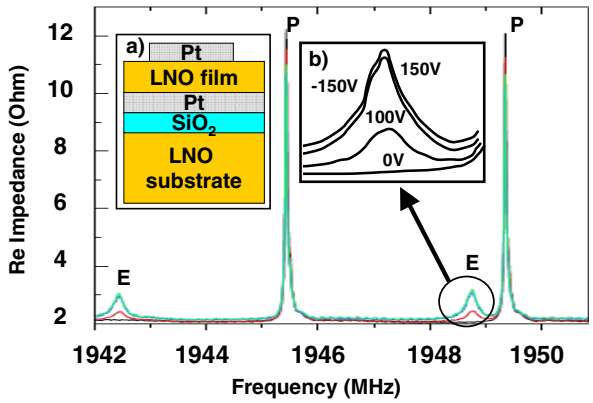

Figure 1. real part of the impedance of LNO MIM capacitor in HBAR configuration. Inset (a): schematic of the cross section of the HBAR resonator. Inset (b): zoom of the dc voltage sensitive peak E, as a result of the electrostrictive effect

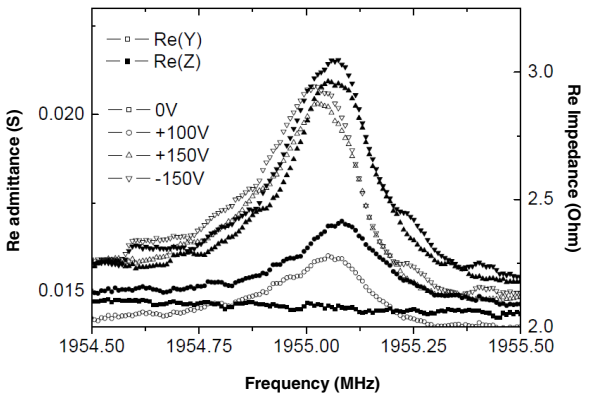

Figure 2. real part of admittance and impedance of the resonator versus frequency with respect to applied dc voltage. Resonances appear when dc voltage is different from zero.

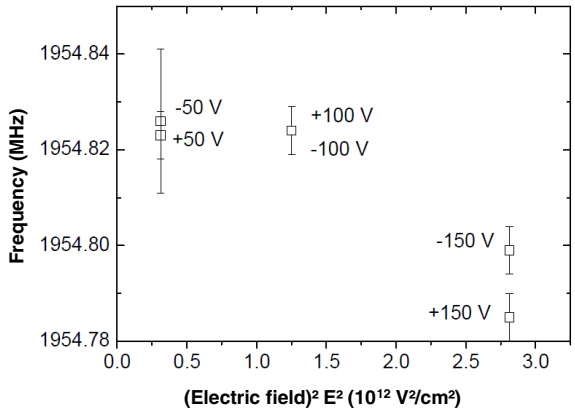

Figure 3. antiresonance frequency extracted from Re(Z) of the resonator versus the square of the dc electric field applied

Apart from Q, one can estimate the tuneable properties of the resonances. An antiresonance frequency f_p corresponding to harmonic at 1954.84 MHz is reported in Figure 3 versus the square of the applied dc electric field. Unlikely one can observe in high-K perovskite electrostrictive materials such as BST [3], the variation of f_p is not linear with E^2. However, this variation seems to be always symmetrical versus the dc electric field E_{dc} as f_p is roughly identical for a given E_{dc} whatever its sign. This suggests how to manage the free energy form in order to explain this variation compared to what was proposed for electrostrictive materials [2]. The idea is to add a fourth order term in the stiffness coefficient, leading to a six order term in the free energy, as reported in the following equation.

$$F - F_0 = \frac{1}{2}c_0^D S^2 + \frac{1}{2}\beta^S D^2 + \frac{1}{4}\gamma^S D^4 + GD^2 S + \frac{1}{2}MS^2 D^2 + \frac{1}{2}M' S^2 D^4 \quad (1)$$

For this equation, we use the following parameters - *S:* strain, T : stress, D : electric displacement, E : electric field, c_0^D : constant value of stiffness, β^S: impermittivity, γ^S: non linear impermittivity, G: first order electrostriction, M: non linear electrostriction, M': fourth order non linear electrostriction. Only *M'* term was added to the standard model. *S* is used as the mechanical variable as it permits working with a 1D model as the substrate avoids all the in-plane strain. Besides, *D* (electrical displacement) is used as electric variable as the antiresonance frequency does not depend on any coupling, but just on c^D and density [2]. For the following, we focus on the stiffness term only. Therefore, after differentiating *F* twice with respect to *S*, one obtains c^D:

$$c^D = c_0^D + MD^2 + M'D^4 \quad (2)$$

This expression of LNO layer stiffness is then introduced in the standard acoustic model of HBAR developed by Lakin [14]. Consequently, one can extract c^D variation from f_p variation experienced by the HBAR when the dc field is applied. It is worth noting that it would be more accurate and convenient to extract c^D variation from a released resonator (Film Bulk Acoustic Resonator (FBAR) configuration). But important technological issues have not been overcome yet. By using f_p variation between 50 and 150V from Figure 3, the extracted stiffness variation for the LNO layer is -120ppm/V. By supposing that the D^4 term is the most prominent one in equation (2), one can deduce that *M'* is -2.5 10^{14} N.m^6/C^4. This relative variation of stiffness can be used to calculate what would be the frequency variation of LNO thin films alone, standing as FBAR resonator. It can be compared to other reported stiffness variations of other materials as AlN [15] and BST. For sake of clarity, a correct comparison figure is *R* the relative antiresonance frequency variation versus applied electric field ($R=\Delta f_p/f_p.1/E$). One obtains R_{AlN}=-$2.6.10^{-11}$m/V, R_{LNO}=-$4.8.10^{-11}$m/V and R_{BST}=-$1.0.10^{-10}$m/V. The LNO frequency variability is around 1% for the maximum applied field which is the same order of magnitude exhibited at the same time by AlN and BST. This rather equivalent variability is due to different breakdown electric fields of these three materials (typically 1MV/cm, 2.5MV/cm and 6MV/cm respectively for BST, LNO and AlN).

IV. CONCLUSION

In this paper, we showed that $LiNbO_3$ single crystals HBAR resonators can be useful to act as high quality factor switchable resonators thanks to their electrostrictive properties and to their intrinsic low acoustic losses. For a resonance frequency at 1.95GHz, Q reaches 9000. This outstanding behavior could be of interest for RF applications.

***Abstract*—We developed a model for the motional impedance Z_m of electrostatic resonators that operate in a nonlinear regime. The model predicts that the Z_m at resonance has the same expression as it has in the linear case. In addition, we developed a new measurement setup, which is based on a variable-phase feedback circuit. This setup enables the measurement of Z_m at operating points that are unobservable with a conventional impedance analyzer measurement. The estimation based on our model matches the measurement with errors less than 10% in the worst case.**

I. Introduction

Micromechanical resonator-based oscillators are considered by many to be the next generation of frequency references [1]. Frequency references are an essential component of electronic devices, and quartz crystal-resonator-based references have dominated the market. Although quartz references have many advantages, they have become a bottleneck in the miniaturization of electronic devices since their manufacturing process is not CMOS-compatible. In contrast, micromechanical resonators can be batch fabricated within a standard CMOS process. They thus have the potential to provide low-cost micro-scale frequency references.

Motional impedance Z_m of electrostatic micromechanical resonators describes the relation between a resonator's input drive voltage, $v_{ac}(t) = V_{ac}\cos(\Omega t)$, and output current, $i_{out}(t) = I_{out}\cos(\Omega t + \theta)$. It is called the "motional" impedance because it is the impedance that stems from mechanical motion of resonators. Estimating and measuring Z_m is important because it is a critical parameter to consider in the design of sustaining feedback amplifiers in a closed-loop oscillator. Furthermore, precise estimation of Z_m is necessary to engineer the phase-noise performance of resonator-based oscillators [2].

Because of its importance, there have been numerous studies on Z_m. Researchers have developed models that allow precise estimation of the Z_m of resonators operating in a linear regime [2]–[5]. However, most micromechanical resonators have nonlinearities. These nonlinearities can be effectively modeled with additional higher-order terms of mechanical displacement in the governing equation [5]–[7]; hence, their effect is negligible when the drive amplitude V_{ac}—which is proportional to the mechanical displacement—is small, but it must be accounted for when V_{ac} becomes larger. In resonator-based oscillators, large V_{ac} is preferred for better signal-to-noise ratio. Therefore, micromechanical resonators in oscillator applications often operate in the nonlinear regime, where the nonlinear effect is not negligible. Furthermore, a conventional measurement method cannot observe some operating points when a resonator is in the nonlinear regime because instability arises. To address all of these issues, a new measurement method must be developed for observing the nonlinear Z_m characteristic.

In this research, we first developed a nonlinear Z_m model. We then demonstrated an all-new closed-loop measurement setup. The measurement results from the setup match the developed model.

II. Theory

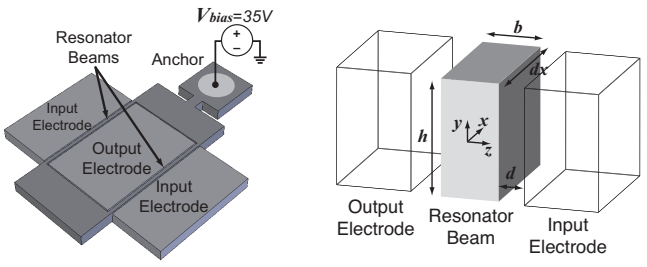
A. Nonlinear mechanical amplitude

The modeling starts with the partial differential equation model of a single-anchored double-ended tuning fork (SA-DETF) resonator, shown in Fig. 1(a). The Euler-Bernoulli equation for the differential beam, Fig. 1(b), is

$$\frac{\partial^2 w}{\partial t^2} + \frac{\hat{c}}{\mu}\frac{\partial w}{\partial t} + \frac{EI}{\mu}\frac{\partial^4 w}{\partial x^4} = \frac{\hat{q}(t)}{\mu}, \tag{1}$$

where $w(x,t)$ is the beam displacement in the $z-$direction, $\hat{c}$ is the damping coefficient per unit length, μ is the mass per unit length, E is Young's modulus, $I = \frac{hb^3}{12}$ is the second moment of area, and $\hat{q}$ is the net electrostatic force per unit length. For a two-port electrode configuration,

$$\hat{q}(t) = \frac{\varepsilon_0 h}{2}\left[\left(\frac{V_{bias} - v_{ac}}{d - w}\right)^2 - \left(\frac{V_{bias}}{d + w}\right)^2\right], \tag{2}$$



(a) SA-DETF resonator diagram (b) differential beam element

Fig. 1. Single-anchored double-ended tuning fork (SA-DETF) resonator and its differential element

where ε_0 is the dielectric constant of vacuum, V_{bias} is a dc-polarization voltage applied to a resonator beam, $v_{ac}(t)$ is an ac-stimulus signal with amplitude V_{ac}, and d is the transduction gap. Applying the Taylor series expansion to Eqn. (2) with respect to w with the assumption of $V_{ac} \ll V_{bias}$ and $w \ll d$, we get

$$\hat{q}(t) \approx -\frac{\varepsilon_0 h V_{bias}}{d^2}\left(v_{ac} - 2V_{bias}\frac{w}{d} - 4V_{bias}\frac{w^3}{d^3}\right). \quad (3)$$

Plugging Eqn. (3) into Eqn. (1), we obtain the governing equation:

$$\frac{\partial^2 w}{\partial t^2} + c\frac{\partial w}{\partial t} + \alpha_0\frac{\partial^4 w}{\partial x^4} - \frac{\beta_1}{\mu}w - \frac{\beta_3}{\mu}w^3 = \frac{\beta_0}{\mu}v_{ac}, \quad (4)$$

where $c = \frac{\hat{c}}{\mu}$, $\alpha_0 = \frac{EI}{\mu}$, $\beta_0 = -\frac{\varepsilon_0 h V_{bias}}{d^2}$, $\beta_1 = \frac{2\varepsilon_0 h V_{bias}^2}{d^3}$, and $\beta_3 = \frac{4\varepsilon_0 h V_{bias}^2}{d^5}$ are defined to make expression concise. Note that the w^3 term from Eqn. (3) introduces nonlinearity.

Preparing modal analysis, we obtain the mode shape functions $\phi_n(x)$: $\phi_n(x)$ is the nth mode Eigenfunction for the Eigenvalue problem

$$\mathcal{L}\left[\phi_n(x)\right] = \omega_n^2\phi_n(x) \quad (5)$$

with a clamped-clamped boundary condition [8], where

$$\mathcal{L} \triangleq \alpha_0\frac{\partial^4}{\partial x^4} - \frac{\beta_1}{\mu}. \quad (6)$$

Solving Eqn. (5), we get $\phi_n(x) = \cosh(k_n x) - \cos(k_n x) + \theta_n\left(\sinh(k_n x) - \sin(k_n x)\right)$, where $k_n l$ is a solution of the characteristic equation $\cos(kl)\cosh(kl) = 1$ and

$$\theta_n = \frac{\cos(k_n l) - \cosh(k_n l)}{\sinh(k_n l) - \sin(k_n l)}. \quad (7)$$

The characteristic equation can only be solved numerically, and it has infinitely many solutions of $k_n l$: for instance, $k_1 l \approx 4.7300$ for the fundamental mode, and $k_n l \approx 7.8532$, 10.9956, 14.1372, 17.2788... for higher modes. We then assume that

$$w(x,t) \approx \phi_1(x)\xi_1(t) \quad (8)$$

because in the general equation, $w(x,t) = \sum_{n=1}^{\infty}\phi_n(x)\xi_n(t)$ —where $\xi_n(t)$ are the generalized coordinates— ξ_1 prevails over the other ξ_i when the driving frequency Ω is near the fundamental natural frequency $\omega_1(\Omega \approx \omega_1)$ [9]. We now apply modal analysis to Eqn. (4) by plugging Eqn. (8) into Eqn. (4) and integrating along the beam length l. Using the orthogonality of the Eigenfunctions $\frac{1}{l}\int_0^l \phi_n\phi_m dx = \delta_{nm}$ (the Kronecker delta) [9] and the relation of $c = \frac{\omega_1}{Q}$ and $v_{ac}(t) = V_{ac}\cos(\Omega t)$, we obtain

$$\frac{d^2\xi_1}{dt^2} + \frac{\omega_1}{Q}\frac{d\xi_1}{dt} + \omega_1^2\xi_1 - \gamma\xi_1^3 = q\cos(\Omega t), \quad (9)$$

where Q is the quality factor, $\gamma = \frac{\beta_3}{\mu l}\int_0^l \phi_1(x)^4 dx$ is the nonlinearity parameter, and $q = \frac{\beta_0 V_{ac}}{\mu l}\int_0^l \phi_1(x)dx$ is the forcing parameter. Eqn. (9) describes the forced Duffing system [10], and it is widely applicable to other types of resonators because we will obtain an ordinary differential equation similar to Eqn. (9) if we apply modal analysis to the model for other types of resonators.

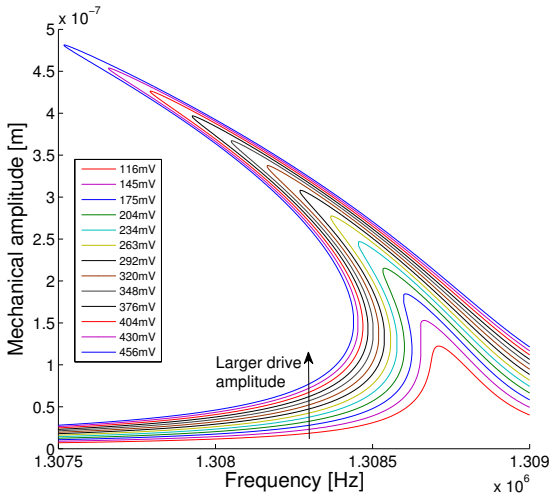


Fig. 2. Amplitude of the generalized coordinate, A in Eqn. (10), at various V_{ac} levels, shown in the legend. For each V_{ac}, we used Eqn. (11) to estimate A for a given range of a driving frequency Ω.

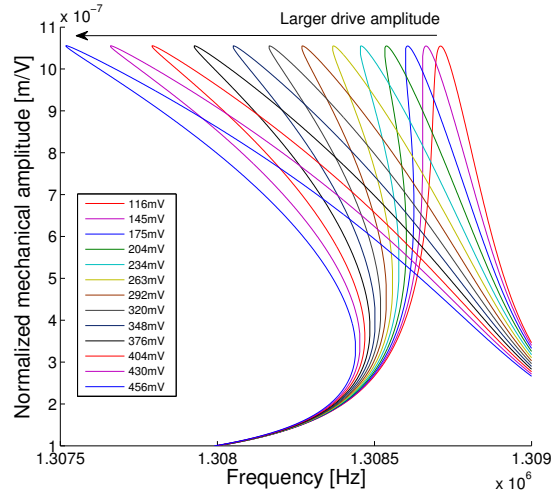

Fig. 3. Normalized mechanical amplitudes ($\frac{A}{V_{ac}}$) at various V_{ac} levels, shown in the legend. For each V_{ac}, we normalized the result in Fig. 2 with V_{ac}.

We obtain an approximate solution of Eqn. (9) by applying the method of multiple scales with the assumption of a weakly nonlinear system and a resonant excitation $(\Omega \approx \omega_1)$ [10]. The steady-state solution of Eqn. (9) is

$$\xi_1(t) \approx A\cos(\Omega t - \psi), \quad (10)$$

where A is given by the solution of the frequency response equation

$$A^2\left[\frac{\omega_1^4}{Q^2} + \left(\frac{3}{4}\gamma A^2 - 2(\Omega - \omega_1)\omega_1^2\right)^2\right] = q^2 \quad (11)$$

TABLE I
PARAMETERS FOR NUMERICAL ESTIMATIONS

beam length: l	200μm
beam width: b	6μm
beam height: h	20μm
transduction gap: d	1.5μm
mass density: ρ	2329 kg/m^3
Young's moduls: E	169 GPa
Polarization voltage: V_{bias}	35 V
Quality factor: Q	8710
Feedthrough capacitance: C_{feed}	40.36 fF

and ψ is

$$\psi = \arctan\left[\frac{-\omega_1}{2Q\left(\Omega - \omega_1 - (3\gamma/8\omega_1)A^2\right)}\right]. \quad (12)$$

Fig. 2 shows estimated A at various V_{ac} levels. The V_{ac} levels are selected to match the V_{ac} levels used for actual measurements shown in Fig. 8. Table I summarizes the parameters for the estimation.

By taking the derivative of Eqn. (11) with respect to Ω and setting $\frac{dA}{d\Omega} = 0$, we can find the resonant frequency Ω_r, which results in the maximum amplitude A_{max}. The Ω_r results in $\left(\frac{3}{4}\gamma A^2 - 2(\Omega_r - \omega_1)\omega_1^2\right)$ in Eqn. (11) being zero [6], [10]; hence, A_{max} becomes

$$A_{max} = \frac{|q|\,Q}{\omega_1^2} = \frac{\varepsilon_0 h V_{bias} V_{ac} Q}{\omega_1^2 d^2 m}\int_0^l \phi_1(x)dx, \quad (13)$$

where $m = \mu l$ is the mass of the beam. Surprisingly, A_{max} is not a function of nonlinearities, but is proportional to $V_{bias}V_{ac}Q$, as in the linear case [4], [11]. Fig. 3 shows the normalized mechanical amplitude ($\frac{A}{V_{ac}}$) estimated with Eqn. (11) at many driving frequency Ω: it shows that $\frac{A_{max}}{V_{ac}}$ is not affected by the level of V_{ac} as Eqn. (13) predicts, even though the resonant frequency Ω_r changes.

B. Nonlinear motional impedance

To estimate Z_m, we start from the total surface charge Q_s at the two output electrodes of a DETF resonator:

$$Q_s = -2V_{bias}\varepsilon_0 h \int_0^l \frac{1}{d-w}dx. \quad (14)$$

Applying the Taylor series expansion to the above equation with respect to w, we obtain

$$Q_s \approx -\frac{2V_{bias}\varepsilon_0 h}{d}\int_0^l \left(1 + \frac{w}{d}\right)dx. \quad (15)$$

Using the single mode assumption in Eqn. (8), we get

$$i_{motion} = -\frac{dQ_s}{dt} \approx \frac{2V_{bias}\varepsilon_0 h}{d^2}\frac{d\xi_1}{dt}\int_0^l \phi_1(x)dx. \quad (16)$$

Plugging Eqn. (10) into Eqn. (16) and defining the non-dimensional parameter $L_n = \frac{1}{l}\int_0^l \phi_n(x)dx$, we obtain

$$i_{motion} \approx \frac{2A\Omega V_{bias}\varepsilon_0 h l L_1}{d^2}\cos(\Omega t + \frac{\pi}{2} - \psi). \quad (17)$$

To estimate the maximum amplitude of i_{motion}, we substitute Eqn. (13) into Eqn. (17) and use the definitions of q and β_0 with the assumption of a resonant excitation ($\Omega \approx \omega_1$). We then get

$$I_{motion,max} \approx 2\left[\frac{V_{bias}\varepsilon_0 h l L_1}{d^2}\right]^2 \frac{V_{ac}Q}{m\omega_1}. \quad (18)$$

Note that $I_{motion,max}$ is not a function of nonlinearities but is proportional to $V_{bias}^2 V_{ac}Q$, as in the linear case [4]. In addition to i_{motion}, the feedthrough current

$$i_{feed} = C_{feed}\frac{dv_{ac}}{dt} = -C_{feed}V_{ac}\Omega\sin(\Omega t) \quad (19)$$

also contributes to the output current $i_{out} = i_{motion} + i_{feed}$. However, when the driving frequency Ω is near the resonant frequency Ω_r, we can often assume that $|i_{feed}| \ll |i_{motion}|$; i_{out} is thus approximated with i_{motion} in this case.

The motional impedance Z_m is generally given by

$$Z_m = \frac{v_{ac}}{i_{out}} = \frac{v_{ac}}{i_{motion} + i_{feed}}, \quad (20)$$

but by using the above the assumption of $\Omega \approx \Omega_r$, $|i_{feed}| \ll |i_{motion}|$, and we can simplify the expression for the minimum motional impedance by using Eqn. (18):

$$Z_{m,min} \approx \frac{V_{ac}}{I_{motion,max}} \approx \frac{1}{2}\left[\frac{d^2}{V_{bias}\varepsilon_0 h l L_1}\right]^2 \frac{m\omega_1}{Q}. \quad (21)$$

$Z_{m,min}$ is often called the motional resistance R_m since Z_m gets to the minimum when the motional inductance L_m and the motional capacitance C_m cancel each other out. Comparing R_m from the linear models to Eqn. (21), we find that nonlinear $Z_{m,min}$ is not affected by nonlinearities and is similar to R_m from the linear models [3]–[5].

Fig. 4 shows estimated Z_m: for the estimation, we plug the solutions of Eqn. (11) into Eqn. (10) and then into Eqn. (17) to estimate i_{motion}; we use Eqn. (19) to estimate i_{feed}; we then estimate Z_m by using Eqn. (20). The result shows that $Z_{m,min}$ is not affected by nonlinearities (or the level of V_{ac}), as Eqn. (21) predicts. This result implies that the assumption of $|i_{feed}| \ll |i_{motion}|$ is valid. Table I summarizes the parameters for the estimation.

III. EXPERIMENTAL SETUPS

A. Conventional open-loop measurement setup

A conventional way to measure Z_m is by using an impedance analyzer (Fig 5(a)). An impedance analyzer provides input voltage signal v_{ac} and measures the output current signal i_{out}. By measuring this open-loop I-V characteristic, the analyzer can measure the Z_m in a given frequency range. This impedance analyzer method is good for resonators that do not have nonlinearities, but not for resonators with nonlinearities.

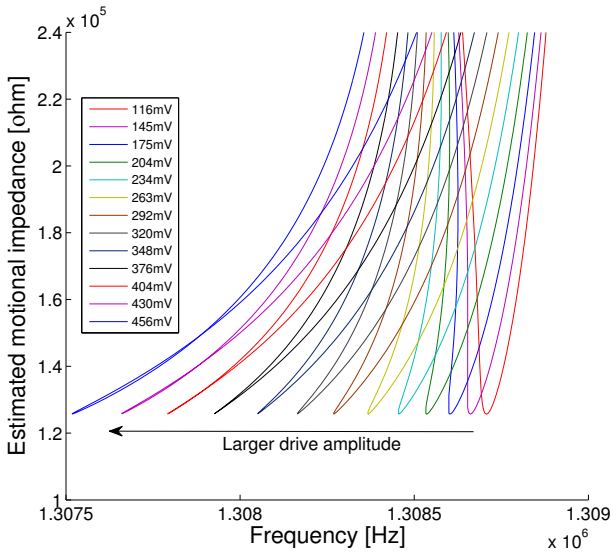

Fig. 4. Estimated $|Z_m|$ at various V_{ac} levels, shown in the legend, for a given range of the driving frequency Ω. For each V_{ac}, we use Eqn. (20) to estimate $|Z_m|$.

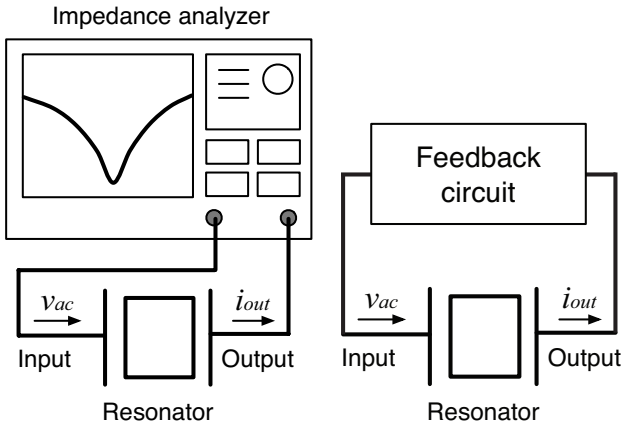
To understand this limitation, we must check the frequency-to-amplitude relation of a resonator in the nonlinear regime.

Nonlinearities in a resonator result in the frequency-to-amplitude relation exhibiting V_{ac}-dependency (Fig. 2) [3], [4], [6], [7], [12]–[14]. When V_{ac} is larger than a critical value ($\approx$ 145 mV in Fig. 2), the frequency-to-amplitude relation becomes indeterministic for some driving frequencies; hence, the amplitude of a resonator can be uncertain for some driving frequencies. This uncertainty leads to unstable states in the impedance analyzer measurement. In the actual measurement, the part of the Z_m response curve that corresponds to the unstable states becomes unobservable, though stable branches in the response curve can be measured by alternating the frequency sweep direction [4], [7], [12]–[15]. To summarize, an impedance analyzer cannot measure the full characteristic of Z_m when a resonator is in the nonlinear regime.

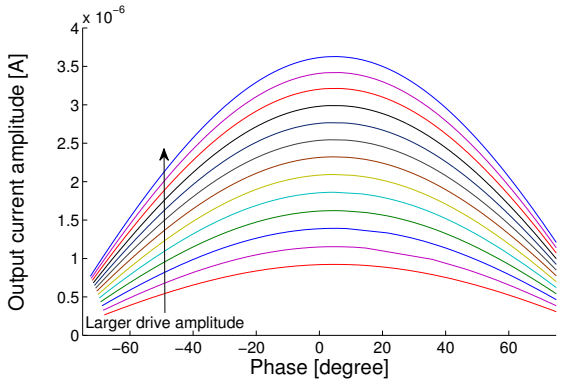
B. Novel closed-loop measurement setup

We propose a new Z_m measurement method by using a feedback circuit (Fig 5(b)). A feedback circuit provides gain for continuous operation of a resonator. By comparing amplitudes of an input voltage signal v_{ac} and an output current signal i_{out}, we can perform closed-loop I-V measurements. The major difference between using a feedback circuit and using an impedance analyzer is that a feedback circuit sets the phase rather than the driving frequency Ω; in other words, in this closed-loop method, phase is an independent variable. Unlike the frequency-to-other relations, the phase-to-amplitude and the phase-to-frequency relations are always deterministic in the closed-loop measurement setup, regardless of nonlinearities. (Fig. 6) [10], [16]. Since the amplitude and frequency are deterministic for any given phase, instability cannot occur and

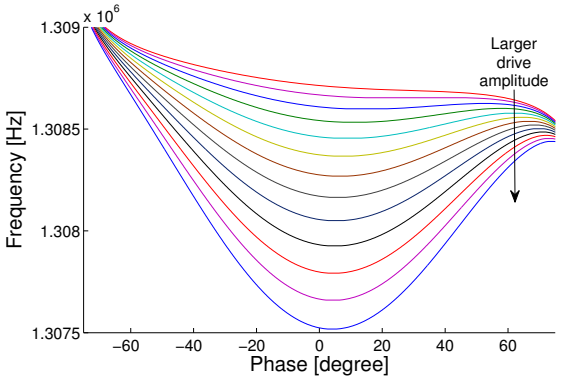


(a) Open-loop setup (b) Closed-loop setup

Fig. 5. Motional impedance measurement setups.



(a) Phase-to-amplitude relation



(b) Phase-to-frequency relation

Fig. 6. Phase-to-other relations at the V_{ac} levels that are used for the estimation in Fig. 2. Eqns. (17) and (19) are used to estimate the output current $i_{out} = i_{motion} + i_{feed}$; the magnitude of i_{out} is then used to estimate the output current amplitude; the phase difference between i_{out} and v_{ac} is used to estimate the phase. The peak amplitude occurs at non-zero phase because of the feedthrough current i_{feed}.

the measurement is not limited by nonlinearities unlike in the open-loop measurement setup [10], [16].

If a feedback circuit has a fixed phase, however, we can

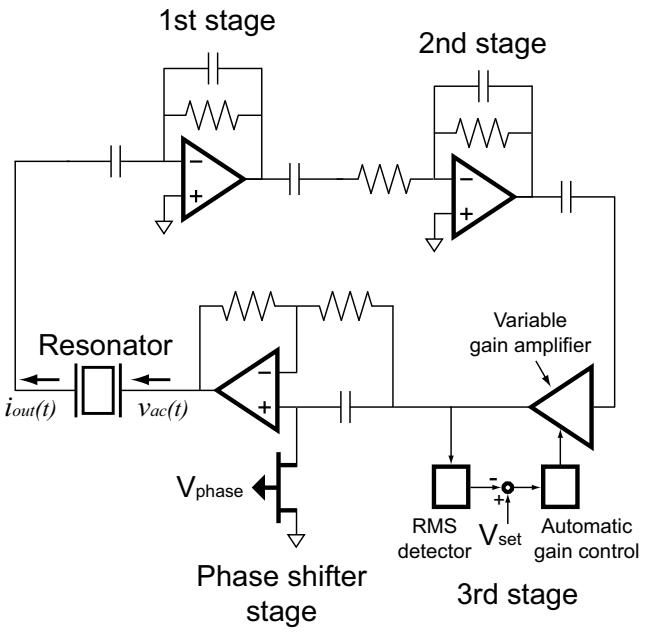


Fig. 7. Circuit diagram of a variable-phase closed-loop feedback circuit

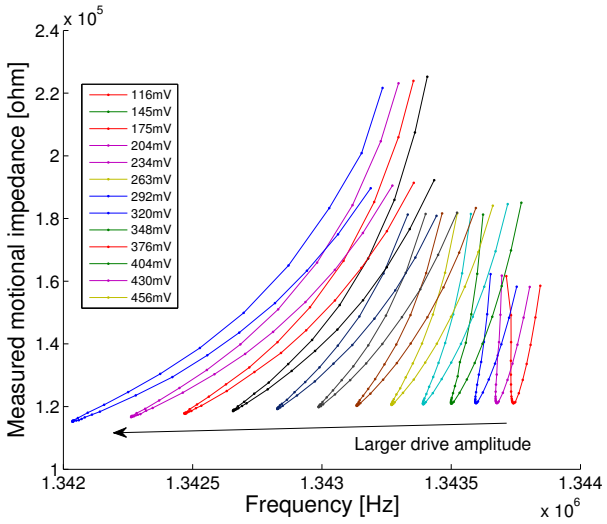

Fig. 8. Measured $|Z_m|$ at various V_{ac} levels, shown in the legend. For each V_{ac}, we used more than 25 V_{phase} values to measure nonlinear Z_m characteristics.

measure Z_m only at one point, which corresponds to the fixed phase, but not at many other points. Therefore, the feedback circuit must perform phase sweep, just as an impedance analyzer does frequency sweep, to measure many operating points. For this reason, we need a variable-phase feedback circuit. To implement the variable-phase feedback circuit (Fig. 7), we add a voltage-controlled phase shifter to an ordinary fixed-phase feedback circuit. The first and the second stages of the feedback circuit act as a trans-impedance amplifier (TIA), which converts current to voltage. The third stage employs an automatic level control, a variable gain amplifier, and a RMS detector to maintain V_{ac} at a desired level, which is externally set by V_{set}. To implement a voltage-controlled phase shifter, we use an all-pass filter with a voltage-controlled resistor, implemented by a JFET: the resistance of the JFET is externally set by V_{phase}. Then, this circuit is connected to a resonator to form a closed-loop oscillator.

IV. Experimental Procedure and Results

We used an SA-DETF type resonator for the experiment (Fig. 1(a)). This resonator was fabricated with the process detailed in [17]. The resonant frequency is about 1.3 MHz, and the Q is about 8710. This resonator experiences first-order electrical softening nonlinearity [13]. We connected a counter to the output of the TIA to monitor the resonant frequency. We also connected an oscilloscope to the output of the TIA and the input to the resonator to measure the amplitude of input and output signals (Fig. 7).

In order to measure Z_m at many phase values and V_{ac} levels, we first set the phase of the circuit; we then estimated Z_m by measuring the input and output amplitudes at many V_{ac} levels: although we measured the voltage amplitude at the output of the TIA, we can estimate I_{out} by using the known gain of the TIA. Repeating this for many phase values, we could measure Z_m at many operating points.

Fig. 8 shows the experimental result. We set more than 25 phase values and 13 V_{ac} levels. The $Z_{m,min}$ ranged from 121 kΩ to 115 kΩ. The curves show that our new method could measure nonlinear Z_m characteristics that an impedance analyzer cannot measure. Since an impedance analyzer cannot measure these characteristics, this is a remarkable result.

Our measured result for the nonlinear Z_m characteristics match well the estimation based on the model we developed. Our model over-estimates Z_m by less than 10% for the worst case. We speculate that the difference stems from uncertainties in dimensional and material parameters for the estimation. A more noticeable difference between the estimation and the measured data is the change of $Z_{m,min}$ with the change of V_{ac}. In the estimation, the $Z_{m,min}$ value is not a function of V_{ac}, and this is expected by the model in Eqn. (21): since we used constant Q for the estimation, $Z_{m,min}$ must be constant. In the measured data, however, $Z_{m,min}$ decreases by 5% as we increased V_{ac} for a given V_{ac} range. Since $Z_{m,min}$ is inversely proportional to Q, Eqn. (21), this result may imply that the Q of the resonator increases by 5% when V_{ac} increases for the given range. However, it may also be an experimental artifact or stem from assumptions we make when we derive the Z_m model in section II, such as a weakly nonlinear system. Therefore, further research is necessary to find the source of the $Z_{m,min}$ change.

V. Conclusion

We developed a nonlinear Z_m model and a new measurement setup, with which we can estimate and measure nonlinear Z_m characteristics of an electrostatic resonator. The Z_m model we developed can precisely estimate the Z_m of a resonator that

operates in the nonlinear regime with errors of less than 10% in the worst case. Although the model was developed for a specific type of resonators, the result of this study can be generally applied to other types of resonators because an ordinary differential equation similar to Eqn. (9) can be obtained after modal analysis is applied to the model for other resonators. In addition, the new closed-loop measurement setup can be also utilized to measure the nonlinear Z_m characteristics of other types of resonators. Therefore, this study is of broad relevance to the resonator community.

ACKNOWLEDGMENT

This work was supported by DARPA HERMIT (ONR-N66001-03-1-8942), the Bosch Palo Alto Research and Technology Center, the Samsung Scholarship, the National Science Foundation Graduate Fellowship, the Stanford Graduate Fellowship, and the National Users Network facilities funded by the National Science Foundation under award ECS-9731294. Abstract— **T2L2 (Time Transfer by Laser Link), developed by both CNES and OCA permits the synchronization of remote ultra stable clocks over intercontinental distances. The principle is derived from laser telemetry technology with dedicated space equipment deigned to record arrival time of laser pulses at the satellite. Using laser pulses instead of radio frequency signals, T2L2 permits to realize some links between distant clocks with a time stability of a few picoseconds and accuracy better than 100 ps. The T2L2 space instrument is in operation onboard the satellite Jason 2 since June 2008. Several campaigns were done to demonstrate both the ultimate time accuracy and time stability capabilities. It includes some experiments implemented in co-location to directly compare T2L2 time transfer residuals with the direct link between stations, and some ground to ground time transfer between ultra stable clocks. Important works have been done, between OCA and OP, to accurately compare T2L2 with microwave time transfer GPS and TWSTFT. These comparisons are based on laser station calibrations with a dedicated T2L2 calibration station designed to accurately set the optical reference of the laser station within the PPS reference of the microwave systems. Other experiments are also planned in the future: 3D localization with the lunar space vehicle LRO, T2L2 coverage extension over the Pacific Ocean (Tahiti), DORIS comparison and a third international campaign.**

I. INTRODUCTION

T2L2 is a time transfer technique based on laser ranging network at ground and a dedicated space segment. The project, developed by CNES (Centre National d'Etudes Spatiales) and OCA (Observatoire de la Côte d'Azur), has been launched in 2008 on the Jason-2 satellite for a 5 years mission [1], [2], [3].

T2L2 relies on the propagation of laser pulses between the clocks to be synchronized. It is an evolution of current radiofrequency time transfer systems profiting from advantages of the optical domain such as higher modulation bandwidth and insensitivity to ionosphere, and also from advantages of the two way technique on a mono-carrier scheme. All these elements permit to enhance the performance of time transfer by one or two order of magnitudes compared to existing microwave techniques such as GPS and Two-Way Satellite Time and Frequency Transfer (TWSTFT).

It provides the capability to compare today's most stable frequency standards with unprecedented stability and accuracy [4]. Ultimate expected T2L2 performances are in the 100 ps range for accuracy, with a time stability of about 1 ps over 1,000 s and 10 ps over one day [5].

II. PRINCIPLE

The T2L2 elementary block is a space to ground time transfer between the ground clock linked to the laser station and the space clock. The ground to ground time transfer between several remote clocks at ground is obtained through such individual space to ground time transfers. It can be obtained in a common view mode, when the distance between the laser stations is smaller than 5000 km, or in a non-common view mode when the distance is larger.

The laser station includes a telescope, a pulsed laser, some photo detection devices and two event timers connected to the ground clock, one to time tag the start event, the other for the return. The energy by pulse is between 400 µJ to 1 J and the pulse width is in the range of 20 ps up to 200 ps. The laser rate is between 5 Hz to 2 kHz. The laser stations range the satellite every 2 hours, 5 to 7 times a day when the weather conditions are favorable.

The space instrument (Fig. 1) includes a photo detector [6] and an event timer [7], [8] linked to the space clock and a laser ranging array (provided by the JPL) used to reflect the laser pulse toward the laser station. The space clock is an ultra-

stable oscillator (USO) fundamentally used by the Doris equipment.

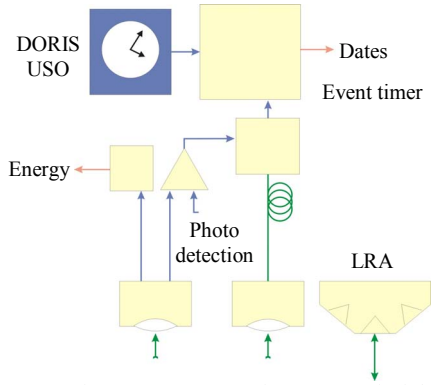

Figure 1. T2L2 Space instrument principle

For a given laser pulse emitted by the laser station, one get a start date and a return date at ground, and also an arrival date at the satellite. From these 3 dates (which are called a triplet) we can extract the time delay between the ground clock and the space clock. T2L2 relies on the laser ranging network which includes 40 international laser stations. Among them, 16 stations provide the full rate data needed for the triplets extraction.

The first step in the T2L2 data reduction is the determination of the ground to space time transfer for every passes acquired. Fig. 2 is an example of what is got for a pass obtained with the MeO Laser Station linked to an H-Maser at OCA.

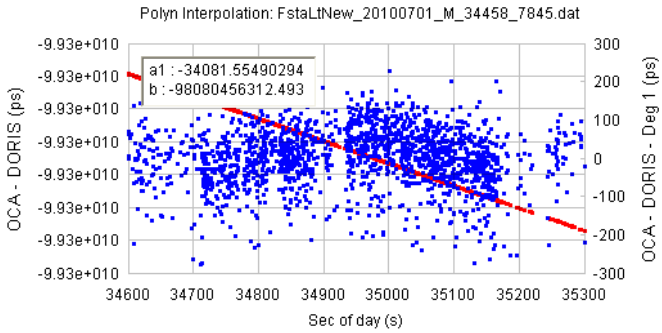

Figure 2. OCA – DORIS time transfer. The red line (left scale) is the direct time transfer. The global slope is coming from the large frequency offset between DORIS and OCA. The blue dots (right scale) are the residuals.

The corresponding time stability is illustrated in Fig. 3.

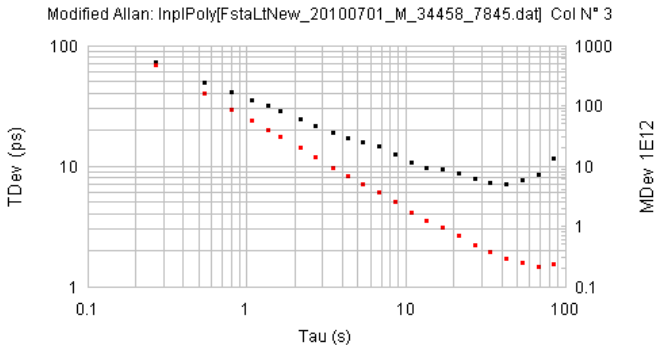

Figure 3. OCA – DORIS Time deviation (black, left scale) and Modified Allan deviation (red, right scale). Performances are in accordance with the DORIS USO.

Accumulation of several consecutive passes over the same station permits to give a mid-term time transfer comparison (Fig. 4). These mid-term monitoring will be used in the next reduction evolution to make time transfer in non common view configuration.

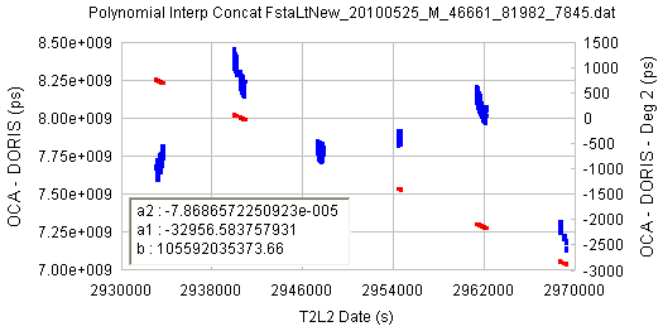

Figure 4. OCA – DORIS comparison over several consecutive passes (Direct comparison, red, left scale; residuals, blue, right scale). Up to 7 passes, giving an overall time comparison of 12 hours, can be acquired consecutively.

III. ACCURATE GROUND TO GROUND TIME TRANSFER

T2L2 has been designed to realize ground to ground time transfer with accuracy better than 100 ps. If one can neglect the noise coming from the individual ground to space time transfer, this accuracy requires the measurement of the laser pulse start times with accuracy in the range of 50 ps.

Usual laser stations are only designed to measure time difference between a start and a stop with an accuracy of the start pulse of typically 100 ns. These 50 ps can only be obtained with a special time calibration based on simultaneous measurements between the usual chronometry of the laser station and a dedicated calibration station. It permits to measure the delay between the optical pulse at the cross axis of the telescope and the electrical reference coming from the time and frequency laboratory. The reference point at the laser station level is the cross axes of the telescope which is also the space reference for laser ranging. The reference at the time and frequency laboratory is a given output of the PPS (Pulse Per Second) distribution unit.

The calibration station gather inside an unique equipment all the metrology required to perform measurements. The station includes a SigmaTime STX301Event Timer and an optical module to grab laser pulses from the laser station.

The event timer STX301 was developed in the T2L2 framework with 3 separate targets:

- to make the T2L2 calibration,
- to upgrade, if necessary, laser stations with no proper chronometry,
- to have a versatile high precision laboratory instrument.

The instrument has an internal frequency synthesis that can be slaved on an external 5, 10 or 100 MHz clock reference, two or four independent channels (electrical and optical: DC - 20 GHz), and a high stability pulse generator. All these metrology instruments are driven by an embedded Windows 7 computer able to control the hardware and to give to the user a friendly Human Machine Interface permitting to

measure both absolute start time and time interval, to sample the frequency, and to determine the shape of a given synchronous signal.

Figure 5. STX301-002R SigmaTime sub picosecond Event timer.

The global characteristics of the timer are given in table 1.

Parameters	Values
Number of independent channels	2 to 4
Time Stability @ 1000s	< 20 fs
Linearity	0.3 ps rms.
Thermal Sensitivity	< 200 fs/°C
Repeatability error Synchronous	< 600 fs rms
Repeatability error Random	700 fs rms
Dead time	130 ns
High speed Acquisition	500 kHz
Continuous rate	35 kHz
Input bandwidth	DC - 20 GHz

Table 1. Sigma Time STX301 main characteristics

Fig. 6 is a typical time deviation of the timer computed from the modified allan variance.

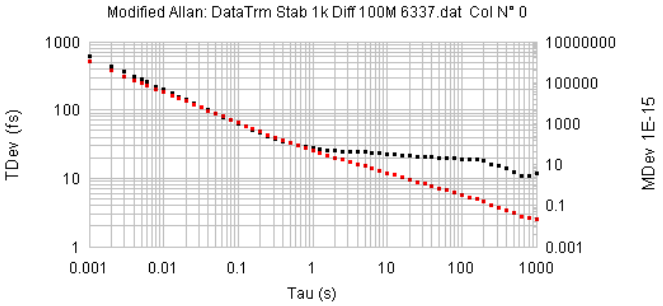

Figure 6. Time deviation (black, left scale) and Modified Allan deviation (red, right scale)of the SigmaTime STX301 event timer obtained from electrical pulses generated with an independent frequency synthesis slaved on a common clock

The optical module is made with a collimation optic connected to a 50 m mono mode optical fiber (532 nm). The delay inside the fiber is currently considered as a constant. In the next future a special instrumentation will permit to measure the variations that could be generated by some temperature changes or constraint variations. The optical module is placed in front of the telescope at a precise distant from the cross axes.

Time equation that permits to accurately time-tag laser pulses is given by:

$$\delta T = \delta_{cal} + \delta_{prg} = \delta_{cal} + \delta_{PPS} - (\delta_{ocx} + \delta_{ocf} + \delta_f + \delta_{det}),$$

where:

δ_{cal} is the difference between absolute measurement (calibration) and station measurement and δ_{prg} the global propagation between cross axes and the PPS unit (Fig. 7).

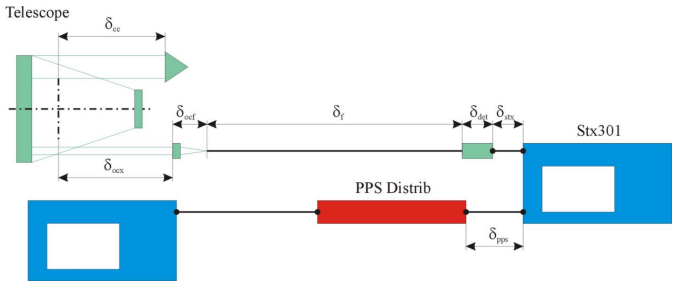

Figure 7. Definition of the propagation term through the telescope to the PPS distribution unit

The term δ_{cal} is determined in two steps:

- PPS Synchronization of the SigmaTime STX301 event timer
- Simultaneous acquisition of an ensemble of laser pulses from the laser station and the calibration station

The PPS synchronization is obtained from a Scan of the PPS signal by the event timer that permits to determine the reference threshold deduced from the inflexion point and the synchronization of the timer with this reference threshold.

The term δ_{prg} depends on three kinds of parameters:

- δ_{PPS} ; δ_f coming from propagation in cables and measured by the calibration station
- δ_{ocx} ; δ_{ocf} coming from propagation in free space and determined form the geometrical distance
- δ_{det} coming from propagation inside the detector (optical-electrical) and deduced form a propagation model (currently studied) [9].

The table 2 is an example of what we get for the MeO station

δ	Label/Ref	Value (ps)	Date
δ_{cc}	CC_{Lune}	12393	2010-07-01
δ_{PPS}	$T2L2CalC_2$	9408	2006-08-06
δ_{ocx}	Ref_{Axe}	12104	2010-07-01
δ_{ocf}	$T2L2MC_2$	58	2010-07-01
δ_f	$T2L2CalF_1$	248300	2006-08-06
δ_{stx}	STX301-001	0	2010-07-01

Table 2. MeO Calibration

IV. T2L2 CO-LOCALISATION AT OCA

OCA has two laser stations (fixed: MeO and mobile: FTLRS) that can be used together in order to realize a time transfer in a co-location configuration (Fig. 8). Being both connected to the same H-Maser, this configuration permits to directly compare the time transfer deduced from the calibration process and time transfer measured by T2L2.

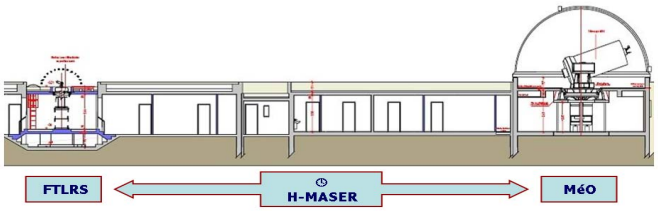

Figure 8. FTLRS (left) and MeO (right) connected to same HMaser reference in order to realize a co-localisation time transfer

13 common passes have been obtained in 2009 during a dedicated campaign (Fig. 9).

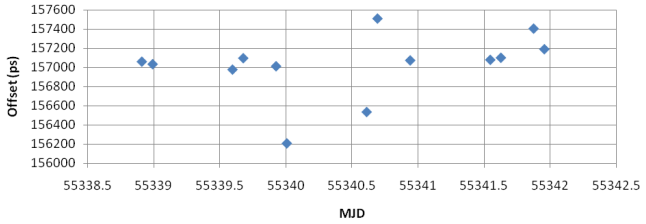

Figure 9. MeO – FTLRS T2L2 Time difference.

The time offset deduced from T2L2 Measurement is:

$$\delta_{TFtlrs} - \delta_{TMeo} = 157\ 019 \text{ ps} ; \sigma = 330 \text{ ps}$$

The time offset deduced from the T2L2 Calibration is:

$$\delta_{TFtlrs} - \delta_{TMeo} = 157\ 030 \text{ ps} ; s = 26 \text{ ps}$$

This gives a very good agreement within the given experimental standard deviation.

V. SECOND INTERNATIONAL CAMPAIGN

The T2L2 international campaigns aim to achieve the best possible time stability measurement between ultra stable clock and the best comparisons between microwave time transfer techniques [10],[11]. A first campaign was done in 2009 involving 4 laser stations. In 2010 one realizes a new 5 months campaign with 9 laboratories (Table 3).

Site	Clock	Time Transfer
Grasse-FRA	Fountain ; HM	GPS TWSTFT Eu
Paris-FRA	Fountain ; HM	GPS TWSTFT Eu
Borowiec-POL	HM	GPS TWSTFT Eu
Koganei-JPN	Fountain	GPS TWSTFT As
Simosato-JPN	Cs/Rb	GPS
Zimmerwald-CHE	Qx/GPS	GPS
Herstmonceux-GBR	HM	GPS
Matera-ITA	Cs ; HM	GPS
Wettzell-DEU	HM	GPS

Table 3. Laboratories global configuration

1155 passes was obtained during the campaign; 650 in common view configuration.

So far, only the link Grasse-Paris (Fig. 10) has been analyzed; the others will be reviewed in the next future.

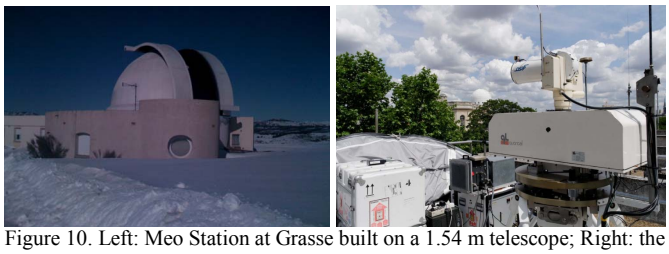

Figure 10. Left: Meo Station at Grasse built on a 1.54 m telescope; Right: the mobile FTLRS station at Observatoire de Paris.

Table 4 is a summary of the instrumental configuration of both laboratories for this Grasse-Paris link.

Location	Station	clocks	MW Time transfer
Grasse OCA	MeO	Fountain (OP) H-Maser	GPS TWSTFT
Paris OP	FTLRS (OCA)	Fountain H-Maser	GPS TWSTFT

Table 4. Clocks and Microwave time transfer systems

The OCA laser station FTLRS was installed on a dedicated platform at OP. Some special authorizations were obtained in order to be able to range with a laser in Paris. The OP mobile atomic fountain (FOM) was installed at OCA during the same period. At OP, FTLRS, the atomic fountain and the Microwave time transfer systems (GPS and TWSTFT) were connected to the same H-Maser. At OCA, MeO, the mobile atomic fountain and the time transfer systems were also connected to a common H-Maser. Both OP and OCA have been calibrated with the same T2L2 calibration station as described in chapter 3. 56 passes in 114 days was recorded. From each pass acquired, an equivalent point representing the average value of the time difference and the average value of the date is computed.

The first result extracted from these comparisons is the T2L2 time difference between H-Masers (Fig. 11, Fig. 12).

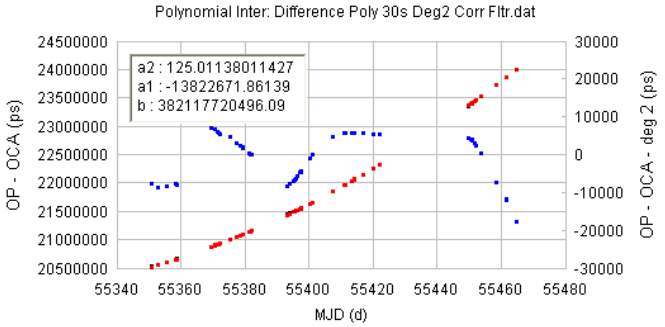

Figure 11. Direct T2L2 time differences between OP and OCA H-Masers (red, left) and difference – order 2 polynomial (blue, right).

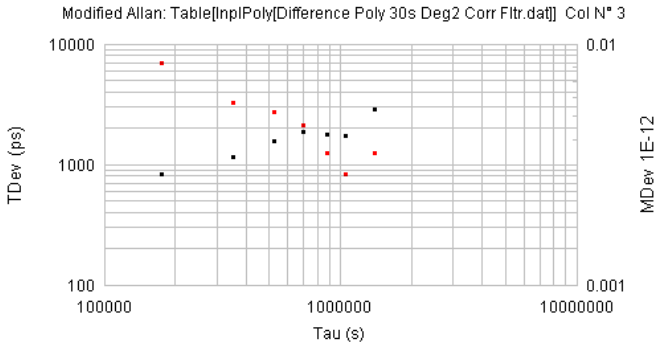

Figure 12. Time deviation (black, left scale) and Modified Allan deviation (red, right scale) of the T2L2 H-Maser differences

With a modified Allan deviation in the range of 3x10-15 over 10 days, one concludes that the noise introduced by T2L2 over several days is significantly below the noise coming from the H-Masers themselves.

The second important result is illustrated in figure 13. The graph shows both the time transfer comparison between T2L2 – GPS (carrier phase based) – TWSTFT (code phase) and the differences between Atomic fountains. The GPS analysis is based on the PPP NRCan algorithm (carrier phase technique). This is a preliminary result in which the absolute calibration hasn't been taken into account: an offset between each curve was introduced to facilitate the graph reading. Regardless of these absolute aspects, the global drift on the Microwave-T2L2 time comparisons are better than 2 ns over 2 months which is in accordance with the classical long term stability of microwave time transfers.

The phase of the atomic fountain comparison is computed from the frequency information between the fountain interrogation and the H-Maser frequency reference. For some technical reasons, the atomic fountains weren't in operation continuously during the whole campaign. This has probably introduced a significant midterm noise: pink and red plots of fig. 13. A more detailed analysis taking into account the real operation period of the fountains, will be made in the future.

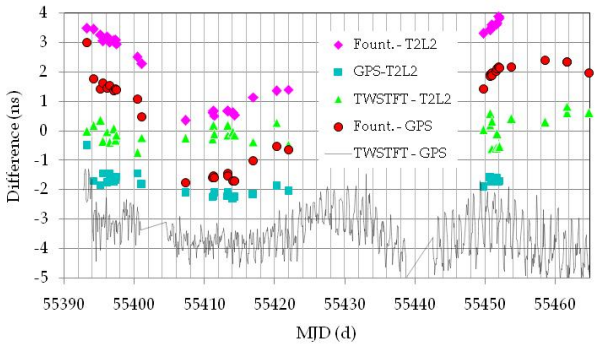

Figure 13. Microwave and T2L2 time transfer comparison and atomic fountain differences. A time offset between each plot is voluntary introduced to facilitate the reading of the graph.

VI. 3D LOCALIZATION WITH LUNAR RECONNAISSANCE ORBITER (LRO)

The primary objective of LRO (NASA project) is to conduct investigations in order to prepare for future lunar exploration. The orbiter has a laser altimeter called LOLA, fundamentally made to measure the relief of the moon surface. This altimeter has also been designed to be used from the earth with a 2 cm aperture telescope oriented toward the earth direction. This system permits to range the orbiter from the laser station network at ground. The range is deduced from the computation of the time difference between start time recorded by the laser stations and the arrival time recorded by altimeter. If one can range simultaneously LOLA with at least 2 laser stations one can resolve the 3D geometry from the differential measurement onboard LOLA (Fig. 14). Because the geometry is very sharp (distance between LRO >> distance between laser stations) the time synchronization between laser stations has to be very precise. Because T2L2 is based on the same laser ranging technologies which are also used for LOLA, T2L2 is perfectly well suited to perform this synchronization.

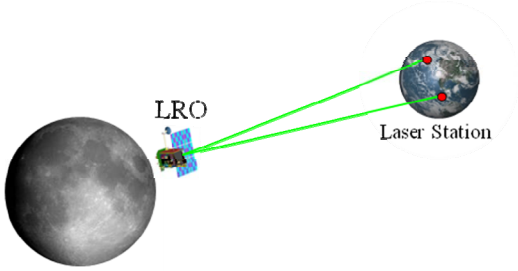

Figure 14. 3D localization of LRO with several laser stations at ground synchronized by T2L2

Several simultaneous observations in common view have already been acquired (Fig.15). So far, data hasn't been yet analyzed with T2L2: everything remains to be done on the subject.

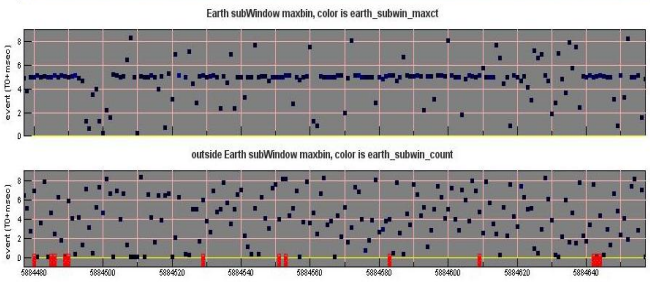

Figure 15. Simultaneous acquisition from Zimmerwal (CH) and MeO (FR)

VII. TAHITI CAMPAIGN

A new dedicated campaign was started in April 2011 on the OGT (Observatoire Geodésique de Tahiti) site (Fig. 16) where a USA Moblass laser station is installed. The campaign implies the installation of the mobile laser Station FTLRS, H-Maser, a devoted T2L2 GPS receiver and the T2L2 calibration station.

The objective is four fold:

- OneWay laser ranging on LRO between McDonald (USA) and Tahiti
- Remote control of the onboard DORIS oscillator over a region currently not observed
- T2L2 - DORIS Inter comparison
- T2L2 FTLRS -Moblass time transfer co-location

Figure 16. Mobile laser Station FTLRS at Tahiti

VIII. PROSPECTIVE-CONCLUSIONS

Four important developments are envisioned in the next T2L2 schedule:

- Ground to ground time transfer in a non common view configuration based on an onboard oscillator model fitted from an ensemble of referenced ultra stable clock at ground.
- International T2L2 calibration campaign. It includes the laser station calibration and also a relative GPS calibration from a mobile GPS Receiver
- A third international campaign. As compared to the standard laser station network, the campaign could be done with two more lab: OP with FTLRS and PTB with TROS (Chinese mobile laser station)
- DORIS comparison between ground to space time transfer deduced from the DORIS frequency measurement and T2L2

ACKNOWLEDGMENT

The authors wish to thanks ILRS and laser stations that have participate to the T2L2 project. They wish also to thanks the French Civil Aviation for laser security at Paris.

***Abstract*— We are presenting a progress in a construction and indoor tests of the photon counting detector for the European Laser Timing (ELT) experiment. ELT is an optical link prepared in the frame of the ESA mission "Atomic Clock Ensemble in Space" (ACES). The objective of this laser time transfer is the synchronization of the ground based clocks and the clock on board the space station with precision of the order of units of picoseconds and the accuracy of 50 ps. The requirements put on the detector package are quite high – temperature stability of the delay better than 20 ps peak to peak within one satellite orbit, operation within a broad temperature, absolute calibration of the photon to electrical signal delay with precision 25 ps and others.**

I. INTRODUCTION

The laser time transfer link is under construction for the European Space Agency (ESA) for its application in the experiment Atomic Clock Ensemble in Space (ACES). The device is expected to be launched toward the International Space Station (ISS) in 2014. The objective of this laser time transfer is the synchronization of the ground based clocks and the clock on board the space station with precision of a few picoseconds and the accuracy of 50 picoseconds [1].

Although the signal photon flux at the ISS orbit is of the order of 10^{13} photons per square meter per one laser shot and multi-photon signal strength may be obtained, the photon counting approach to the optical signal detection has been selected in order to reduce the systematic biases as much as possible.

The project is a spin-off of the existing projects of laser ranging to artificial Earth satellites [2] (SLR). The on-board hardware consists of a Comer Cube Retro-reflector (CCR), an optical receiver based on a Single Photon Avalanche Diode (SPAD) and an event timing device connected to the local time scale, see Fig. 1. The ultra short laser pulses fired towards the satellite by a ground laser ranging station will be time tagged with respect to the ground time scale ***T.*** They will be detected in space and time-tagged in the local time scale ***E***. At the same time, the CCR will re-direct the laser pulse towards the ground station providing precise ranging information ***D*** and hence providing the information about the ground-to-space signal propagation delay. This procedure should provide, among others, the time transfer ground to space with precision and accuracy outperforming the radiofrequency techniques.

Because of the ISS is at low orbiter (400-500 km) the signal photon flux at the detectors input optics is of the order of 10^{13} photons per square meter per one laser shot and multi-photon signal strength may be obtained, the photon counting approach to the optical signal detection has been selected in order to reduce the systematic errors as much as possible. Hence the requirements put on the detector optics are large attenuation of the receiving signal and the compensation of the radar equation. The input optics must not influence the timing and stability properties.

It is required that the detection timing resolution must be 25 ps with the timing stability of 1 ps per day. The entire ELT package must be able to operate at temperatures from -10 to +40 °C and the maximum mass can not exceed 0.5 kg with maximum power consumption 1 W. The ELT project is planned for three years mission in space and there will be no sun protection included.

The absolute calibration of the signal delays within the laser time transfer signal chain is very challenging. Among others the optical to electrical detection delay of the photon counting receiver itself should be calibrated with the uncertainty of 25 ps maximum.

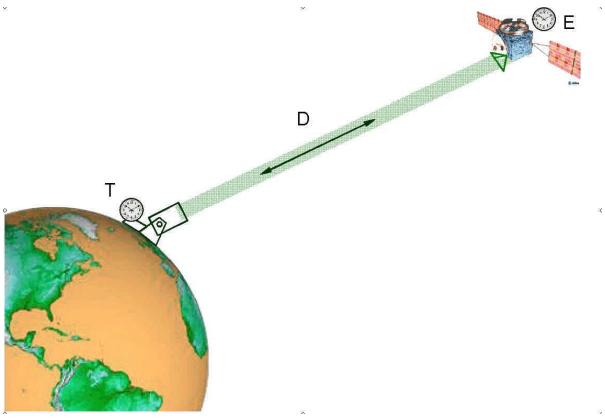

Figure 1. The principle of the laser time transfer ground to space and vice versa.

II. ELT CONSTRUCTION

The detector under construction is based on the Single Photon Avalanche Diode (SPAD) having an active area of 100 µm in diameter. The detection chip is manufactured by the K14 technology and is mounted in un-cooled socket and is operated in active quenching and gating mode. Designing the detector electronics with detection delay stability of 20 ps peak to peak (with the goal of 10 ps) over one satellite orbit, the operating temperature range of -10 °C to +40 °C and last but not least the radiation stability in a near Earth orbit environment were rather challenging. The classical schemes used until now could not be used. The space qualified electronic components had to be used whenever possible. The electronics block diagram is in Fig. 2.

Two linear stabilizers provide the biases +5.0 V and +3.3 V for the detector logic. The DC-DC converter provides +35 V, 10 mA for the SPAD bias stabilizer. The SPAD bias stabilizer is stabilizing the SPAD reverse bias according to the detector temperature hence the detector delay temperature dependence is compensated. The ultra-fast PECL comparator is sensing the SPAD break down after a photon is detected. The gate and quenching logic is based on LVDS and CMOS circuits. The circuit enables to operate the SPAD chip 0.1 V up to 2.0 V above its break down.

The photograph of the bread board (BB) version of the active quenching and gating circuit is in Fig. 3. The detection chip is connected in the centre from the bottom side of the printed circuit board. The power, gating signal, and test signals are connected via a multi-pin connector (left). The DC-DC converter providing the SPAD bias voltage is in the lower part, the SPAD bias stabilizing and temperature control circuit is in the left. The +5.0 V and +3.3 V power stabilizers are on the top, the fast comparator sensing the SPAD electrical output is in the center with the gating and level converting circuits on the right. The total board dimensions are 74 × 74 mm, its mass is 42 g.

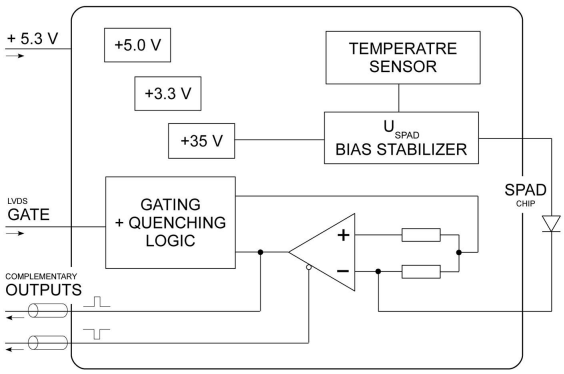

Figure 2. The ELT detector eletronics block diagram.

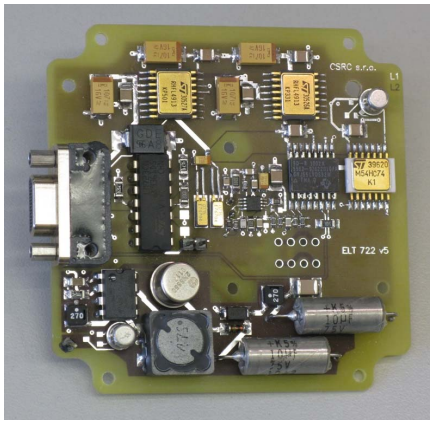

Figure 3. Bread board version of the active quenching and gating circuit. Entire components are space qualified or their military specified pin to pin compatible versions.

Entire components which are used for ESA ELT mission are space qualified and where approved by ESA except of the fast comparator sensing the SPAD breaks down. Due to extreme requirements on the propagation delay stability over a broad temperature range the Analog Devices ADCMP 553 was selected for our purpose. The manufacturer claims propagation delay of 500 ps with the temperature coefficient of 0.2 ps / K. We were allowed to test the comparator by ourselves by ESA approved radiation test procedure. The comparator survived three times larger radiation dose then it was prescribed and any of the comparator parameters had changed.

III. TEST PROCEDURE

The ELT detector package was tested in series of Time Correlated Photon Counting (TCPC) experiments. The Block diagram of the experimental setup is in Fig. 4. The gate pulse opens the detector detection window and consequently it is programmable delayed to trigger picoseconds laser. The picoseconds optical pulses were generated using Hamamatsu laser pulsar C4725, which provides optical pulses 42 ps long at the wavelength of 778 nm. The emitted picoseconds laser pulses are then spitted in to a strong signal and single photons pulses. The strong optical signal triggers photo-diode working in linear mode and the single photons are detected using ELT detector and the first photon detection closed the detection window. The time intervals between strong signal and single photos detections were measured by CTU sub-picoseconds Event Timer [3]. The recorded histogram corresponds to the optical waveform. The typical timing resolution of this setup was 18 ps rms.

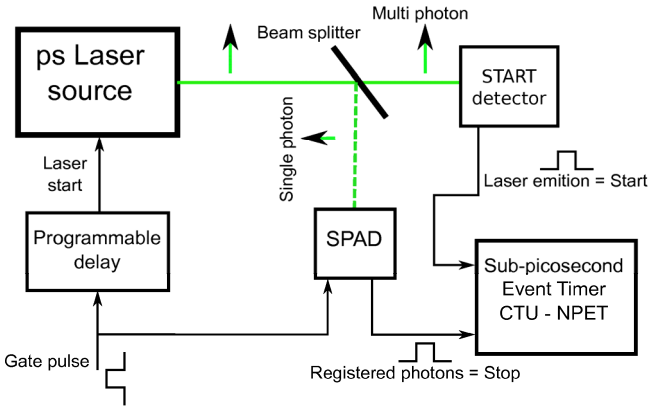

Figure 4. Time Correlated Single Photon Counting experimental setu.

IV. THERMAL PROPERTIES

The electronics together with the detection SPAD chip were installed into the housing of the engineering model. The thermal properties of the detector were tested in TCPC experiment where the internal temperature was monitored using the build in temperature sensor sensing the board temperature.

At first the temperature as a function after Power ON was measured. The heat exchange to the surrounding environment was minimized by thermal insulation of the entire package. From the measurement one can conclude, that the normal operation and high delay stability of the detector can be achieved as soon as 5 minutes after Power ON, because the delay stability is maintained for temperature range 6.5 °C peak-to-peak change. The detection delay in 80 minutes changed by 1 ps after 5 minutes after Power ON.

One of the most challenging requirements on the detector design was its long term stability and stability versus operating temperature changes. The detector is expected to be operated within the temperature range of -10°C to +40°C. The ESA requirements put on detection delay change is 20 ps with the goal of 10 ps for the temperature variation, which is expected during one ISS orbit. The estimation of the temperature change is 6.5°C. The temperature variations of the detection delay were tested in the TCPC experiment, where the detector was installed inside the thermostat. The detections delay was measured for a set of board temperatures, the results are in Fig. 5. The measured characteristics was fitted with a linear slope of 0.6 ps/K hence for 6.5 °C temperature range the maximum detection delay change is 3.9 ps. This value is well below the required 20 ps and much less to the 10 ps goal.

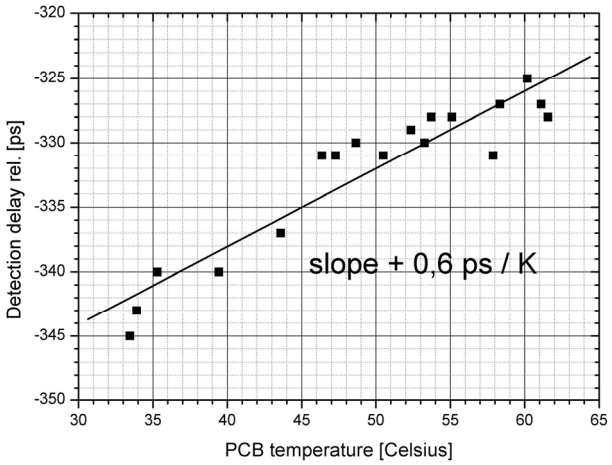

Figure 5. The detection delay temperature dependance, room temperature up to 60 °C. The detection delay coefficient is 0.6 ps/°C.

V. DETECTION LONG TERM STABILITY

The long term stability was tested in standard TCPC experiment. The experiment was carried out during the weekend in standard laboratory conditions where was no special intention put on temperature stabilization of the room temperature. The temperature changed during the experiment by -4 °C. The measured time delays were plotted with a linear fit with the slope of 280 fs/°C, see Fig. 6.

The experiment was repeated for different repetition rates of measurement (10, 30, 100 and 300 Hz) with typical data rates of 6 to 10 % and single shot jitter of 23 ps rms. The entire experiment temperature changed was ±2 °C. The resulting detection delay stability in the form of the time deviation T_{DEV} graph is plotted in Fig. 7. The detection timing stability for repetition rate of 30 Hz was measured to be 400 fs/day. It should be mentioned here, that the long term stability is influenced by a number of additional contributors: laser source, CTU event timing unit, coaxial cables and additional electronics stability.

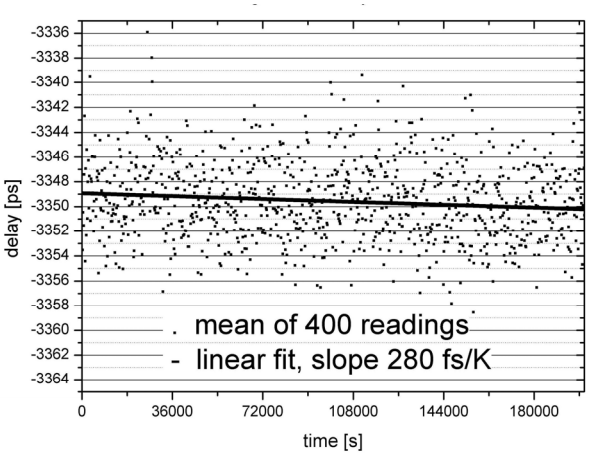

Figure 6. Detection delay long term stability test, the Time Correlated Photon Counting (TCPC) experiment was carried out during the weekend, temperature changed by -4 °C. The detection delay change has slope 280 fs/°C.

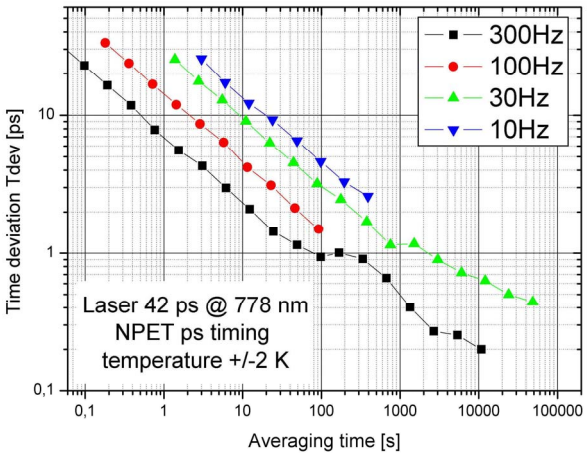

Figure 7. The ELT detector package timing delay stability. The standard TCPC experiment setup was used. The optical pulses 42 ps @778 nm, the sub-picoseconds timing system by CTU. The data rate was 6 - 10 %, the single shot timing jitter was 23 ps rms. The Tdev algorith Stable32 was used. The operating temperature changed ±2 K.

VI. Absolute Detection Timing Delay

We have developed the measurement technique and have measured the absolute value of the optical to electrical detection delay of the solid state photon counter. The individual contributions to the photon detection delay with rough estimate of their typical values are listed in Fig. 8. It should be mentioned that all the listed contributions are temperature dependent. The overall dependence of the change in detection delay with temperature was measured in an independent experiment, which was described in previous paragraph. The photon counting is a quantum mechanical process, the event of arrival of the photon of interest at the detector input can be determined only indirectly. The entire experiment is described in [4]. The absolute value of the time interval between the time of arrival of the signal photon onto detector input aperture and the time when the electrical output signal is exceeding the predefined level was determined with the precision of 10 to 12 ps. The acceptable mean values reproducibility and entire experiment stability was achieved. We have also demonstrated the dependence of the measured detection delay and hence the final result on the recording bandwidth.

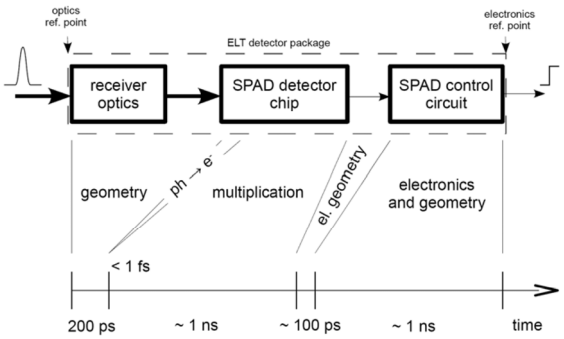

Figure 8. The individual contributions to the photon detection delay with rough estimate of the typical values.

VII. Receiver Optics

The ELT detector front-end consists of input aperture with diffuse polycarbonate 3 mm in diameter, narrow bandwidth interference filter, stack of pinholes and SPAD, as it is shown in Fig. 9. Because the entire experiment will work only with optical signal strength in single photon level, the impacting energy level must be kept as constant as it is possible for entire range of angles. It is not possible to range in angle interval form 0 to 5 degree, hence the detector should be blind in this angle interval otherwise the background photon noise scattered from the Earth will undesirably increase the detector effective dark count rate on the other side the angle interval is limited by the SLR station minimum ranging elevation, in most of the stations it is possible to range up to 60 degree from the zenith in all directions.

When the previous limitations will be taken on account, the detector optics Field of View (FoV) should be designed from 5 to 60 degree. The main advantage, which should be considered in designing the ELT optics, is that the signal must be attenuated by the optics. The expected signal strength is to be 10^{13} photons/m^2 in pulse length of 10 to 100 ps FWHM and the signal must be attenuated to the single photon level. The main attenuation is set by the distance between front aperture and SPAD.

The narrow bandwidth interference filter is used to effectively filter the background photon noise scattered from the Earth and coming from the sunlight. SLR stations work with second harmonic Nd:Yag laser - 532 nm thus the interference filter is centered at 532 nm with bandwidth of 3 nm. It should be pointed out, for several tests at CTU laboratory picoseconds laser of wavelength 778 nm was used, hence the 532 nm interference filter was replaced by 778 nm filter. However the interference filter has narrow FoV in units of degrees. The stack of pinholes is used for blocking the signal coming from larger angels and which do not propagates alongside the optical axis. The diffuse polycarbonate is used to increase the detector FoV, but it still prefers the perpendicular light. To increase the signal to noise ration the steal shield is used to block out the scattered photons from the Earth atmosphere. To minimize the angle dependency for angels from 5 to 60 degrees the circular shield was improved with conical cuts. The relative intensity varies only from 0.05 to 0.8 through entire interested interval with en-counted radar equation. The construction overview of the ELT optics can be find in [5].

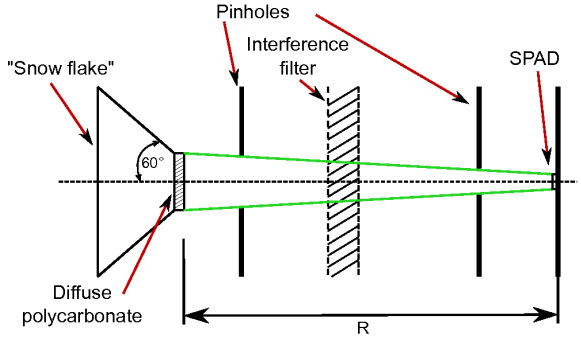

Figure 9. Schematic drawing of the receiver front-end optics.

VIII. CONCLUSION

We have developed and constructed a photon counting receiver, which is prepared for the European Laser Timing (ELT) experi-ment in space. The photon detection probability > 20 % at 532 nm wavelength, timing resolution better than 25 ps rms and the detection delay long term stability better than 1 ps were achieved. The detector package is capable to operate within a temperature range of -10 °C up to +40 °C, the detection delay change with the temperature is +0.6 ps/°C. The delay between the event of photon absorption and the appearance of the electrical pulse on the detector output was determined. The newly developed experimental technique permits to determine this detection delay within accuracy of 12 ps. The new configuration of the optical receiver should maintain uniform sensitivity over a wide field of view of ±5 to 60 degrees from nadir. Several radiation tests according ESA and ASTRIUM specifications were completed. The detector passed the ESA Critical Design Review; recently the engineering module is under construction.

ACKNOWLEDGMENT

This work has been carried out at the Czech Technical University in Prague. The research and development of solid state photon counting detectors and their applications is supported MSM6840770015.

***Abstract*—A precise two-way satellite time and frequency transfer (TWSTFT) data by using the Dual Pseudo-random noise (DPN) signal was correspondingly compared with the regular TWSTFT and GPS Precise Point Positioning (GPSPPP) between the National Institute of Information and Communications Technology (NICT) and Telecommunication Laboratories (TL) in this study. Our result shows that the frequency stabilities of DPN are competitive with those of the GPSPPP. There was less obvious diurnal in the DPN time transfer data. Since the DPN system has advantages of higher precision and lower bandwidth cost when compared with the regular TWSTFT, it is one of the most potential methods to improve the international time transfer links.**

I. INTRODUCTION

International Atomic Time (TAI) and Coordinated Universal Time (UTC) are generated based on the comparison of atomic time scales between time-keeping labs around the world. The Two-Way Time and Frequency Transfer (TWSTFT) technique has been widely employed to achieve a high precision of time comparison [1]-[4]. Two labs perform TWSTFT for exchanging the time information by transmitting and receiving the time signals by using two earth stations and a limited bandwidth from a commercial satellite. Because the two-way signal paths are almost reciprocal, the 1 ns uncertainty of time accuracy and a few 10^{-15} frequency stability can be achieved at the averaging time of one day [3][4].

Based on code division multiple access (CDMA) architecture, the pseudo-random noise (PRN) signal has been employed for regular TWSTFT [5]. Recently, regular TWSTFT employs PRN signal with chip rate 2.5 Mcps or 1 Mcps [6]. Each time-keeping lab can receive the desired PRN signal from remote labs. In order to improve the precision, the possible way is to increase the chip rate of PRN signal. However, the link fee of bandwidth will be increased when increasing the chip rate. To improve TWSTFT precision without increasing the link fee, the National Institute of Information and Communications Technology (NICT) has developed the Dual PRN (DPN) signal [7], which is based on the Binary Offset Carrier (BOC) signal that will be further used on Galileo and GPS civil navigation systems. The first zero-baseline DPN test has been performed through 2006 [8]. It is a common clock test through the JCSAT-1B satellite. On this experiment, a software-defined radio technique was employed and the resulting data were post-processed. In 2008, another common clock DPN test with 500 m short baseline has been performed via IS-8 satellite [9]. In 2010, the first international DPN link was established by NICT and Telecommunication Laboratories (TL) [10]. The DPN TWSTFT experiment was performed to compare the UTC(NICT) and UTC(TL) with a baseline longer than 2000 km. It used parallel computing technique to achieve near-real-time data processing.

The aim of this paper is to demonstrate the high precision of the DPN data. We show the DPN data as well as those of the GPS Precise Point Positioning (GPSPPP) [11] in the short-term, and compare them with those of regular TWSTFT in the long-term. Since DPN system has not been fully developed, we list some challenges to be further overcome in performing DPN experiment, and propose some methods to improve its robustness and precision.

II. EXPERIMENT SETUP

The NICT in Tokyo and TL in Taoyuan have performed the first oversea international DPN experiment for a consecutive 9 months during 2010. The baseline between NICT and TL is about 2113 km, and both use H-Maser as their primary clock. This link was established via a geo-stationary satellite INTELSAT-8 (IS-8) as the signal relay. Meanwhile, the regular Asia-Pacific TWSTFT experiment was also conducted via the same satellite. The DPN modem was developed by NICT, employing the software-defined radio technology. Each lab had a DPN modem composed of an Arbitrary Waveform Generator (AWG), an Analog-to-Digital Sampler (SMP) and a personal computer. We used a customized AWG to generate the time signal. The AWG's memory can store any data pattern digitalized voltage level, and the data in memory can be periodically generated with a fixed rate 204.6 MHz. On this experiment, the time signal was

This work is support in part by the Bureau of Standards, Metrology & Inspection, Ministry of Economic Affairs, Taiwan under Grant number BSMI 100-1403-05-05-13.

configured as the combination of two replica PRN signals with a chip rate of 127.75 kcps and separated by 20 MHz. Fig. 1 shows the comparison of the signal spectra between the DPN and the conventional PRN signals. The conventional PRN signals with a chip rate of 2.5MHz occupied a bandwidth of 4 MHz. The occupied bandwidth of DPN was only a double of 250 KHz. But, the DPN's cover of spectra can be a bandwidth of 20 MHz.

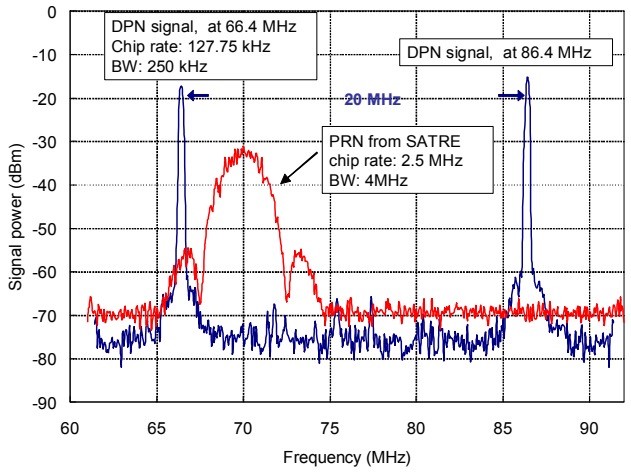

Figure 1. Power spectra of DPN (blue line) and regular TWSTFT (Red line).

For the receiving signal, we used the SMP to digitalize it and a series of sampled data stored in a buffer ring was fed. The quantization level and the sampling frequency were set to 4 bits and 64 Msps, respectively. It was necessary to set the first time tag carefully on the SMP so that all the samplings had a unique and correct time tag. The customized SMP needed manually set the first time tag, and the time tag can automatically count up when external 1PPS trigger came in.

All the samples were fed to a personal computer. The computer with a commercial GPU graphical card can provide Compute Unified Device Architecture (CUDA) library for parallel computation so as to reduce signal processing time. The DPN software was developed by using parallel computation to achieve near-real-time signal processing. NICT and TL exchanged 1-sec data through the internet and the time difference results can be derived.

III. RESULTS

Currently, two independent techniques, TWSTFT and GPSPPP, are widely used for comparing precise time difference between two time-keeping labs. TL performed the regular and DPN TWSTFT experiments last year. In the following, we demonstrate the experimental results of the regular TWSTFT, DPN and GPSPPP, to compare UTC(NICT) and UTC(TL).

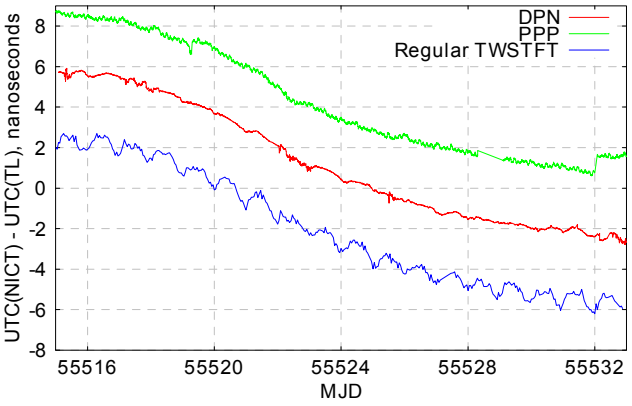

Figure 2. The time difference results of DPN (red line), GPSPPP (green line) and regular TWSTFT (blue line).

The time differences from MJD 55515 to 55532 are compared in the Fig. 2. Three curves are in a good agreement in a long term except a 0.9 ns jump on GPSPPP at MJD 55532. That jump reduces the performance, and it is regarded as a month boundary because GPSPPP's data are processed every month. The diurnal effect is about 0.85 ns on regular TWSTFT data, while that is 0.25 ns on DPN data.

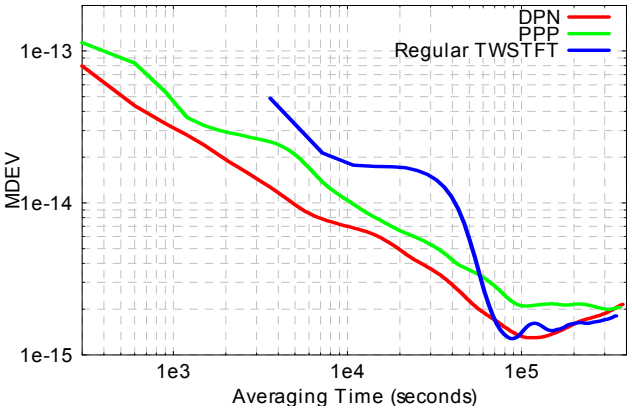

Figure 3. The modified Allan deviations of DPN (red line), GPSPPP (green line) and regular TWSTFT (blue line)

The modified Allan deviations (MDEV) of these experimental results are shown in Fig. 3. Among these results, DPN performs as well as GPSPPP in comparing the frequency stability. They could reach the 10^{-15} level for the averaging times longer than 10^4 seconds. In order to avoid the time scale discontinuity, the DPN data are aligned with the regular TWSTFT. Therefore, its frequency stability is steered by regular TWSTFT in long-term.

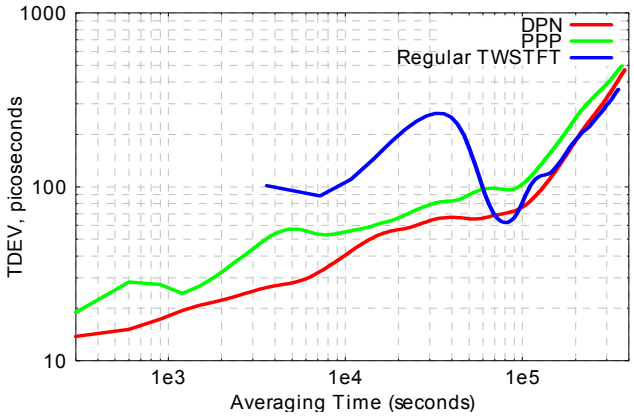

Figure 4. The time deviations of DPN (red line), GPSPPP (green line) and regular TWSTFT (blue line)

The time deviations (TDEV) are shown in Fig. 4. From this figure, the time stabilities of DPN and GPSPPP reach a level of 10 ps in the short term. On TWSTFT, we can find the diurnal exists both on regular TWSTFT and DPN results, for the curves are bumped around the averaging time of half a day.

The diurnal effect of TWSTFT leads a bad performance, and was discussed in many precious materials [12]-[15]. We found the DPN resulting data are much less diurnal than regular TWSTFT data. It can be well degraded by employing the DPN technology. Although the diurnal effect always exists in the TWSTFT system, its level should be affected by signal design and receiver methodology.

IV. CHALLENGES ON DPN

In this section, we would like to discuss some deficiencies that would affect the performance of the DPN experiment. In Fig. 5, we observe that the time difference data are somewhat noisy in the daytime. We found the AC power was not stable because of its overloading. A UPS was helpful to filter unstable AC power. After adding the UPS between the AC power and the input power supply, the time difference data became less noisy.

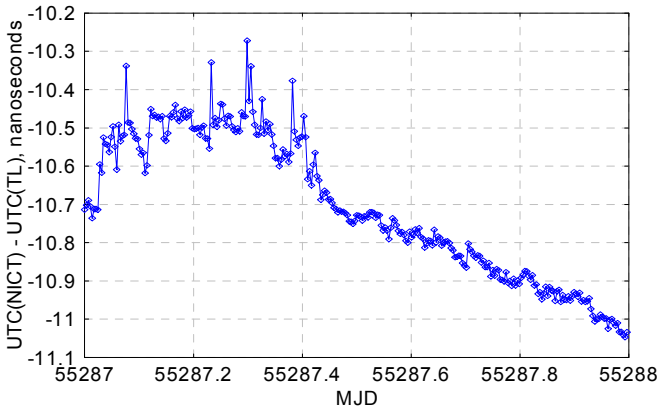

Figure 5. The unexpercted jumps occurred from MJD 55287 to MJD 55287.4 caused by the AC power instabilities

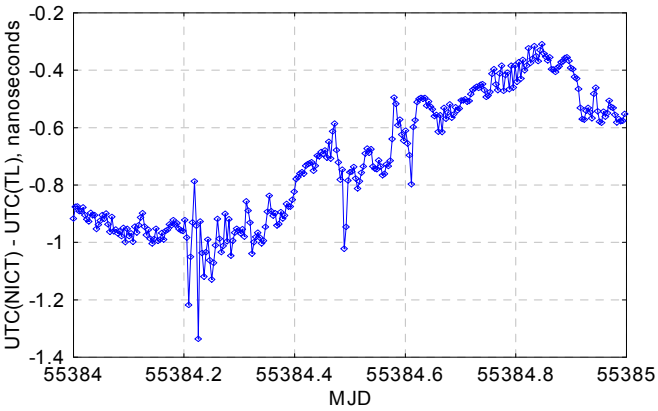

Figure 6. The unexpercted variation around MJD 55384.2 and MJD 55384.5 caused by rain fade

Sensitivity to the rain fade is another instable source on DPN experiment. The tracking process would be failed when outdoor environment was in high humidity. In Fig. 6, there are some the discontinuities of time difference data when the tracking process suspended. To improve data discontinuity due to rain fade, the integration time was increased from 4 ms to 20 ms.

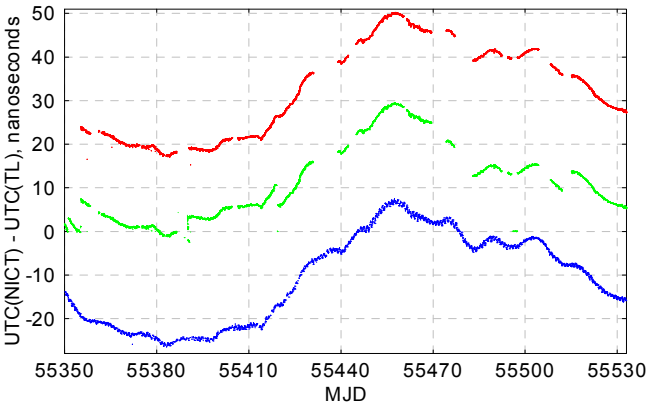

Figure 7. The time difference results of DPN with alignment (red line), without alignment (green line) and that of regular TWSTFT (blue line).

For power blackout, the DPN experiment had been restarted for some times. The on-off power switching made the time difference results piecewise continuous. The internal delays of AWG and SMP would change whenever rebooting their power. To avoid the discontinuity, internal delays of AWG and SMP need to be externally monitored in the future work. Nevertheless, regular TWSTFT data were helpful to compensate this discontinuity on DPN results. Since regular TWSTFT and DPN were performed on the same Asia-Pacific link, their results should be consistent in long-term. In Fig. 7, we aligned DPN data with regular TWSTFT in one-day average. Thus aligned DPN results can be seen as a combination whose performance was determined by DPN in short-term and by regular TWSTFT in long-term.

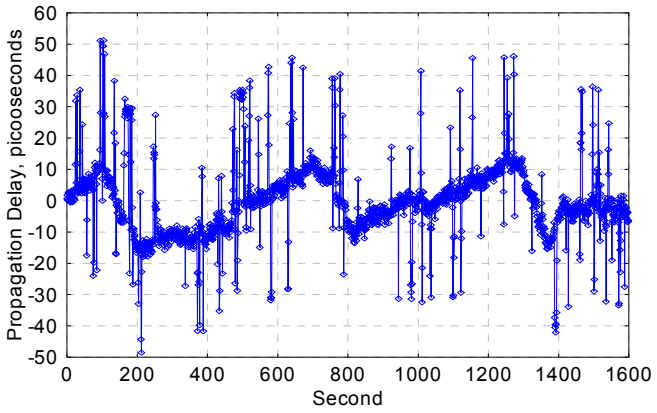

Figure 8. The spurious noise randomly occurred when measuring a propagation delay over a 10 km optical fiber by DPN mothod.

Finally, we carried out a loop-back test to check the basic performance of DPN. We measured the signal propagation delay over a 10 km optical fiber by using DPN technology. The carrier to noise ratio after passing the fiber is still larger than 80 dB/Hz, which is much higher than the 55 dB/Hz as in the satellite system. In Fig. 8, some spurious noise can be seen on the time difference data. With this spurious noise, the standard deviation of delay data is only 14 ps. After filtering out the noise, the standard deviation of 3 ps can be reached. This means that the short-term stability of DPN could be even better if the spurious noise could be avoided in the future design.

V. CONCLUSION

The DPN modem developed by NICT is composed of commercial devices and using software-defined radio technology. The first oversea DPN experiment has been successfully performed between NICT and TL in 2010. We compared the time transfer measurements among DPN, regular TWSTFT and GPSPPP for the consecutive 18 days. The DPN shows an outstanding performance which is competitive with that of GPSPPP in the short-term stabilities. And, it is clear that DPN has much less diurnal variation than the regular TWSTFT. Moreover, the main advantage of the DPN is its lower satellite bandwidth cost. In the future work, we hope to overcome some noise sensitivities of DPN to enhance its precision and keep using this technology for time comparisons.

ACKNOWLEDGMENT

The authors would like to express their gratitude to Tadahiro Gotoh, Jun Amagai, Thomas Hobiger and other staff at NICT for developing the GPU-based DPN modem and a great deal of cooperation of these experiments.

***Abstract*—From August 2010 to April 2011, NIST and OP conducted an experiment of using surface acoustic wave (SAW) filters in transatlantic two-way satellite time and frequency transfer (TWSTFT) with 2.5 MChip/s pseudo-random noise (PRN) codes. The SAW filters used in the experiment are 2.5 MHz band-pass filters with a center frequency of 70 MHz. Instead of using 3.5 MHz bandwidth required for the 2.5 MChip/s signal, the use of SAW filters allows the 2.5 MChip/s TWSTFT to use only 2.5 MHz bandwidth on a satellite transponder. We evaluated the SAW filters. We compared the time transfer instability of the filtered 2.5 MChip/s TWSTFT to the 1 MChip/s TWSTFT with and without the SAW filters. This paper presents the experiment results.**

I. INTRODUCTION

The timing information of TWSTFT signals is carried by PRN codes [1]. The resolution of TWSTFT measurements is proportional to the chip-rate of the PRN code being used. The minimum bandwidth required for a TWSTFT signal is approximately 1.4 times the chip-rate of the PRN codes [2].

The transatlantic TWSTFT network used 2.5 MChip/s PRN codes with 3.5 MHz bandwidth, in Ku-band, from the early 1990s, when the network was established, until a satellite change in July 2009. The TWSTFT operation was then changed to use 1 MChip/s PRN codes with 2.5 MHz bandwidth. The chip-rate reduction was made because of the significant increase in satellite subscription cost, and our previous study [3] showed the time transfer instability, as measured by the Time deviation (TDEV), of the 1 MChip/s TWSTFT was about the same as the TDEV of the 2.5 MChip/s TWSTFT for averaging times of one day and longer. The SAW filters were not available at the time of our previous study. We acquired 2.5 MHz bandwidth on the new satellite so we could do experiments on the 2.5 MChip/s TWSTFT with SAW filters after the filters were made available in early 2010.

The concept of 2.5 MChip/s TWSTFT with SAW filters was proposed by colleagues at the National Institute of Information and Communication Technology (NICT) in Japan. Previous experiments were conducted in the Asian-Pacific TWSTFT network. The scheme takes advantage of the high measurement resolution of the 2.5 MChip/s codes, but limits the TWSTFT signal to 2.5 MHz bandwidth with SAW filters. To study the performance of the filtered 2.5 MChip/s TWSTFT with SAW filters across a transatlantic link, NIST and OP conducted an experiment from August 2010 to April 2011with the SAW filters kindly loaned to us by TimeTech GmbH* of Germany. We show characteristics of the SAW filters used in our experiment and the experiment configuration in Sections II and III. Analysis of the 2.5 MChip/s TWSTFT with SAW filters is presented in Section IV. Section V summarizes the experiment results.

II. CHARACTERISTICS OF THE 2.5MHZ BAND-PASS SAW FILTER

Figure 1 shows the spectrum of the 1 MChip/s code (in red), main lobe of the 2.5 MChip/s code (in green) and the

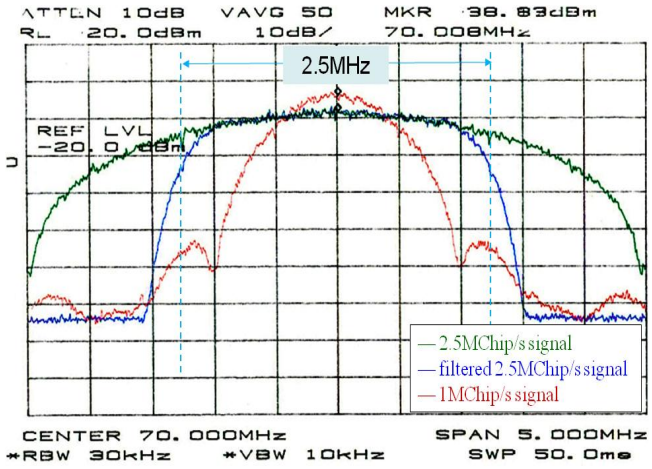

Figure 1. Spectrum of the 1 MChip/s (in red), main lobe of the 2.5 MChip/s (in green) and the filtered 2.5 MChip/s (in blue) TWSTFT signals.

This paper includes contributions from the U.S. government and is not subject to copyright.
*Commercial products and companies are identified for technical completeness only, and no endorsement by authors and organizations is implied

filtered 2.5 MChip/s code (in blue). When comparing the filtered 2.5 MChip/s signal to the 2.5 MChip/s signal, we see that the SAW filter provides unity gain to the 2.5 MChip/s signal in a range of about 2 MHz centered at 70 MHz. The 2.5 MChip/s signal is attenuated about 15 dB at the 2.5 MHz boundaries. Because the main lobe of the 1 MChip/s signal is bounded by 2 MHz, passing a 1 MChip/s signal through the SAW filter does not distort the main lobe.

We evaluated the SAW filter's characteristics by a loop test using a SATRE* modem manufactured by TimeTech and the SAW filter unit at NIST. The peak-to-peak variation of the one-second measurements increases by about 50 ps for each SAW filter added in the loop [4]. The use of the SAW filter inserts a large signal path delay of about 5.2 µs. This delay is sensitive to temperature variations, with a temperature coefficient estimated to be 200 ps/°C. However, the delay sensitivity to temperature can be compensated by use of SAW filters in both the transmit (TX) and receive (RX) paths. Figure 2 shows the SAW filter's delay response to frequency change. The measurements were made with SAW filters in both TX and RX paths. We shifted TX and RX frequencies from -10 kHz to +10 kHz in 2 kHz steps with respect to 70 MHz. The delay dependence on frequency varies between 184 ps/2 kHz and 289 ps/2 kHz.

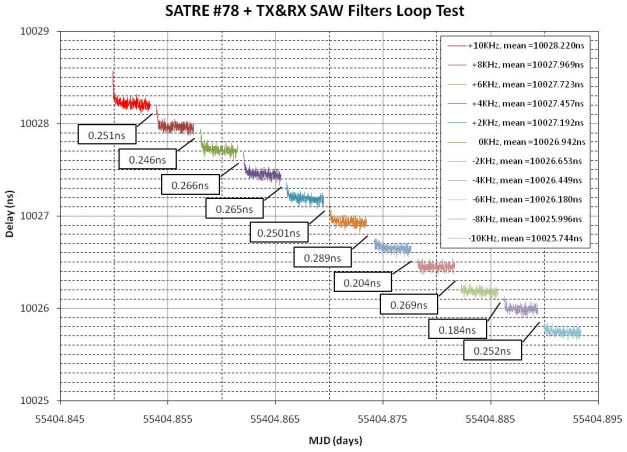

Figure 2. SAW filter's delay response to frequency change of ±10 kHz with respect to 70 MHz. Each step corresponds to the delay for a 2 kHz frequency change.

The SAW unit at OP was also evaluated by use of a vector analyzer. Figure 3 shows the measurement results of return loss (Trace 1, in yellow), insertion loss (Trace 2, in blue) and delay response to frequency change (Trace 3, in red). These characteristics were evaluated for frequencies from 68.9 MHz to 71.1 MHz. After correcting for the delays and for the losses from the cables and adaptors used in the measurements, the return loss is about 30 dB, which means the SAW filters have a very good impedance match. The insertion loss is about 0.4 dB for 70 ± 1 MHz. The delay through a SAW filter is 4.842 µs at 70 MHz, which is about 360 ns different than the SAW filter unit at NIST. Figure 3 also shows the SAW filters' delay response to frequency change is not linear.

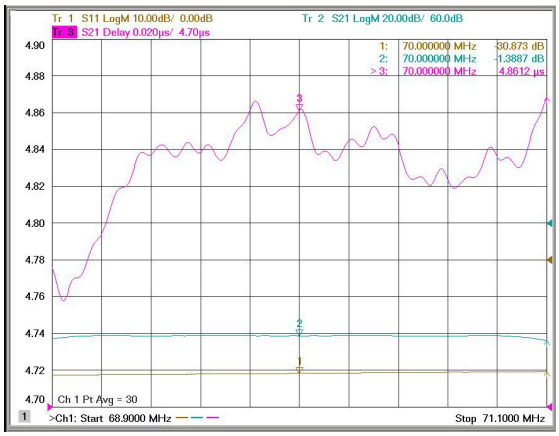

Figure 3. SAW filter's return loss (Trace 1, in yellow), insertion loss (Trace 2, in blue) and delay response to frequency change (Trace 3, in red) measured by a vector analyzer

Although the large constant delay introduced by SAW filters will be mostly canceled in the TWSTFT difference, TWSTFT links using SAW filters should be recalibrated to correct for the residual of delay difference of the two directions. The frequency of the received TWSTFT signal varies due to the daily satellite motion, or due to free running internal oscillators in some transceivers. The SAW filter's delay response to frequency change will increase the uncertainty of TWSTFT.

III. EXPERIMENT CONFIGURATION

The regular NIST/OP 1MChip/s TWSTFT measurements are made in a 2-minute session during even hours of Coordinated Universal Time (UTC), 12 times a day. The experiment measurements were made in three 2-minute sessions during odd hours of UTC. Table 1 shows the measurement schedule. The measurement of odd-hour 1 MChip/s TWSTFT without SAW filters was added in March 2011 to study the effect of SAW filters on the 1 MChip/s TWSTFT. No other station, but NIST and OP, transmitted signals during the three odd-hour sessions.

TABLE 1 TWSTFT measurement schedule

Measurements	Measurement sessions	Measurement period
1 MChip/s without SAW filter (regular transatlantic link)	2-minute in even hours, 12 times a day	August 18, 2010 to April 11, 2011 (MJDs 55426 to 55662)
1 MChip/s without SAW filter	2-minute in odd hours, 12 times a day	March 25, 2011 to April 11, 2011 (MJDs 55645 to 55662)
1 MChip/s with SAW filter	2-minute in odd hours, 12 times a day	August 18, 2010 to April 11, 2011 (MJDs 55426 to 55662)
2.5 MChip/s with SAW filters	2-minute in odd hours, 12 times a day	August 18, 2010 to April 11, 2011 (MJDs 55426 to 55662)

Figure 4 shows a block diagram of the experiment configurations at NIST and OP. Both NIST and OP used

SATRE modems for all the TWSTFT measurements. A TimeTech SAW filter unit contains two SAW filters, one for the TX path and one for the RX path. The signals for the TWSTFT with SAW filters went through the TX and RX SAW filters at both NIST and OP.

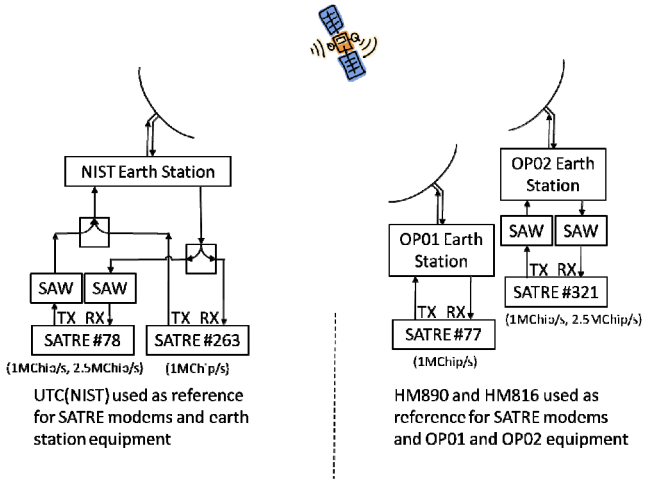

Figure 4. Block Diagram of NIST/OP TWSTFT with and without SAW filters.

At NIST, the same earth station and same radio-frequency (RF) equipment were used for both TWSTFT with and without SAW filters. A pair of power combiner and power splitter was used to channel the TWSTFT signals between the earth station equipment and the two modems. At OP, earth station OP01 was used for TWSTFT without SAW filter, and earth station OP02 was used for the TWSTFT with SAW filters.

Reference signals for the NIST TWSTFT were derived from the NIST time scale, UTC(NIST). During the experiment, reference signals for the OP TWSTFT were derived from two hydrogen MASERs, HM890 and HM816. The HM816 was used for MJDs 55496 to 55593 (October 27, 2010 to February 1, 2011) during the maintenance of HM890. The corrections for converting the OP reference signals to UTC(OP) are available, but were not used in our analysis.

IV. RESULTS OF THE 2.5 MCHIP/S TWSTFT USING SAW FILTERS

We compared the 2.5 MChip/s TWSTFT using SAW filters to the 1 MChip/s TWSTFT with and without SAW filters. We also investigated the effect of SAW filters on the 1 MChip/s PRN codes by comparing the 1 MChip/s TWSTFT with and without SAW filters. Because the NIST/OP link with SAW filters is not calibrated with respect to the NIST/OP link without SAW filters, we are not able to estimate the delay change from use of SAW filters. We will focus our analysis on the time transfer instability of the TWSTFT using SAW filters. The experiment results are shown in Figures 5 through 7.

Figure 5 shows the three TWSTFT differences between UTC(NIST) and OPH (hydrogen MASER) for MJDs from 55433 to 55662. The three differences are for the even-hour 1 MChip/s TWSTFT without SAW filters (in red), the odd-hour 1 MChip/s TWSTFT with SAW filters (in blue) and the odd-hour 2.5 MChip/s TWSTFT with SAW filters (in green). The frequency offset, drift and mean time difference are removed from the direct NIST/OPH differences. The even-hour 1 MChip/s TWSTFT without SAW filter contains larger short-term variations than the odd-hour 1 MChip/s and 2.5 MChip/s TWSTFT with SAW filters until around MJD 55610. The larger short-term variation might be introduced by interference from other TWSTFT signals transmitted at the same time with about the same frequency during even hours [4]. The reduction of short-term variation after MJD 55610 is partially attributed to a frequency offset in the NIST TX signal introduced to mitigate the multi-signal interference. Figure 5 also shows a big difference fluctuation when the HM816 was used as the reference clock at OP.

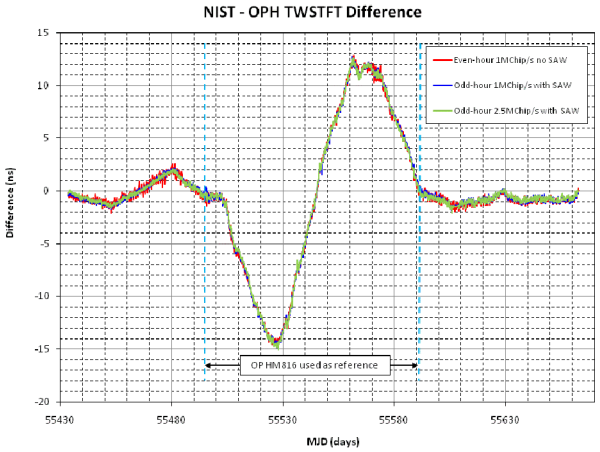

Figure 5. NIST/OPH TWSTFT differences for even-hour 1 MChip/s without SAW filters (in red), odd-hour 1 MChip/s with SAW filters (in blue), and 2.5 MChip/s with SAW filters (in green). Frequency offset, drift and mean time difference are removed from the differences.

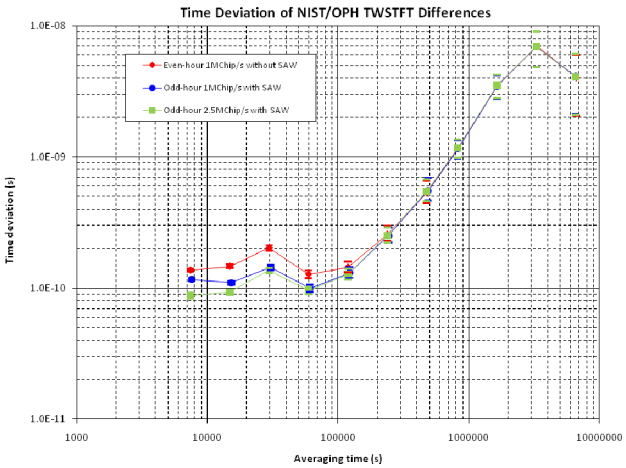

Figure 6. Time transfer instability of the NIST/OPH TWSTFT for MJDs 55433 to 55662.

TDEVs for the three differences are shown in Figure 6. All of the TDEVs are 200 ps or less for averaging times less

than 32 hours. The TDEVs are dominated by clock noise after averaging times longer than 32 hours. For averaging times of 32 hours and less, the TDEVs of the odd-hour TWSTFT with SAW filters contains less transfer noise than the even-hour TWSTFT without SAW filter which reflects the larger short-term variations in Figure 5. For averaging times from 2 hours to about 16 hours, the time transfer instability of the filtered 2.5 MChip/s TWSTFT shows a small improvement when compared to the filtered 1 MChip/s TWSTFT. This means the change of measurement noise due to chip-rate change between 2.5 MChip/s and 1 MChip/s is only a small contributor to the short-term instability. The dominant short-term instability for the transatlantic TWSTFT comes from the sources described in a 2005 study [5].

The frequency instability, as measured by the Allan Deviation (ADEV) for the three differences are shown in Figure 7. At averaging times of 1 day, the ADEVs are about 6×10^{-15} for the even-hour 1 MChip/s TWSTFT, and about 4×10^{-15} for the odd-hour 1 Mchip/s and 2.5 Mchip/s TWSTFT with SAW filters. The ADEVs are continuously averaged down to about 2×10^{-15} at averaging times of about 2.5 days. After that, the ADEVs demonstrate frequency instability mainly from the OP HM816 clock, visible in Figure 5.

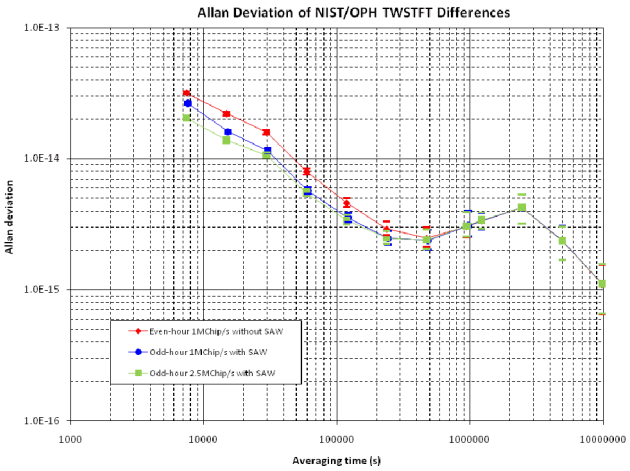

Figure 7 Frequency instability of the NIST/OPH TWSTFT for MJDs 55433 to 55662.

The comparison of time transfer instability for the 1 MChip/s TWSTFT with and without SAW filters is shown in Figure 8. Data used in computing the TDEVs were obtained from the two 2-minute measurement sessions in odd hours from MJD 55645 to MJD 55662. The measurements were made in odd-hours to minimize the interference from other TWSTFT signals transmitted at the same time with about the same frequency. The measurements of 1 MChip/s TWSTFT without SAW filters were obtained from the NIST_SATRE #263/OP01_SATRE #77 link. The measurements of 1 MChip/s TWSTFT with SAW filters were obtained from the NIST_SATRE #78/OP02_SATRE #321 link. The two measurement sessions were seven minutes apart. The TDEV for the 1 MChip/s TWSTFT with SAW filters is about 100 ps, and it is higher than that of the 1 MChip/s TWSTFT without SAW filters for averaging times of two hours and four hours. Based on our loop test results, the high level of TDEV at averaging times of two hours and four hours for the 1 MChip/s TWSTFT with SAW filters might come from the noise contributed by SAW filters. The TDEV for the 1 MChip/s TWSTFT without SAW filter increases after averaging longer than one day. That could come from the instability of the NIST_SATRE #263/OP01_SATRE #77 link.

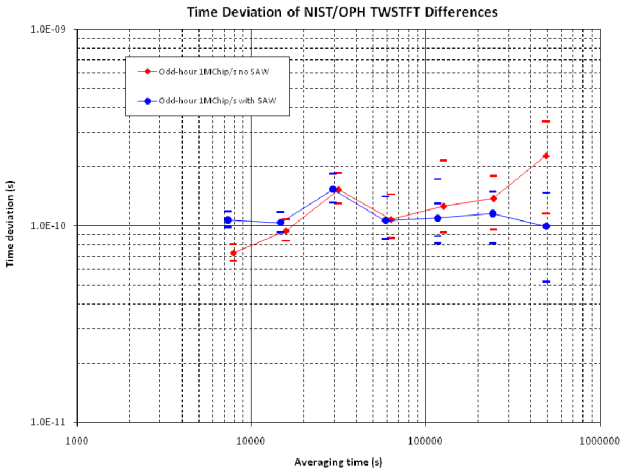

Figure 8 Comparison of 1 MChip/s TWSTFT with and without SAW filters. The TDEVs are computed with TWSTFT difference for MJDs 55645 to 55662.

All the TDEVs in Figures 6 and 8 show a diurnal at and below 200 ps. The diurnal is not from the use of SAW filters because it is also visible in the TWSTFT without SAW filters.

V. CONCLUSIONS

Our study shows the SAW filters can be used for 2.5 MChip/s TWSTFT with only 2.5 MHz bandwidth. The noise from SAW filters contributes to the short-term time transfer instability. The SAW filter's frequency dependent delay can increase the uncertainty of the TWSTFT. The 2.5 MChip/s TWSTFT with SAW filters provides a small improvement, about 10 to 20 ps in TDEV, over the 1 MChip/s TWSTFT without SAW filter for averaging times from two hours to 16 hours. The TDEV and ADEV for the filtered 2.5 MChip/s TWSTFT with SAW filters are about 100 ps and 4×10^{-15} at averaging times of one day. The TDEV and ADEV could be a little better if the TWSTFT differences had no diurnal. Because of the noise introduced by SAW filters, the 1 MChip/s TWSTFT works better without the SAW filters.

ACKNOWLEDGMENT

We thank TimeTech GmbH of Germany for loaning us the SAW filters used in our experiment. We also thank Dr. Wolfgang Schaefer for his support and advice to our study.

Abstract: *The new station delay calibration system, to be implemented in the VSL TWSTFT station, will perform a complete calibration of the ground station delays. The new dual-stage quad-mixer satellite simulator promises improved repeatability and less susceptibility for environmental influences. The true power of the system is the multidirectional transceiver operation within the satellite simulator. This allows including additional measurement paths, enabling absolute measurement of the path delays. Hence, the new station delay calibration system is completely stand-alone and no additional, time consuming, periodic VNA calibrations are required.*

Introduction: Soon after the introduction of the first primary time standards, the need of accurate time comparison techniques for long distances was felt. The TWSTFT has been a widely used technique for long distance time comparison since the early 90's [1]. Continuous developments and enhancements in time generation is enforcing more stringent performance from such comparison techniques as well. This text first studies the sources of instability in the TWSTFT station. In order to provide a compound solution for the problems, the TWSTFT system at VSL is completely redesigned. Resulting in a more stable and accurate delay measuring system. In figure 1 the time scale comparison principle is shown.

TA	: Time scale at station
TI	: Time Interval Counter reading
ζ_{tx}	: Transmission path delay
ζ_{rx}	: Reception path delay
ζ_{up}	: Uplink propagation delay
ζ_{dw}	: Downlink propagation delay
ζ_{trp}	: Satellite transponder delay
TC_{up}	: Sagnac correction in the uplink
TC_{dw}	: Sagnac correction in the downlink

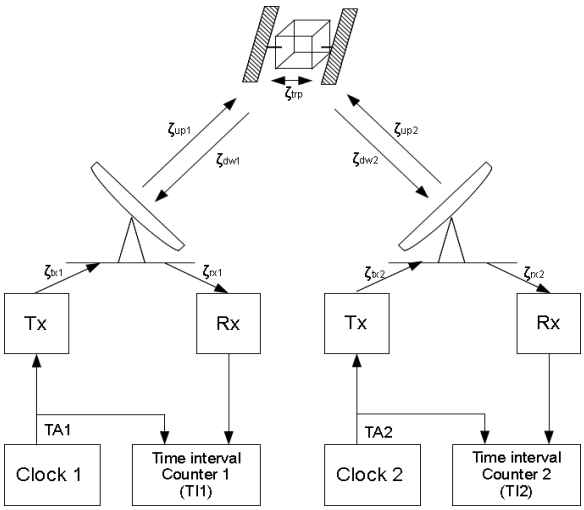

Figure 1 Principle of two way satellite time and frequency transfer system using PRN codes

$$TI_1 = (TA_1 - TA_2) + (\zeta_{tx1} + \zeta_{rx2}) + (\zeta_{up1} + \zeta_{dw2}) + \zeta_{trp} \quad (1)$$

$$TI_2 = (TA_2 - TA_1) + (\zeta_{tx2} + \zeta_{rx1}) + (\zeta_{up2} + \zeta_{dw1}) + \zeta_{trp} \quad (2)$$

The term $(TA_1 - TA_2)$ indicates the actual difference between the two compared time scales. However, to calculate the difference other terms are to be known. In [1] additional sagnac correction terms were included in equations 1 and 2, resulting in the following equations:

$$TI_1 = (TA_1 - TA_2) + (TC_{up2} + TC_{dw1}) + (\zeta_{tx1} + \zeta_{rx2}) + (\zeta_{up1} + \zeta_{dw2}) + \zeta_{trp} \quad (3)$$

$$TI_2 = (TA_2 - TA_1) + (TC_{up1} + TC_{dw2}) + (\zeta_{tx2} + \zeta_{rx1}) + (\zeta_{up2} + \zeta_{dw1}) + \zeta_{trp} \quad (4)$$

The accuracy of the compared time scales is directly linked to the accuracy of the delay components of the above equations. This text focuses on measurement of the transmitter and receiver path delays within the ground station. Detailed description of the TWSTFT principle can be found in [6],[1],[2].

Satellite Simulator Principle: The primary function of a satellite transponder is to provide a stable frequency transformation between the respective receive and transmit frequencies. A common additional function a transponder provides is the gain to compensate for the high signal path loss.

To measure receive and transmit delay components of a TWSTFT station a satellite simulator concept is used [2]. In order to simulate a satellite transponder, it is essential to provide a same frequency transformation between the respective receive and transmit frequencies of the satellite. This enables a measurement of the delay of transmit and receive path as a single component. As the satellite simulator is placed directly in front of the transmitter and the receiver antenna, the reference point of the delay component is a fixed point just in front of the TWSTFT antenna. The signal path loss is low and no additional gain is required from the satellite simulator. To determine the transmit and receive delay component separately additional measurements are needed. The additional measurements require the satellite simulator to receive and transmit PRN signals independent of the receiver and the transmitter of a TWSTFT station [2].

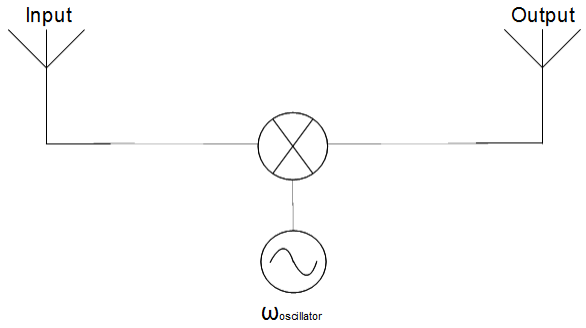

Figure 2 Single-mixer satellite simulator concept

Single-mixer architecture: In figure 2 the most simple implementation of a satellite transponder, known as the single-mixer satellite simulator , is shown [2]. Using this scheme it is only possible to measure the transmit and receive path delay as one component and it is not possible to separate the respective delay components. The main advantage of this architecture is its simplicity. This concept is very useful to monitor relative delay variation in a TWSTFT station.

Dual-mixer architecture: A satellite simulator scheme using two mixers is shown in figure 3. The two mixers perform the similar frequency transformation as the satellite transponder. Using two separate mixers driven by 70 MHz (oscillator 1) and (f_{diff} - 70 MHz) (oscillator 2) signals, the transmit and receive delay components can be measured separately. The 70 MHz oscillator port is also used to transmit and receive the PRN coded signals. Due to non-symmetrical delay path for the 70 MHz signal to the simulator's transmit and receive antennas, a systematic offset is introduced [2]. In figure 4 the spectrum transformations within the dual-mixer satellite simulator are shown.

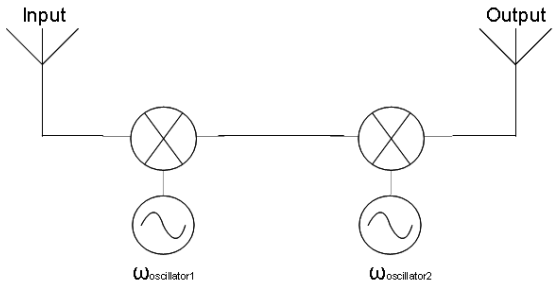

Figure 3 Dual-mixer satellite simulator concept

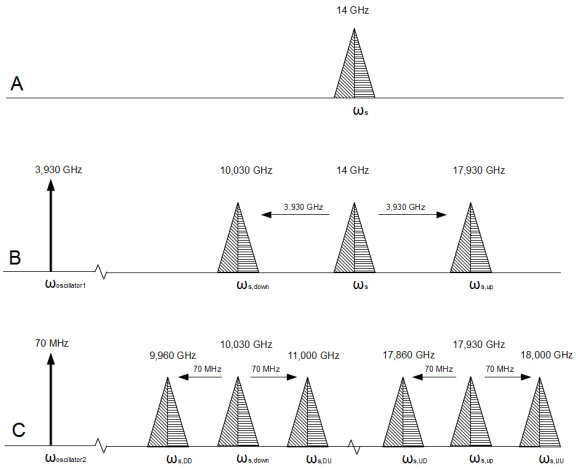

Figure 4 Spectrum transformations of the dual-mixer satellite simulator.

Modified single-mixer architecture: A modified single mixer satsim scheme is shown in figure 5 [2][4]. Using a power combiner the two oscillator signals, as shown in the dual-mixer concept, are combined and used to drive the mixer at the same time. The advantage of this architecture is the symmetrical delay path between the receive and transmit antennas. The frequency transformation is realized by utilizing the non-linear voltage-current characteristic of a diode.

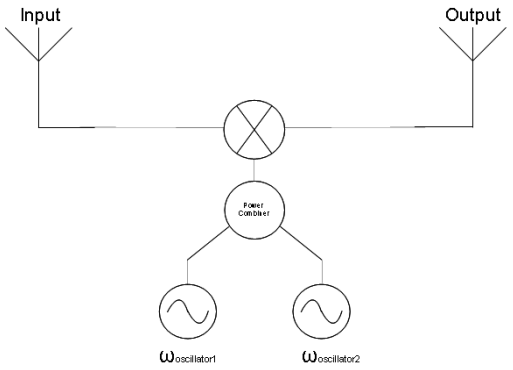

Figure 5 Modified single-mixer concept

Dual-stage quad-mixer architecture: The new proposed concept of satellite simulator is shown in figure 7. To make the satellite simulator delay measurements less sensitive for environmental influences, it is partly moved from the rooftop to the TWSTFT up- & down- conversion room. The temperature and humidity are well controlled in this room. Only a coaxial transfer switch 'M' remains mounted in front of the TWSTFT antenna, as it serves to set the reference point for transmit and receive delay components. The dual-stage quad-mixer architecture relies on four mixers for its multidirectional transceiver capability. Mixer *1A* provides down conversion from 14 GHz to 1.5 GHz. Mixer *1B* provides either up conversion from 1.5 GHz to 11 GHz or down conversion from 14 GHz to 1.5 GHz. Both mixers use the same oscillator signal and no frequency shifting is required. Similarly mixer *2A* provides down conversion from 1.5 GHz to 70 MHz and mixer *2B* provides either up conversion or down conversion between 1.5 GHz and 70 MHz. Mixer 2A and 2B also use the same oscillator signal.

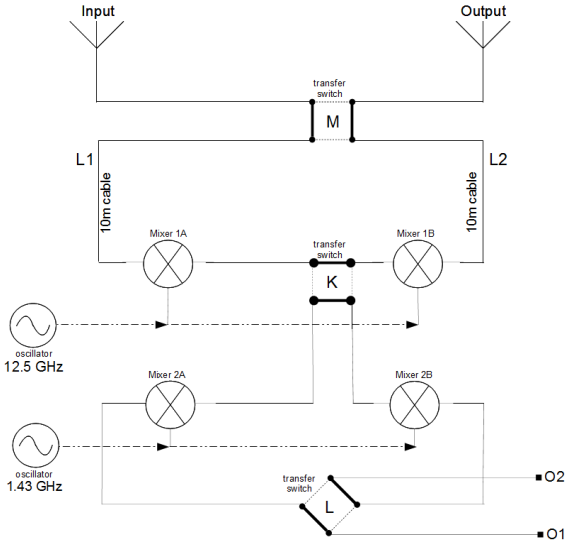

Figure 6 Dual-stage quad-mixer satellite simulator

Environmental sensitivities and biasing : To achieve a sub nanosecond accuracy for TWSTFT station measurements, sensitivity of the group delay towards environmental influences for the equipment used in TWSTFT station should be addressed adequately. However, almost no information is available for the equipment used in TWSTFT station and only a few studies have addressed this issue with significance.

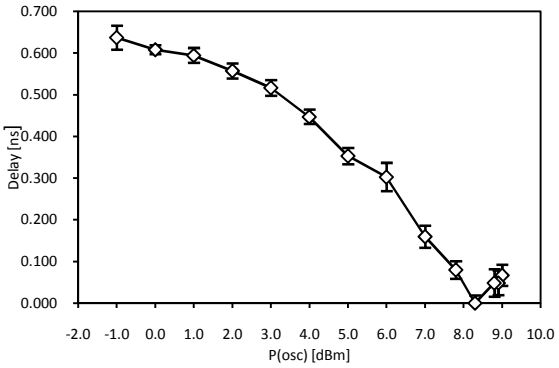

Figure 7 Mixer delay for varying oscillator power level at room temperature [22.0 ± 1.0 C]. Each measurement was performed for at least one day, with 12 measurement cycles per day.

The temperature coefficient for devices used in a TWSTFT station is typically less than 20 ps [7]. Diode-ring based mixers tend to be one of the most sensitive devices used in TWSTFT station. Another import aspect when utilizing mixers is the stability of the oscillator signal. In figure 7 the power level of the oscillator signal was varied for a double balanced diode-ring mixer. The delay decreases for higher power levels. This is caused by the larger voltage generated across the diodes. In this

region of biasing the mixer also exhibits higher group delay sensitivity towards oscillator power level variations. For lower power levels the magnitude of the group delay component is somewhat larger, but less sensitive to power level variations. Biasing the mixer at lower power level also increases noise level, as the conversion loss would be somewhat larger. Hence a tradeoff is to be made between system noise figure and group delay sensitivity to oscillator signal power level. Depending on the location of the mixer, stability of the environmental parameters, a proper setting of the biasing power level can be selected.

Automated delay calibration in a TWSTFT station: The TWSTFT station at VSL is located at three separate locations. Time scale generation, signal modulation and up conversion to 70 MHz intermediate frequency (IF) is performed in the Time & Frequency Laboratory. The time scale is generated using high performance cesium standards. For modulation and IF up conversion a SATRE modem is used. The 70 MHz signal is then sent to the TWSTFT up- & down- conversion room through 100 meter coaxial cables. In this room the required up- and down- conversion is performed to the transmit and receive microwave frequencies and sent to the rooftop. Finally the signals are amplified to the appropriate power level using a transmission amplifier and receiver LNA (Low Noise Amplifier) mounted on the antenna. See figure 8 for a layout of the present TWSTFT station at VSL.

As the TWSTFT station is located at three separate locations, three sets of delay measurements are performed. The first set of measurements is performed to determine the group delay components up to the TWSTFT up- & down- conversion room. In order to measure the delay component of the A and B cable, an additional third cable, *C*, is introduced in the system, shown in figure 8. This set of three cables allows three different loop delay measurements. From these measurements, the delay of the individual cables can be derived using linear algebra. As no frequency transformation takes place within these paths and all devices involved are located within the building, very stable delay measurements are achieved.

The second set of measurements is performed to determine the delay components of the quad-mixer satellite simulator itself, including delay paths up to the transfer switch at the TWSTFT antenna. In the case, the O1 and O2 ports in figure 6 are connected to the Rx and Tx paths of the TWSTFT modem.

The third set of measurements is performed to determine the delay of the TWSTFT transmit and receive paths respectively. The measurements are performed with the satellite simulator receive and transmit ports, hence the results from second set of measurement are required.

Meas.	Components of the measured delays
AB	$T_{switch-1} + T_{switch-2} + T_{cable-A} + T_{switch-A} + T_{pc} + T_{switch-B} T_{cable-B}$
CA	$T_{cable-A} + T_{switch-C} + T_{pc} + T_{switch-B} + T_{cable-B}$
CB	$T_{cable-C} + T_{amplifier} + T_{switch-C} + T_{pc} + T_{switch-A} + T_{cable-A} + T_{switch-2}$
M1	$T_{switch-1} + T_{switch-2} + T_{cable-A} + T_{switch-A} + T_{up-con.} + T_{cable-3} + T_{Tx-amplifier} + T_{cable-1} + T_{Satsim,mix1A} + T_{switch-K} + T_{Satsim,mix1B} + T_{cable-2} + T_{Rx-LNA} + T_{cable-4} + T_{down-con.} + T_{switch-B} + T_{cable-B} + T_{switch-2}$
M2	$T_{switch-1} + T_{switch-2} + T_{cable-A} + T_{switch-A} + T_{up-con.} + T_{cable-3} + T_{Tx-amplifier} + T_{cable-1} + T_{Satsim,mix1A} + T_{switch-K} + T_{Satsim,mix2A} + T_{switch-L} + T_{switch-D} + T_{switch-C} + T_{pc} + T_{switch-B} + T_{cable-B} + T_{switch-2}$
M3	$T_{switch-1} + T_{switch-2} + T_{cable-A} + T_{switch-A} + T_{up-con.} + T_{cable-3} + T_{Tx-amplifier} + T_{cable-1} + T_{Satsim,mix1B} + T_{switch-K} + T_{Satsim,mix2B} + T_{switch-L} + T_{switch-D} + T_{switch-C} + T_{pc} + T_{switch-B} + T_{cable-B} + T_{switch-2}$

M5	-	-	-	-
M6	-	-	14 GHz	14 GHz

Table 2 New TWSTFT delay measurements

Design & Measurement results: In figure 9 the final prototype of the satellite simulator is shown. Besides up- & down-convertors all hardware required to perform the TWSFTF station delay measurements is integrated into a single unit. Only transmission amplifier, the LNA and switch-M remain at the rooftop. External signal generator are required to bias the satsim mixers. The transfer switches are through RS485 interface.

Figure 9 Final prototype of the new satellite simulator switch box designed and assembled at VSL.

The TWSTFT station delay measurements are scheduled for twelve measurement sessions per day (once every two hours). In figure 10 the measurement results for AB, CB, and CA delay paths are shown.

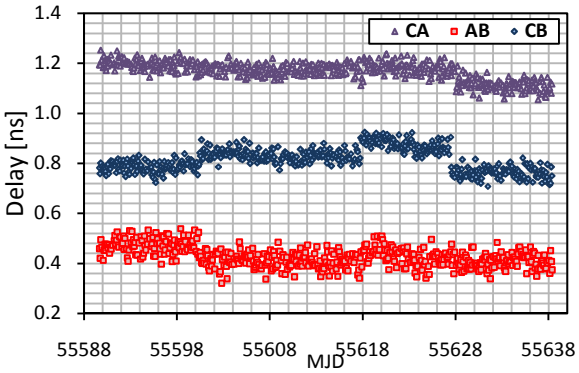

Figure 10 Measurement results of AB, AC, and BC paths. The delay values of the measurements are adjusted to be able to fit the data on a single graph. Using three different path measurements, delay values of A, B and C cables can be calculated using linear algebra.

The total fluctuation in time for the AB, CB, and CA delay paths does not exceed 200 ps over the whole measurement period (after correction of the offsets). In figure 11 the time stability of the AB delay path is shown. Time stability of 10 ps/s is achieved for averaging time of 1d. The 10 ps limitation is set by the noise floor of the modem.

After installing the new satsim unit a series of measurements were performed to test the functionality of the satsim unit. The measurements of the delay component M1-M3 are shown in figure 12.

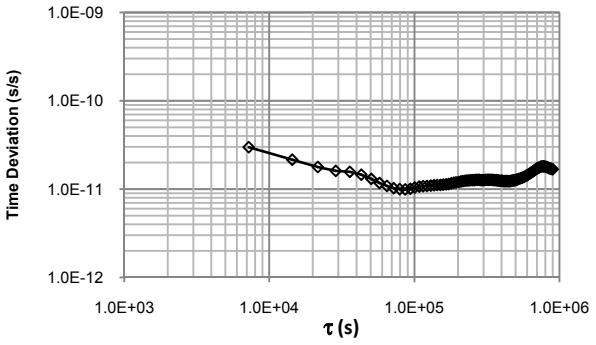

Figure 11 Time stability of AB path measurements

These measurement results are not to be takes as final values achievable by the delay measurement system, as every delay path is yet to be optimized.

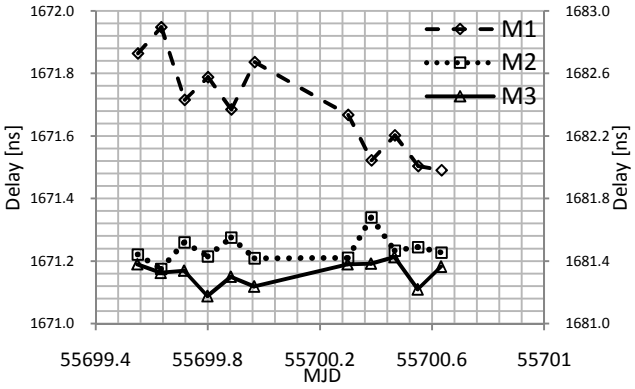

Figure 12 Measurement results of M1-M3, scheduled for twelve sessions per day (once every two hours). M1 results are displayed on the left vertical axis and M2-M3 results are displayed on the right vertical axis.

As the delay paths of M2 and M3 are almost identical, the delay components were expected to be equivalent as well. This is noticeable in figure 12 for M2 and M3. Measurement results of M1 seem to be drifting. However, the measurement period is rather short to draw concrete conclusions regarding the stability. In figure 13 the influence of C/N-ratio on the stability of delay measurement is shown.

Conclusions: A new dual-stage quad-mixer satellite simulator has been designed and assembled. With this satellite simulator all delays in the TWSTFT station can be determined in absolute terms. The implementation of the satellite simulator in the TWSTFT station is such that the delay calibration measurements are completely automated.

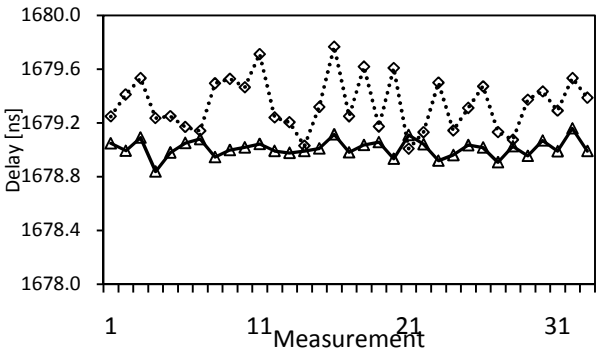

Figure 13 Measurement results for M1 for C/N-ratio of 56 dB/Hz [dotted line] and C/N-ratio of 62 dB/Hz [solid line].

Furthermore, the new satellite simulator was designed in a way that the sensitive components can be placed in-doors in a controlled environment.

Initial test measurements have started and are running 12 times per day (every two hours). The first results are quite promising, but it is too early to draw conclusions on the long term behavior. In future, for each measurement path an optimum transmission power level will be determined to achieve an optimal signal-to-noise (S/N) ratio.

Acknowledgements: Authors are greatly thankful to Henk van Ulden for helping with assembling the satellite simulator unit. Authors are also thankful to fellow colleagues for many useful discussions.

Carrier-envelope phase dependent photoemission from a nanometric metal tip

Markus Schenk, Michael Krüger, and Peter Hommelhoff
Max-Planck-Institut für Quantenoptik, 85748 Garching, Germany
Email: peter.hommelhoff@mpq.mpg.de

***Abstract*— We tightly focus $\sim 6\,\mathrm{fs}$ Ti:sa pulses onto a nanometric metal tip and record photoelectron spectra at laser intensities of about $\sim 4\times10^{11}\,\mathrm{W/cm^2}$. Here we present a strong carrier-envelope phase (CEP) dependent current modulation. In the high energy region of the spectra the CEP modulation rises up to 100%, meaning that the CEP can switch the photocurrent fully on and off. The metal tip resembles a record sensitive miniaturized CEP sensor with a precision exceeding about $15\,\mathrm{mrad}$ in $20\,\mathrm{s}$ measurement time. Even CEP-stabilizing a Ti:sa-oscillator with the signal of the emitted photoelectrons of a tip seems feasible.**

I. Introduction

The versatile use of femtosecond laser frequency combs relies on the possibility of CEP-stabilizing the pulses. Typically this is done via f-2f self-referencing the comb [1], [2]. Experimental effort, comparably high costs and a complicated setup are needed, especially if the CEP is kept konstant from pulse to pulse. A potential alternative approach is discussed in t paper. As already proposed and discussed in the IEEE Proceedings of the same conference series by one of the authors and former colleagues in 2006 [3], we report here on the experimental observation of a strong CEP modulation in the photocurrent. The pulse energy used is about $240\,\mathrm{pJ}$. Such a low pulse energy suffices because of optical field enhancement: boundary effects (small tip radius) and collective electronic excitations in the metal lead here to a up to six-fold increase in laser electric field strength (mimicking a factor of 36 higher laser intensity) [4].

The paper is organized as follows: In Section II we mention results previously achieved in photoemission experiments from sharp metal tips and on CEP effects in photoemission from metals. Section III describes the experimental setup, which is followed by Section IV describing the main results of this paper. Section V concludes the article by a discussion of tip-based carrier-envelope (CE) frequency ($\mathrm{f_{CEO}}$) stabilization of the oscillator.

II. Photoemission Studies - Related Work

Nonlinear photoemission from planar metals has been studied in detail in various papers (for a review see [6]). CEP effects in nonlinear photoemission are theoretically predicted [7], [8] but experimentally hard to observe [9], [10]: In Ref. [9] record-short $4\,\mathrm{fs}$ IR laser pulses were focused on a gold cathode leading to a minuscule CEP modulation in the total current. The difficulty in observing these effects is presumably caused by two effects. First, the emission area in photoemission from a planar surface is typically on the order of the focal spot

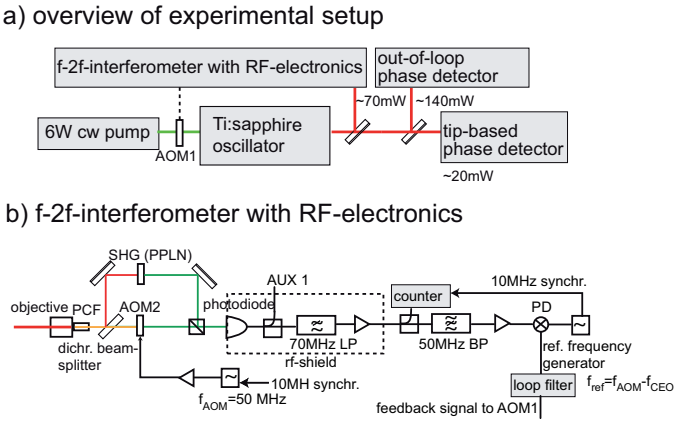

Fig. 1. Schematic experimental setup and CEP-stabilization scheme. a) A large fraction of the power of the Ti:sa laser is needed for phase-stabilization (70 mW) and out-of-loop monitoring of the phase (140 mW). For the photoemission only a small fraction of light is needed ($\sim 20\,\mathrm{mW}$). b) Detailed sketch of the CEP-stabilization setup. In the optical setup (left) the pulses are spectrally broadened to span a full octave in a photonic crystal fiber (PCF). Long and short wavelength regions are seperated by a dichroic beamsplitter. In the long-wavelength arm the second harmonic generation (SHG) is achieved with a periodically poled lithium niobate (PPLN) crystal. Both green beams are superimposed onto a photodiode. The photodiode signal is then RF-filtered and amplified in a RF-shielded box. This signal and a reference frequency are superimposed in a phase detector (PD) yielding the error signal. The feedback signal is generated and fed into the acousto-optic modulator (AOM1) in a). The offset-frequency and phase are set via this reference frequency generator. A 10 MHz signal is distributed amongst all components to provide a common clock. LP and BP stands for low pass and band pass filter. AOM2 shifts the frequency in one arm of the interferometer. This way $\mathrm{f_{CEO}}$ can be stabilized to 0 without being sensitive to DC drifts.

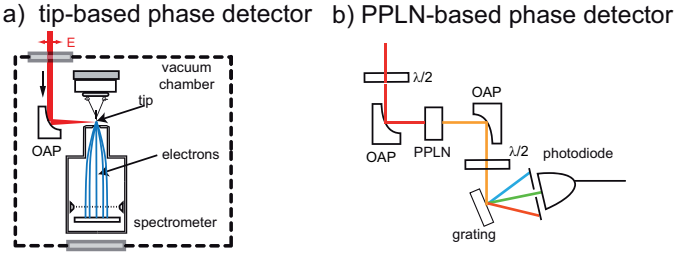

Fig. 2. The two out-of-loop CEP detectors. a) The pulses are focused onto the tip with an off-axis-parabolic mirror (OAP). The photoemitted electrons are then spectrally analyzed and detected. b) PPLN-based phase-detector [5]. The light is spectrally broadened and frequency doubled inside the PPLN. The f-2f-offset beat is then detected in the green spectral region with a photodiode.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

size. The observed signal is therefore usually integrated over the spatial intensity profile. This intensity averaging may lead to blurring of the electron spectra and hence washing out of CEP effects. Second, on a surface there are typically several hot spots with varying field enhancement that contribute to electron emission and may also obscure CEP effects. One way of circumventing those difficulties is to confine the emission area to a single well-controlled hot spot. This is the basic idea of using sharp metal tips, where the very localized optical field enhancement leads easily to an emission site area down to several $100\,\mathrm{nm}^2$.

III. Experimental Setup

A. Laser and phase stabilization

The setup consists of the laser with CEP stabilization and a tip inside a vacuum chamber (see Fig. 1 a)). The laser is a Kerr-lens mode-locked Ti:sapphire laser with $80\,\mathrm{MHz}$ repetition rate at a center wavelength of $\sim 800\,\mathrm{nm}$ and pulse duration of ∼6-fs. The CEP stabilization is achieved with a homebuilt f-2f-interferometer. The feedback mechanism is pump power modulation of the cw pump laser via an acousto-optic modulator (AOM1) [1]. Note that with another acousto-optic modulator in the f-interferometer arm (AOM2), it is possible to lock $\mathrm{f_{CEO}}$ to zero, meaning that CEP is constant. We change the phase in discrete steps by changing the phase of the reference frequency generator. We can monitor the CEP change in the PPLN-based out-of-loop interferometer (see Fig. 2b) [5]).

B. Tip environment

The nanometric metal tip is an electrochemically etched tungsten W(310) field emitter with a radius of curvature of about 10-20 nm. It is placed inside an ultrahigh vacuum chamber (base pressure of $\sim 3\times10^{-8}\,\mathrm{Pa}$)(see Fig. 2a)). The laser beam is tightly focused on the apex of the tip with a spot size of $\sim 2.4\,\mu\mathrm{m}$ ($1/e^2$ intensity radius). A small negative voltage is applied to the tip resulting in a maximum d.c. static electric field of $\sim 0.4\,\mathrm{GV/m}$ at the tip's apex. The emitted electrons are spectrally analyzed with a retarding field spectrometer (for details see [11]). Typically not more than one electron per pulse is emitted to avoid space charge effects.

IV. Carrier-envelope phase dependent photoemission

We record electron energy spectra as shown in Fig 3a) (blue solid curve) by focusing light pulses onto the tip. This spectrum is averaged over CE-phases. Two main observations can be made here. First, peaks are visible and separated roughly by the photon energy ($\sim 1.6\,\mathrm{eV}$). These represent above-threshold photoemission peaks [11]. Second, next to the dominant main contribution a plateau-like high-energetic region is found between 5 and 15eV. It is roughly two orders of magnitude smaller in count rate than the low-energetic part. It ends with a cut-off, i.e. a rather sharp decrease in count rate, at about $\sim 15\,\mathrm{eV}$. The green data points in Fig. 3a) indicate the CEP-dependent current modulation depth at the respective

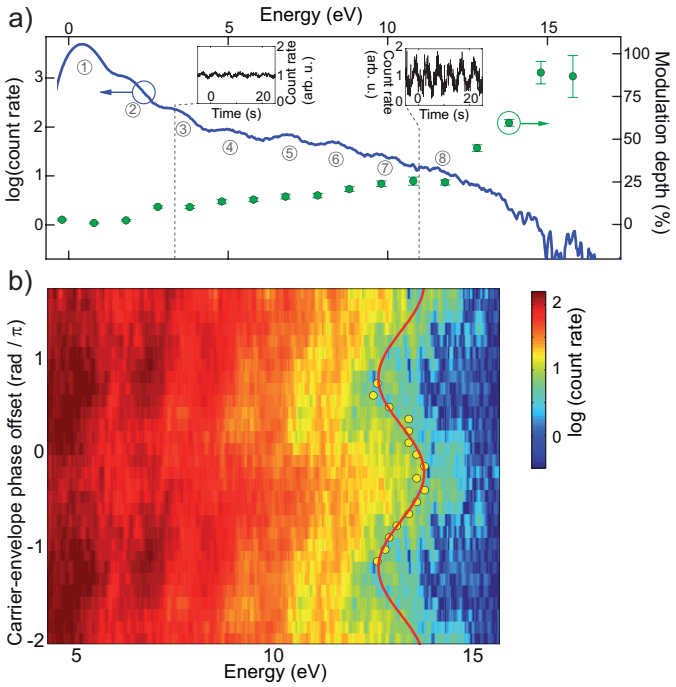

Fig. 3. Electron spectra and observed CEP effects. a) Phase-averaged measured electron spectra (blue line) in a logarithmic plot. A plateau-like structure is visible from about $5-15\,\mathrm{eV}$. The insets show the C-E phase modulation in the photocurrent with the spectrometer acting as energy high-pass filter at 3 eV and 11 eV (with the C-E offset frequency set to $f_{\mathrm{CEO}} = \dot{\phi}_{\mathrm{CE}}/2\pi = 0.2\,\mathrm{Hz}$). The CEP-modulation depth (green points) rises from few percent in total current up to near 100% for the high-energetic electrons (see Ref. [12] for details). b) Color map plot of the CEP dependent spectra in the high energy region. Clearly a modulation in the cut-off position is visible (red line). Measured data range spans 2π and is extended to $\sim 4\pi$ for better visibility.

energy. In this contribution we focus our attention on the high-energy electrons, since the CEP effects are most pronounced in that energy region. Fig. 3b) shows electron spectra in this high energy region for varying CE-phase. The position of the aforementioned cut-off is strongly modulated with the CEP (red line is sinusoidal fit in Fig. 3.). The amplitude of the cut-off modulation is $\sim 1.3\,\mathrm{eV}$. The CE-phase for the highest cut-off energies is at -0.22π.

We modeled these observation theoretically using two approaches. In the first model we numerically integrated the time-dependent Schrödinger equation. The basis for this is a rather simple 1-D model of the potential as described in Ref. [12]. We chose to calibrate the experimental CE phase offset according to the behaviour of the cut-off in the TDSE model. CE-phase of 0 means that the pulse is cosine-like, with the electric field pointing away from the tip surface. It is noteworthy that the phase of the driving field is expected to be phaseshifted with the enhanced near-field at the tip surface due to the collective excitation response of the metal [8], [13]. The second model employs the Simple-Man's model. Both models give good agreement with the experimental parameters as pulse length and laser intensity [12]. We attribute the occurence of the observed high-energetic electrons to rescattering taking

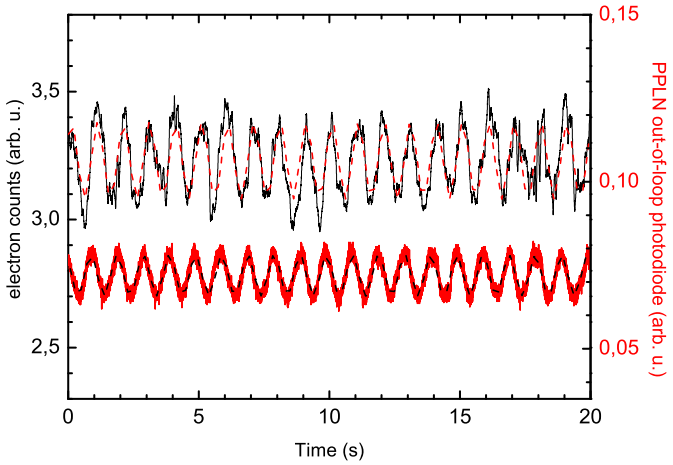

Fig. 4. Comparison between tip-based CEP-signal and PPLN-based signal for an offset-frequency set to $f_{\mathrm{CEO}} = 1\,\mathrm{Hz}$. The lower curve (red) is the PPLN based photodiode signal, the upper (black) the energy-filtered photoemission current ($E >\sim 6\,eV$). The dashed curves are sinusoidal fits. From the fit error one can extract a phase error of about $15\,\mathrm{mrad}$ for the photoemission signal (for $20\,\mathrm{s}$ measurement time).

place at the metal surface.

Next, in a crude first study we study the sensitivity of the tip-based CEP detector. For this we set $f_{\mathrm{CEO}} = 1\,\mathrm{Hz}$ and record signal of the high-energetic electrons ($E >\sim 6\,\mathrm{eV}$, see Fig. 4). From sinusoidal fits we can extract the precision in CEP determination of about $15\,\mathrm{mrad}$ for the photoemission signal in $20\,\mathrm{s}$ measurement time.

V. Outlook

The tip already represents a solid-state based CEP detector [14]. This contribution represents therefore the realisation of the idea proposed in the proceedings of the same conference [3]; however there are more possible applications: As an outlook one might ask whether it is feasible to stabilize the offset-frequency of the Ti:sa oscillator using the CEP-modulation in the electron current as feedback. Under the assumption that a signal-to-noise power ratio of $30\,\mathrm{dB}$ at $10\,\mathrm{kHz}$ resolution bandwidth is needed and assuming that the detection may be shot-noise limited we arrive, after a short calculation, at a minimum electron count rate of about $10^7\mathrm{s}^{-1}$. The maximum observed CEP-modulation amplitude is still 3 orders of magnitude smaller.

Several means to bridge this apparently large gap might be taken. Ideas include improving the collection efficiency of the emitted electrons, or using higher repetition rate Ti:sa oscillators [15], trying different tip materials or many emitters in an array.

Abstract— This work presents formation of molecular monolayers on silicon surfaces of micromechanical resonant devices and measurement of the mass of the deposited monolayer using such. Thermally actuated single crystalline silicon micromechanical resonators with resonant frequencies in the 20-30 MHz range were used as highly sensitive mass sensors. Monolayers of long chain amine molecules were formed by reacting the amine groups with epoxide groups covalently bonded to the silicon surfaces. As a result a consistent negative frequency shift of ~100ppm was measured for the resonators. Mass calculations based on the measured frequency shift show a 6.9% surface coverage for the monolayer. XPS surface analysis shows existence of nitrogen atoms on the resonator surface confirming that the measured frequency shifts are due to the addition of the amine molecules.

I. INTRODUCTION

Highly sensitive biosensors capable of detecting and measuring smallest quantities of biochemicals in biological samples are needed in various biotechnology and biomedical applications. Most of the commercially available biosensing and bioanalysis platforms, such as the biomedical diagnostics micro-arrays are based on optical methods requiring costly and sophisticated readout instrumentation with a very complex and time consuming procedure including fluorescent labeling, incubation and hybridization steps. Furthermore, such techniques only show the end results and do not provide any real-time information, e.g. about the reaction rates and effect of different parameters on it. For example measuring the affinity binding constant of the protein-protein reaction is desirable to study the disease biochemical pathways that can involve several millions of assays performed over several months [1]. Therefore, label free biomolecular sensors with fully electronic readout capable of real time monitoring of molecular absorption events can be highly beneficial in state of the art biomedical science and engineering.

Electromechanical resonant microbalances such as Quartz Crystal Microbalances (QCM) [2,3] or surface acoustic wave (SAW) sensors [4] are capable of label-free molecular detection by direct real-time monitoring of the added mass to their surfaces. However, such devices have relatively large sizes and cannot compete with fluorescent microarrays in terms of size, cost and throughput. In many cases their sensitivity is not adequate either. Micro-electromechanical resonators are smaller integrated versions of the same devices and can potentially lead to highly sensitive label-free sensor arrays with electronic readout capable of eliminating the need for amplification process such as PCR [5].

In order to use such devices as a biosensor capable of detection and concentration measurement of specific biomolecules of interest, the resonators surface is modified by attaching receptor molecules that can selectively absorb the target molecules. Upon exposure to the target molecules and absorption of such on the resonator surface, the added mass leads to an electronically measurable change in the resonance frequency of the resonator.

II. THERMAL PIEZO-RESISTIVE RESONATORS

Thermally actuated single crystalline silicon resonators with piezoresistive readout [6] have been used in this work as highly sensitive mass sensors. The simplicity and monolithic structure of such devices makes them very robust and durable and therefore suitable for sensory applications where the device needs to be in direct contact with the surroundings. Operation in liquid is generally a major challenge for

This work was supported by National Science Foundation (NSF) under grants MRI-RAPID #1061489 and MRI #0923518.

microscale resonators due to large surface to volume ratio and excessive viscous damping from the liquid. However, disk-shaped thermal-piezoresistive resonators can be designed for operation in liquid with relatively high quality factors [7]. Although all the measurements in this work have been performed in air after drying the resonators, the eventual goal is to perform direct analysis with resonators while immersed inside a biological solution.

Fig. 1 shows the COMSOL finite element thermal analysis of the resonator structures used in this work referred to as I-shaped resonators. Thermal actuation occurs by passing a current between the two pads on the two sides of the structure resulting in an ohmic power loss in the structure. The fluctuating power loss by passing a combination of AC and DC currents, results in a fluctuating temperature gradient and therefore fluctuating thermal expansion of the structure. Due to their higher electrical resistance, most of the heat gradient is generated in the narrow beams in the middle of the structure. The AC extensional force resulting from the fluctuating temperature in the beams can actuate the resonator in its in-plane extensional resonance mode. As the resonator vibrates, the alternating tensile and compressive stress in the pillars results in fluctuations in their electrical resistance (due to the piezo-resistive effect). This results in fluctuations in the DC current passing through the resonator that represents the vibration amplitude (output signal) of the resonator. (Fig.1.)[8].

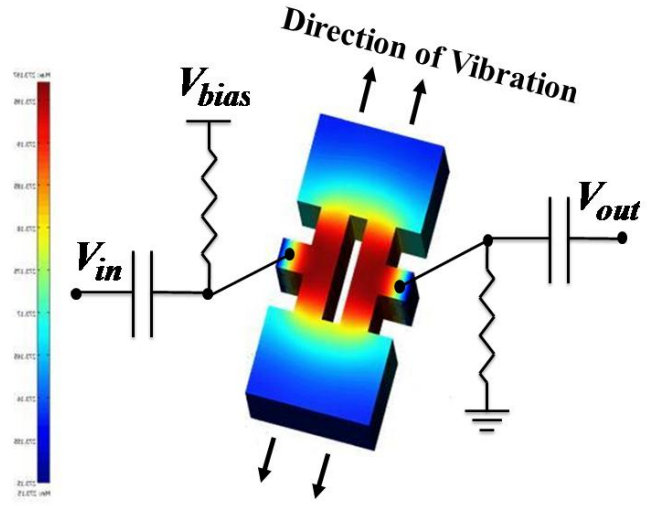

Figure 1. COMSOL finite element analysis of a thermally actuated I-shaped resonator showing the vibration direction and the qualitative distribution of AC temperature fluctuation amplitude (red being the maximum and blue minimum).

The resonators were fabricated on low resistivity N-type Silicon-On-Insulator (SOI) substrates. This was done using a single mask micromachining process by patterning the silicon device layer and undercutting the structures in hydrofluoric acid (Fig. 2a). Fig. 2b shows the SEM view of a fabricated array of resonators as well as zoomed in view of a single resonator.

III. Experiments and Measurements

A. Surface Linkage Synthesys and Frequency Measurements

The goal is to form a stable chemical linkage, via covalent bonds, between the silicon surface and the amino groups present in octadecylamine molecules (an amine molecule with a straight chain of 18 carbon atoms), which is the target molecule in this work. For this purpose intermediate molecules containing epoxide groups, which are reactive towards amino groups, are to be attached to the silicon surface first. The previously fabricated device surfaces were activated by oxidation in 1N HNO_3 for 30-60 min followed by a rinse in DI water, acetone, and ethanol for 5 min each. In order to attach the epoxide groups to the silicon surface, the chips were soaked for 5 h at 80~ in a solution consisting of 24 parts xylene, 8 parts 3-glycidoxypropyltrimethoxysilane and 1 part N,N-diisopropylethylamine (Fig. 3a). Excess reagents were removed by three washes in acetone and ether. The first frequency measurement was performed in this step after drying the resonators.

After measuring and recording the resonator resonance frequencies with different bias currents, octadecylamine attachment was performed by immersing the chips in a 5mM solution of octadecylamine in ethanol overnight (Fig. 3b). The excess reagents on the chips were rinsed off in methanol and ether. Device resonance frequencies were measured again after drying the sample. Comparing the measured frequencies before and after octadecylamine attachment shows a clear and consistent frequency shift of ~100ppm for 3 out of the 4 tested resonators (Table 1, Fig 4). The 4rd resonator shows a larger frequency shift of 140ppm, which is suspected be due to addition of contaminants during the several chemical synthesis and rinsing steps, or absorption of airborne particles during exposure of the sample to air (e.g. during testing or transferring from one place to another).

TABLE I. SUMMARY OF MEASUREMENT RESULTS FOR DIFFERENT FUNCTIONALIZED RESONATORS

L_1, L_2,W_1, W_2,W_3 (μm)	f_1(MHz) Functionalized	f_2(MHz) Octadecylamine	Δf (Hz)	Δf (ppm)
23,36,33,4,2	30.437427	30.434413	3014	99
23,36,33,4,2	29.891373	29.888322	3051	100
23,36,33,--, 2	23.809419	23.805919	3400	140
23,36,33,--, 2	27.001593	26.998914	2679	99

Figure 5 shows the measured frequencies for a 30.4MHz resonator before and after octadecylamine attachment at different bias currents showing a consistent shift at each bias current due to the added mass.

B. Surface Coverage Analysis

During the surface fictionalization, each crystal with a lattice constant of $5.43A^0$ consists of eight open bonds on 100 silicon surface exposed to reaction reagents (Fig. 6). Attachment of each epoxide group requires linking to three silicon atoms on the surface (fig. 8). This means that if all the available bonds are used for linking with 100% packing, 8.8 epoxide groups will be available in every nm^2 of silicon surface.

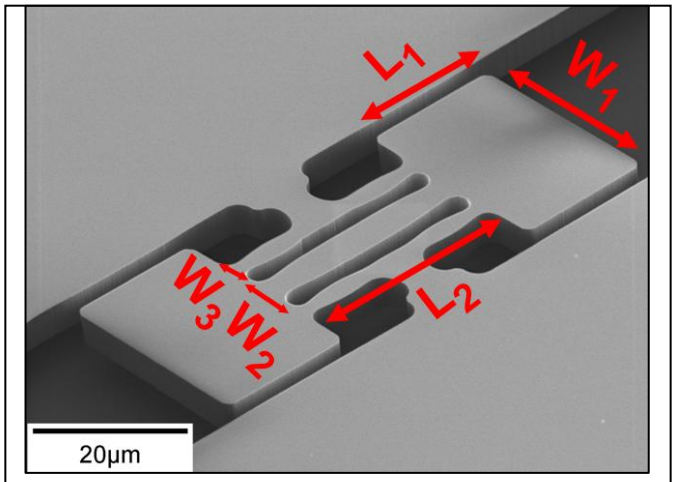

Figure 4. SEM view of a 3-bar I-shaped resonator with different resonator dimensions labeled on it.

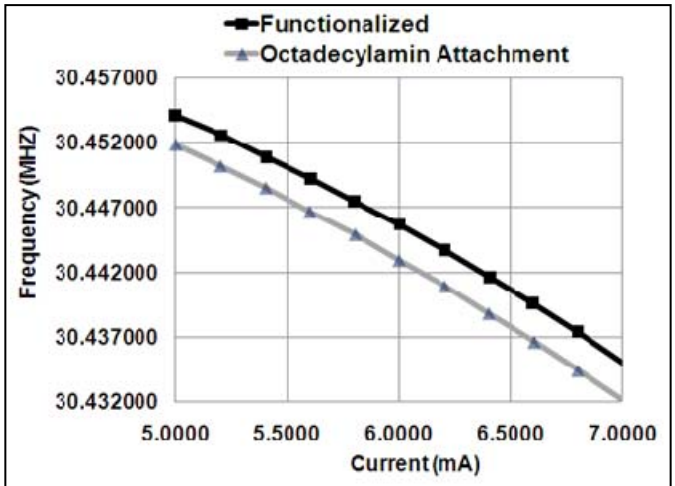

Figure 5. Consistent frequency shift for different resonator bias currents before and after octadecylamine attachment.

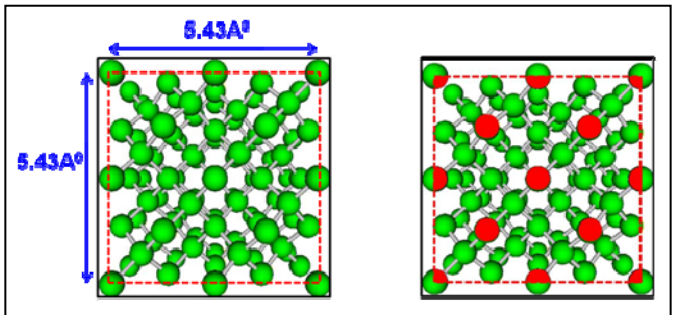

Figure 6. (a) Model of a silicon crystal as seen on the 100 surfaces, The area of every single silicon crystal is equal to $0.3nm^2$; (b) 8 silicon atoms on the surface with open bonds in every single silicon crystal unit available for surface linking .

On the other hand, according to the device mass, reference frequency value and frequency shift after octadecylamine attachment, the added mass for the 1st measured resonator with the resonance frequency of 30.4 MHz is: $\frac{\Delta f}{f} = -\frac{\Delta m}{m} \rightarrow \Delta m = 1.0pg$.

Therefore, considering octadecylamine molecular weight, the added 1.0pg of octadecylamine is equal to 2.2×10^{9} added molecules on the on the surface. Based on the resonator surface area of $3.6 \times 10^{-9} m^2$, we will end up having 0.61 molecules in every nm^2 which is equivalent to 6.93% of the calculated theoretical limit of the added molecules in $1nm^2$.

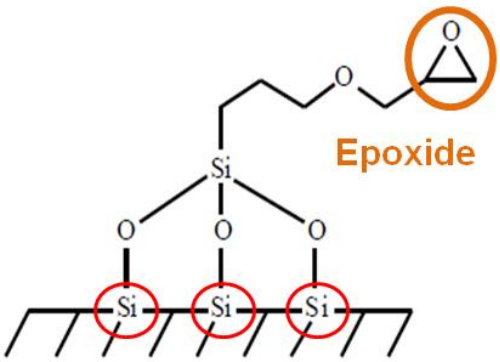

Figure 8. Each epoxide group links to the surface by bonding to three silicon open bonds on the surface

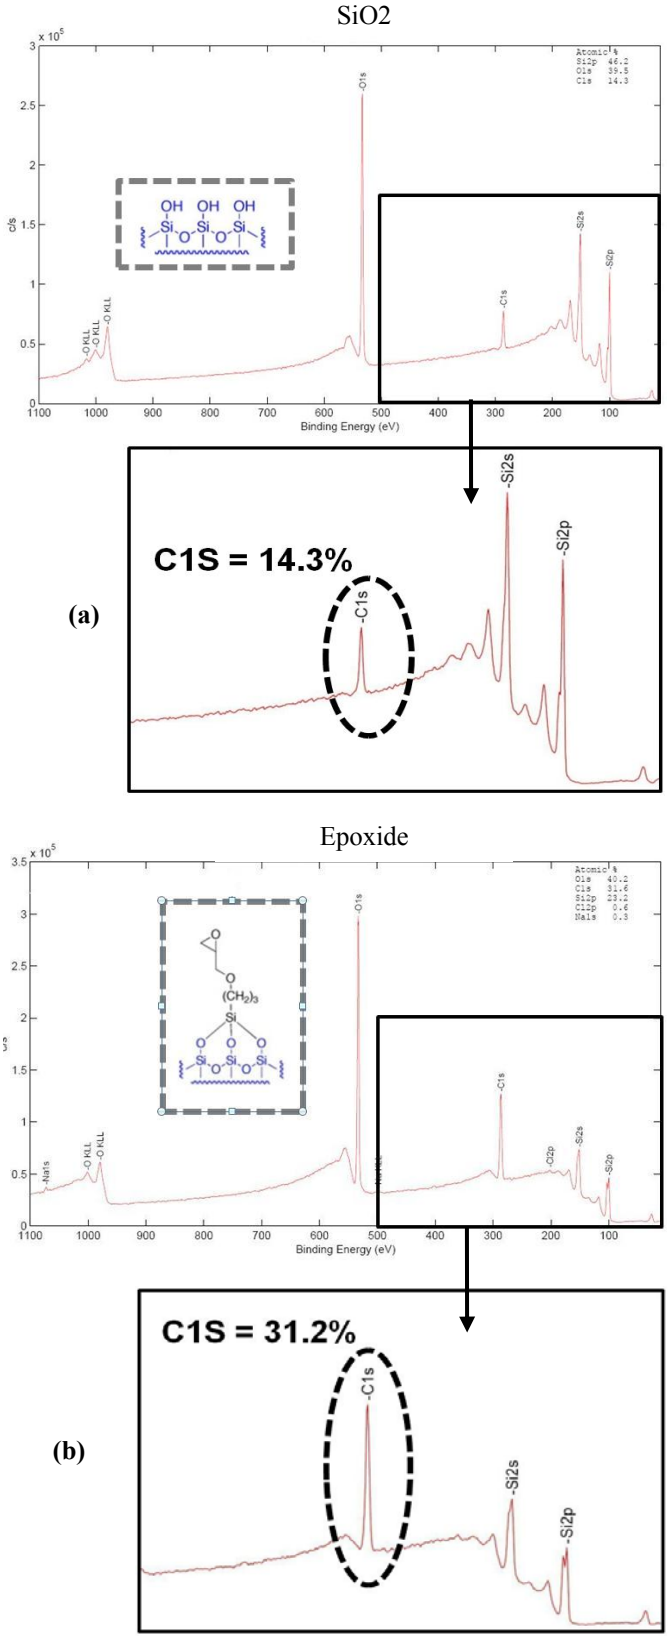
C. *Surface XPS Analysis*

To make sure that the surface linking has resulted in the attachment of the expected molecules and groups to the silicon surface and that the measured resonator frequency shifts are not a result of measurement errors or contamination, X-ray Photoelectron Spectroscopy (XPS) was performed on samples at different steps of the process. The elemental compositions on the surface support the addition of the desired molecules after each reaction. In silicon dioxide surface analysis a considerable amount of carbon was detected which is most likely due to the organic contaminants or residues (e.g. solvents used to clean the surface or airborne particles) (Fig. 9a). The carbon concentration on the surface increased significantly after the surface modification by linking the epoxide groups (Fig. 9b). After octadecylamine attachment a small amount of nitrogen (from the amine groups) could be detected on the surface while the carbon concentration further increased (Fig. 9c).



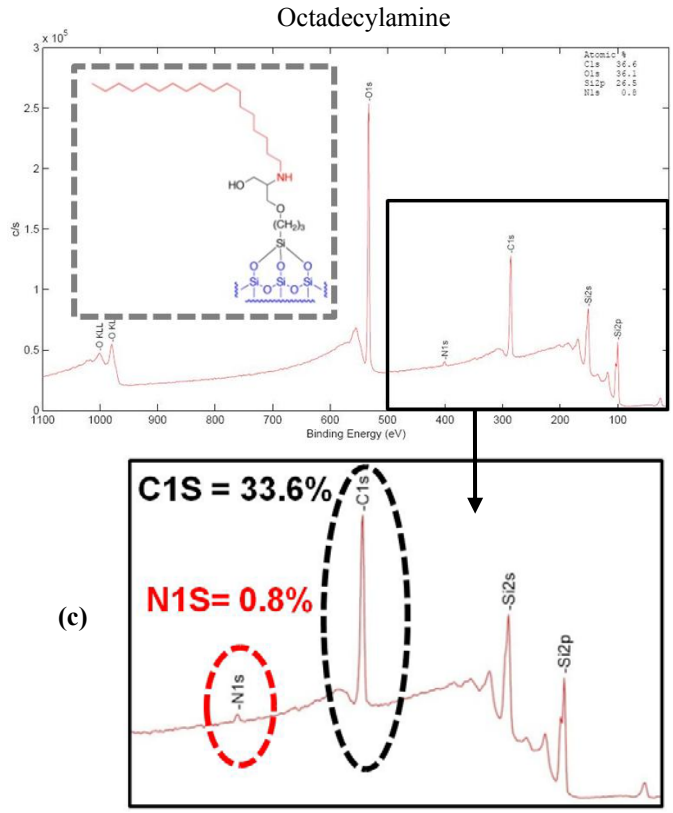


Figure 9. XPS analysis results of the resonators surfaces confirms addition of the carbon and nitrogen containing amine groups to the surface in different reaction steps. (a) SiO2, (b)Epoxide, (c) Octadecylamine

IV. Conclusions And Future Work

Thermally actuated micro-electromechanical resonators were functionalized successfully to form a monolayer of octadecylamine. Using the resonators as ultra-sensitive balances, the mass of the deposited molecular monolayer was measured by measuring resonant frequency of the resonators before and after addition of the amino-terminated carbon chains. A consistent negative frequency shift of ~100ppm after amine attachment shows a 6.9% surface coverage. Given that the attached carbon chains are relatively long (18 carbon atoms, ~2.5nm long), the calculated coverage is close the maximum achievable molecular density for such molecules.

The same surface linking chemistry can be utilized to attach amino terminated DNA single strands or other bio-receptors to the silicon surface to be used as molecular probes for detection of complementary target molecules.

Abstract— **The effect of liquid viscosity and density on the characteristics of laterally excited microcantilevers is investigated and compared to transversely excited microcantilevers. When immersed into a viscous liquid medium such as water from air, the resonant frequency of laterally (in-plane) vibrating microcantilevers is shown to decrease by only 5-10% as compared to ~50% reduction for transversely (out-of-plane) vibrating microcantilevers. Furthermore, as the viscosity of the medium increases the resonant frequency of a laterally vibrating beam is shown to decrease at a slower rate than that of a transversely vibrating beam. The decreased viscous damping also leads to increases in the quality factor of the system by a factor of 4-5 compared to beams vibrating transversely. The mass sensitivities of laterally vibrating beams are also theoretically predicted to be roughly two orders of magnitude larger in water for some cantilever geometries. The increase in the quality factor and mass sensitivity indicate that operating in the in-plane flexural mode (lateral vibration) will decrease the limit of detection compared to operating in the more common out-of-plane flexural mode (transverse vibration). These improvements in device characteristics indicate that microcantilevers excited laterally are more suited for operating in media of high viscosities.**

I. INTRODUCTION

Microcantilevers are microelectromechanical devices that can be used as highly sensitive chemical sensing platforms. When coated with a chemically selective layer, shifts in the resonant frequency of these beams can be related to changes in the ambient concentration of specific analytes in the medium of operation. A change in mass in the range of picograms has been detected using these devices, with projected detection limits on the order of femtograms or attograms [1,2]. However, when these beams are operating in a viscous liquid medium as opposed to air, the increased fluid damping and displaced fluid mass cause the resonant frequency and the mass sensitivity of the device to decrease. The increased fluid damping also causes the quality factor to decrease drastically, which increases the frequency noise and the limit of detection.

It was previously proposed that exciting microcantilevers in the in-plane flexural mode (instead of the more common out-of-plane flexural mode) would decrease the amount of viscous damping and displaced fluid mass, making the device a more appropriate platform for liquid phase sensing applications [3]. In a previous work, a semi-analytical expression for the hydrodynamic forces acting on laterally vibrating beams was derived to analyze these in-plane flexural mode cantilevers [3]. The expression predicts values for the hydrodynamic forces that compare well with other results presented in the literature [4].

In the present study, this semi-analytical expression for the hydrodynamic forces will be used to predict the characteristics of laterally vibrating microcantilevers operating in media having higher viscosities than that of water (e.g., up to 20% aqueous glycerol solution). The characteristics of interest are the resonant frequency, the quality factor, and the mass sensitivity of the device. The predicted values for the resonant frequency and quality factor will be compared to experimentally obtained values, and the trends in these characteristics investigated. The predicted mass sensitivity for these devices will also be discussed, both as a function of the beam's geometry and as a function of the medium of operation. Finally, as the expressions for the characteristics of microcantilevers vibrating transversely are well-known, analytical expressions for the ratio of the characteristics of laterally and transversely vibrating beams of similar geometries will be determined. Such expressions will help to indicate the geometries and characteristics of interest for operation in the in-plane flexural mode.

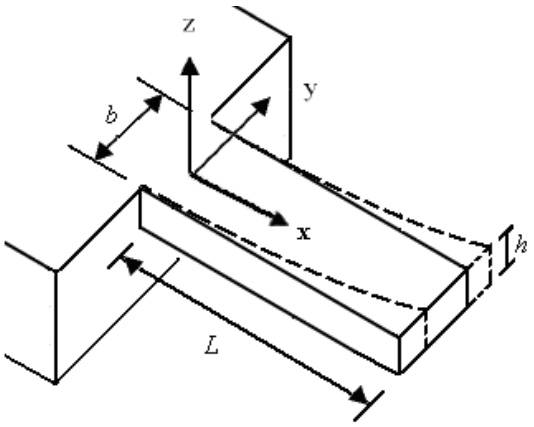

Figure 1: Geometry of a microcantilever of length *L,* width *b,* and thickness *h* deflecting laterally

II. Theoretical Analysis

A. Resonant Frequency

The geometry of a laterally excited microcantilever is shown in Fig. 1. The resonant frequency of a laterally vibrating beam in a viscous liquid medium was previously shown to be [3]

$$f_{res,lat,i} = \frac{\alpha_i^2}{2\pi}\sqrt{\frac{k_{lat}}{M_{lat}}} \tag{1}$$

where α_i is a constant dependent on the mode number ($\alpha_1 \cong 1.875$ for the fundamental in-plane flexural mode) and the effective spring constant, k_{lat}, and effective mass, M_{lat}, are given by

$$k_{lat} = \frac{Eb^3h}{12L^3}, \tag{1a}$$

$$M_{lat} = \left(\rho_B bhL + Lg_{2,lat}\right) + L\frac{\left(\left(g_{1,lat}/\omega_{res,lat}\right) + \left(\frac{\omega_{lat}}{2}\right)\frac{d}{d\omega}\left(g_{1,lat}/\omega\right)\right)}{\left(\rho_B bh + g_{2,lat} + \left(\frac{\omega_{lat}}{2}\right)\frac{d}{d\omega}\left(g_{2,lat}\right)\right)}\left(g_{1,lat}/\omega_{lat}\right) \tag{1b}$$

Here, ρ_B denotes the beam density and the variables $g_{1,lat}$ and $g_{2,lat}$ are related to the amount of viscous damping and the amount of displaced fluid mass, respectively, and are given by

$$g_{1,lat} = \frac{\pi}{4}\rho_L b^2 \Gamma_{lat,I}(\mathrm{Re}, h/b)\omega_{lat}, \tag{2}$$

$$g_{2,lat} = \frac{\pi}{4}\rho_L b^2 \Gamma_{lat,R}(\mathrm{Re}, h/b). \tag{3}$$

The terms $\Gamma_{lat,R}$ and $\Gamma_{lat,I}$ are the real and imaginary parts, respectively, of the hydrodynamic function, a normalized version of the hydrodynamic force defined in [3] that depends only on the aspect ratio *h/b* and the modified Reynolds number (Re) of the medium. The modified Reynolds number is a measure of the ratio of inertial forces to the viscous forces acting on the beam, and is defined as [5]

$$\mathrm{Re} = \frac{\rho_L \omega_{lat} b^2}{4\eta}, \tag{4}$$

where ρ_L and η are the mass density and dynamic viscosity of the fluid, respectively. It is assumed that the medium of operation is infinitely large and incompressible. It is also assumed that the velocity is continuous at the fluid-beam interface and the deflections of the beam are small compared to the dimensions of the beam. The beam's length is also assumed to be much greater than its width and thickness. Since the microcantilevers investigated in this study are composite beams made up of several layers, the Young's modulus, *E*, used in the theoretical predictions will be the effective Young's modulus

$$E_{effective} = 12\rho_B\left(\frac{2\pi L^2 f_0}{\alpha_i^2 b}\right)^2, \tag{5}$$

where f_0 is the resonant frequency in vacuum. In this work, we used the experimentally determined resonant frequency of the beam in air instead, which has approximately the same value as the resonant frequency in a vacuum. An effective beam density, ρ_B, of 2330 kg/m^3 will be assumed as the density of each layer is approximately that of silicon.

Immersed in a fluid, the resonant frequency of a laterally vibrating beam decreases from its value in vaccum, f_0, [6] by

$$\Delta f = f_0\left(1 - \sqrt{\frac{\rho_B Lbh}{M_{lat}}}\right). \tag{6}$$

As the viscous damping or displaced fluid mass increases, the total effective mass will increase, decreasing the resonant frequency. Since the amount of viscous damping is smaller when operating in the in-plane flexural mode compared to the out-of-plane flexural mode, the resonant frequency is expected to decrease by a smaller amount. The resonant frequency of the fundamental flexural mode of a laterally vibrating beam in a viscous liquid medium, $f_{res,lat}$, can be compared to the resonant frequency, $f_{res,trans}$, of the same beam vibrating transversely. Dividing (1) by the expression for the transverse resonant frequency in [7], the ratio of these two values is predicted to be

$$\frac{f_{res,lat}}{f_{res,trans}} = \frac{b}{h}\sqrt{\frac{M_{trans}}{M_{lat}}} \tag{7}$$

where M_{trans} is

$$M_{trans} = \left(\rho_B bhL + Lg_{2,trans}\right) + L\frac{\left(\left(g_{1,trans}/\omega_{res,trans}\right) + \left(\frac{\omega_{trans}}{2}\right)\frac{d}{d\omega}\left(g_{1,trans}/\omega\right)\right)}{\left(\rho_B bh + g_{2,trans} + \left(\frac{\omega_{lat}}{2}\right)\frac{d}{d\omega}\left(g_{2,trans}\right)\right)}\left(g_{1,trans}/\omega_{trans}\right) \tag{7b}$$

and $g_{1,trans}$ and $g_{2,trans}$ are defined by [7]. Note that using thinner beams (or beams with larger values for *b/h*) will result in larger differences in their resonant frequency when

operating in the in-plane flexural mode. Also note that as the dynamic viscosity and density of the medium increases, the ratio of effective masses increases.

B. Quality Factor

Microcantilevers operating in the liquid-phase suffer from a drastic decrease in their quality factors. This decrease in the quality factor increases the frequency noise (which is proportional to $f_{res,lat}/Q_{lat}$ when operating in an oscillator configuration [8]), thus increasing the limit of detection in biochemical sensing applications. The quality factor is defined as 2π times the ratio of the maximum energy stored in a resonating system to the amount of energy dissipated in one cycle [9]. However, when a resonating device is used in an oscillator configuration, the quality factor is commonly obtained using the 3-dB bandwidth Δf_{3dB} of the device and is given by

$$Q_{lat,3dB} = f_{res,lat} \Big/ \Delta f_{3dB} \,. \tag{8}$$

When the damping is small, (8) represents a good approximation to the exact definition [9]. The quality factor of a laterally vibrating beam was previously derived as [3]

$$Q_{lat} = \left(2\left(1 - \sqrt{1 - \frac{g_{1,lat}/\omega_{lat}}{\rho_B bh + g_{2,lat}}} \right) \right)^{-1} \tag{9}$$

and, when Re>>1, the quality factor can be approximated as

$$Q_{lat,approx} = 2\pi f_{res,lat} \frac{\rho_B bh + g_{2,lat}}{g_{1,lat}} \,. \tag{10}$$

The quality factor of laterally vibrating beams is predicted to be higher than that of transversely vibrating beams due to the decreased damping. The ratio of the quality factor of a laterally vibrating beam to that of a transversely vibrating beam of similar geometry is approximately given by

$$\frac{Q_{lat,approx}}{Q_{trans,approx}} = \frac{\rho_B bh + g_{2,lat}}{\rho_B bh + g_{2,trans}} \frac{\Gamma_{I,trans}}{\Gamma_{I,lat}} \,. \tag{11}$$

Note that the first fraction on the right hand side of (11) is smaller than one (when $b>h$), as transversely vibrating beams displace more fluid compared to laterally vibrating beams. The second fraction is the ratio of the amounts of viscous damping which is normally much greater than one for the cases considered.

C. Mass sensitivity

The sensitivity of the resonant frequency to changes in the beam mass, or the mass sensitivity, can be defined as [8]

$$S_m = \left| \frac{\Delta f}{\Delta m} \right| . \tag{12}$$

An analytical expression for the mass sensitivity can be obtained using the same procedures described in [7]. The expression for the mass sensitivity of a laterally vibrating beam is then the same as the expression for the transversely vibrating beam [7], but with different values for the hydrodynamic function, Γ_{lat}, and the moment of inertia I_{lat}. If the thickness of the sensing layer is considered small enough, then the mass sensitivity can be given as

$$S_m = \lambda_{m,lat} f_{res,lat} \tag{13}$$

where

$$\lambda_{m,lat} = \frac{\left(g_{1,lat} \Big/ \omega_{lat} \right)\left(g_{1,lat} \Big/ \omega_{lat} + \left(\frac{\omega_{lat}}{2} \right) \frac{d}{d\omega} \left(g_{1,lat} \Big/ \omega \right) \right) L^2}{2M_{lat} \left(\rho_B bhL + Lg_{2,lat} + L\left(\frac{\omega_{lat}}{2} \right) \frac{d}{d\omega} \left(g_{2,lat} \right) \right)^2} - \frac{1}{2M_{lat}} \tag{13a}$$

The second term in (13a) dominates the first term when Re>>1. The mass sensitivity, S_m, can then be approximated as

$$S_{m,approx} = \left| \frac{\alpha_i^{\,2}}{2\pi} \frac{\sqrt{Eb^3 hL^{-3}}}{4\sqrt{3}\left(M_{lat} \right)^{3/2}} \right| . \tag{14}$$

When the beam is operating in air or low viscosity media, the effective mass can be approximated as the beam mass, $M_{lat} \cong \rho_B Lbh$. In this case, the mass sensitivity has a geometric dependence of $h^{-1}L^{-3}$. As the decrease in the resonant frequency from air to water is small for laterally vibrating beams, this geometric dependency mostly holds when operating in a viscous liquid medium. Since the chemical sensitivity is proportional to the mass sensitivity multiplied by the volume of the sensing layer (e.g., Lbh_2, where h_2 is the thickness of the sensing layer) the chemical sensitivity is predicted to be proportional to $(h_2/h)*(b/L^2)$. As the resonant frequency is known to be proportional to b/L^2 (e.g., [3]), beams with higher resonant frequencies are then predicted to have higher chemical sensitivities.

The ratio of the mass sensitivity of a laterally vibrating beam and that of the same beam vibrating transversely is also dependent on the beams' geometry. Using (14), this ratio can be approximated as

$$\frac{S_{m,lat,approx}}{S_{m,trans,approx}} = \frac{f_{res,lat}}{f_{res,trans}} \frac{M_{trans}}{M_{lat}} = \frac{b}{h} \left(\frac{M_{trans}}{M_{lat}} \right)^{3/2} . \tag{15}$$

The effective mass of transversely vibrating beams is larger than that of laterally vibrating beams. Thus, the increase in the mass sensitivity when using lateral excitation compared with transverse excitation will be equal to or greater than b/h. Note again that thinner beams will benefit more when operating in the in-plane flexural mode than thicker beams. Also note that this ratio will be larger than the ratio of the resonant frequencies by a factor of M_{trans}/M_{lat}.

III. Results and Discussion

Experimental results for the resonant frequency and the quality factor of laterally vibrating beams both in water and aqueous mixtures of glycerol were obtained. The set-up used to extract the experimental data is described in [10]. The microcantilevers were laterally excited using thermal excitation. The beam's deflection as a function of excitation frequency was obtained using a Wheatstone bridge fabricated on the beam with the sensing resistors oriented so that the bridge voltage could be related to the lateral deflection of the beam. Solutions of varying aqueous percent glycerol (from pure water to 20% w/w) were placed in a flow cell containing the microcantilevers so that the beams were completely immersed in the solution. The spectrum of each device was then obtained and the resonant frequency and quality factor of the first in-plane flexural mode were extracted. Several microcantilevers were tested and sample results will be discussed for selected geometries. The silicon-based microcantilevers used in this work have a nominal silicon thickness of either 4.8 or 9.0 µm and are covered with a 1.9 µm passivation layer on the top made up of alternating layers of silicon nitride and silicon oxide (for fabrication details, see [10]).

The decrease in the resonant frequency of a 200x60x6.7 μm^3 laterally vibrating beam due to the increase in the viscous damping and displaced fluid mass as a function of the percent aqueous glycerol is shown in Fig. 2. The theoretical results calculated using (1) show similar trends; however, the decrease in the experimentally determined resonant frequency is smaller than the decrease in the theoretically predicted resonant frequency. The predicted resonant frequency in water is slightly different from the experimentally determined value (1390.7 kHz vs. 1381.3 kHz, respectively). The predicted decrease in the resonant frequency also has better agreement with the experimental results for longer beams, i.e. 1000x90x10.9 μm^3 beam. This suggests that the difference could be due to effects that are not accounted for when the assumption of a long beam is made. This assumption neglects the effects of the shear and rotational inertia of the beam, which cause the resonant frequency to be lower. These effects tend to be larger for shorter beams.

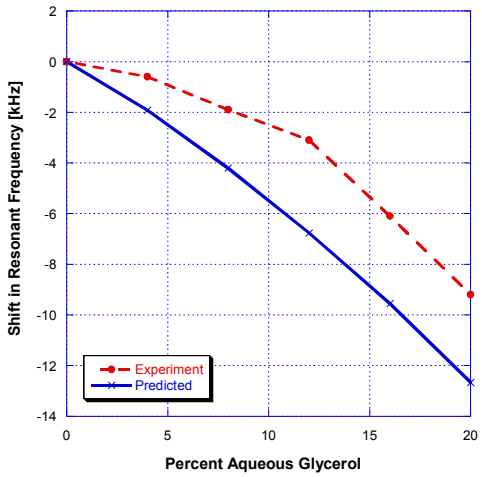

Figure 2: Predicted and experimentally determined shift in the resonant frequency of a 200x60x6.7 µm laterally vibrating microcantilever from water to a solution of aqueous glycerol.

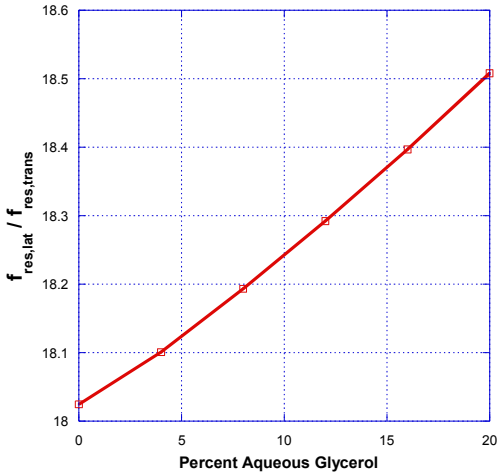

Figure 3: The predicted ratios of the first lateral and transverse resonant frequencies as a function of the medium's percent aqueous glycerol for a 200x60x6.7 µm beam

Due to the increased stiffness of operating in the in-plane flexural mode, the resonant frequencies of laterally vibrating beams will be higher than those of transversely vibrating beams of similar geometry. When the effective mass can be approximated by the beam mass (such as when operating in vacuum or air), the predicted ratio of resonant frequencies of laterally and transversely vibrating microcantilevers is approximately equal to the ratio of their width and thickness. When the beam is operating in a more viscous liquid medium, this ratio of frequencies increases. The predicted ratio of the resonant frequencies of a laterally and transversely vibrating 200x60x6.7 μm^3 microcantilever is given in Fig. 3 as a function of the percent aqueous glycerol in the operational medium. This ratio is larger than the width to thickness ratio of 8.95 due to the differences in the effective mass. As noted before, the resonant frequency of a laterally vibrating beam decreases with increasing percent aqueous glycerol. This means that the increase in the ratio is due to the transverse resonant frequency dropping more drastically than its lateral counterpart as the viscosity is increased. Because a high

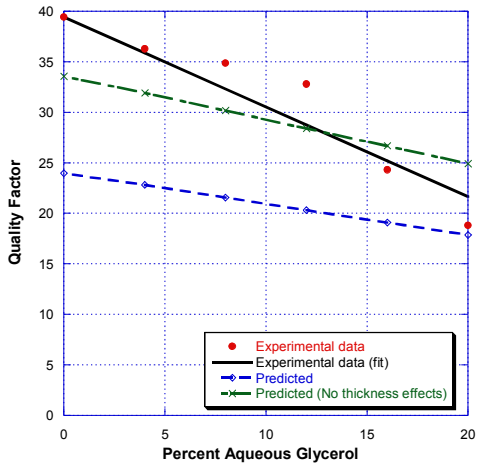

Figure 4: Predicted and experimentally determined quality factors of a 200x60x6.7 µm laterally vibrating microcantilever as a function of percent aqueous glycerol.

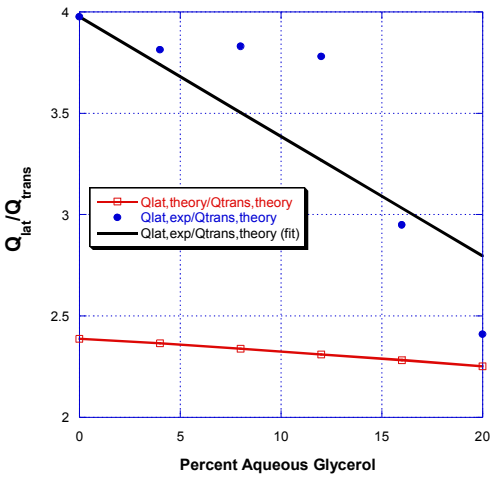

Figure 5: The ratios of the quality factors of laterally (both predicted and experimentally determined) and transversely vibrating beams (200x60x6.7 µm) as a function of percent aqueous glycerol (medium of operation).

resonant frequency is desired for sensing applications, it is thus more advantageous to operate in the in-plane flexural mode when operating in high-viscosity media.

The quality factor as a function of percent aqueous glycerol for the same beam (200x60x6.7 µm^3) is given in Fig. 4. The experimentally determined quality factors are larger than the commonly obtained values for transversely vibrating beams, which are usually on the order of 10 [11]. While the experimental results show similar trends as the theoretically predicted results, the experimentally determined quality factors are larger than the theoretically predicted quality factors. Calculated values for the quality factor using a simpler expression given by [12] are also shown in Fig. 4. However, this expression neglects the pressure effects of the fluid on the smaller faces (of dimension *h*), i.e., it is based on assuming only a Stokes-type fluid resistance on the top and bottom faces of the beam. The theoretically predicted quality factors would be smaller if the shear deformation and support compliance effects were taken into account. Thus, these effects are not the source of the discrepancy. Another assumption made when the hydrodynamic forces were estimated in [3] was that the beam was infinitely long. This assumption was made to neglect the edge effects near the end of the beam in the lengthwise direction, and might not be appropriate for the given geometry. It is noted that the quality factors of longer beams (e.g. 1000x90x10.9 µm^3) more closely match the characteristics predicted by theory.

Regardless of the length used, the quality factor tends to be higher when operating in the in-plane flexural mode compared to the out-of-plane flexural mode. It is predicted, when operating in air, that the quality factor of a 200x60x6.7 µm beam is a factor of 6.16 times larger for the in-plane flexural mode than for the out-of-plane flexural mode. This increase, unlike the resonant frequency, is expected to be smaller when operating in a viscous liquid medium. Fig. 5 shows the predicted ratio of the quality factor of a 200x60x6.7 µm^3 laterally vibrating silicon microcantilever and that of a transversely vibrating microcantilever of the same geometry as a function of percent aqueous glycerol. As the experimental results show higher quality factor values than the predicted theoretical results, this improvement is expected to be higher when using the experimental results for comparison. The improvement in the quality factor is also a function of the beam's geometry. For example, longer and narrower beams will have a smaller increase in quality factor when compared to shorter and wider beams. This is because shorter and wider beams have higher resonant frequencies, Reynolds numbers, and thus larger damping ratios.

The mass sensitivity was not experimentally determined in this study. However, the mass sensitivity can still be estimated for the 200x60x6.7 µm^3 microcantilever as a function of percent aqueous glycerol, and is given in Fig. 6. While the predicted mass sensitivity is expected to decrease as the percent aqueous glycerol increases, the rate of decrease is much smaller than that of similar beams vibrating transversely. For example, a 200x60x6.7 µm^3 laterally vibrating microcantilever in water is predicted to have a 3.26 Hz/pg mass sensitivity compared to a 0.0443 Hz/pg mass sensitivity of the same beam vibrating transversely. When the viscosity of the operational environment is increased to 1.734 cP (20% aqueous glycerol), the mass sensitivity of the transversely vibrating beam decreases by 10.4% to 0.0397

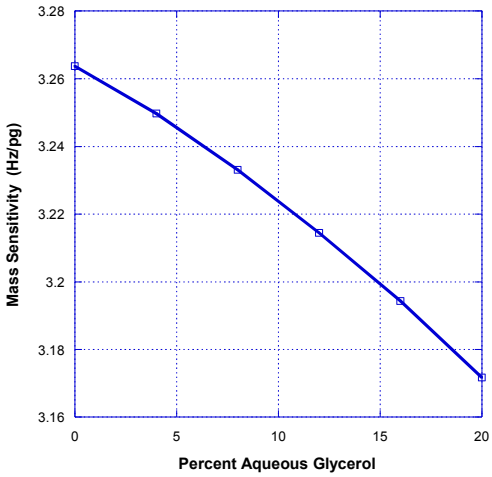

Figure 6: Predicted mass sensitivity of a 200x60x6.7 µm laterally vibrating microcantilever as a function of percent aqueous glycerol.

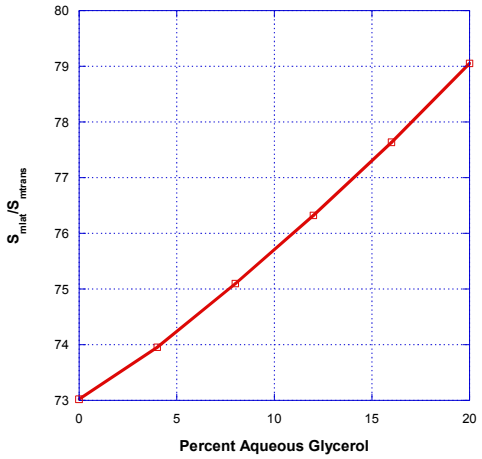

Figure 7: The ratio of the mass sensitivities of a laterally and a transversely vibrating beam for a 200x60x6.7 µm microcantilever as a function of percent aqueous glycerol in the operational medium.

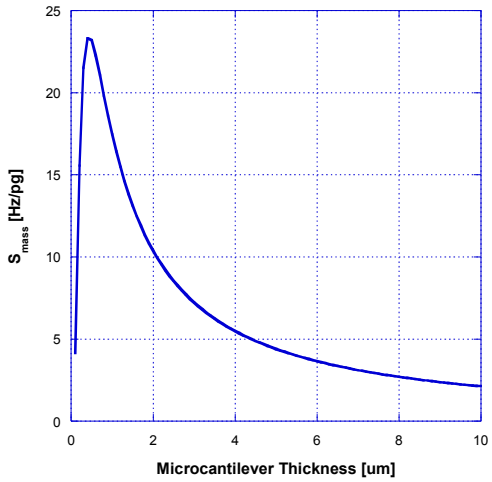

Figure 8. The mass sensitivity of a laterally vibrating 200x60 µm microcantilever in water as a function of beam thickness.

Hz/pg, while the same beam laterally vibrating only decreases by 2.76% to 3.17 Hz/pg. This indicates a further improvement in more viscous fluid. The ratio of the mass sensitivity as a function of percent aqueous glycerol is given in Fig. 7.

The ratio of the chemical sensitivities, assuming the same geometry and sensing layer, is the same as the ratio of the mass sensitivities. If the thickness of the beam is decreased, this ratio would be even larger, as the mass sensitivity is also a function of the beam's geometry. Shorter and thinner beams are expected to have higher mass sensitivities. The predicted mass sensitivity of a 200x60 μm^2 silicon microcantilever in water as a function of thickness is given in Fig. 8. Note that the mass sensitivity is predicted to initially increase with increasing thickness. This increase occurs because, for small thicknesses, the fluid mass dominates the beam mass. It's noted that the stiffness is linearly dependent on the thickness. When the beam mass dominates the fluid mass as the thickness increases, the mass sensitivity decreases. However, as discussed in [3], the quality factor will also increase with increasing thickness. As the limit of detection is a function of both the chemical sensitivity (which depends on the mass sensitivity) and the quality factor, both must be considered when choosing the appropriate thickness of a microcantilever for a given application. However, increasing the width will increase the quality factor while not greatly affecting the mass sensitivity of laterally vibrating beams; and decreasing the length will increase both the quality factor and the mass sensitivity of laterally vibrating beams.

IV. CONCLUSIONS

It is shown that laterally vibrating microcantilevers can be excited and have relatively high (20 to 60) quality factors, even when operating in media with higher viscosity than water. The resonant frequency of laterally vibrating beams in a viscous liquid medium is also observed to experience relatively insignificant decreases (compared to its resonant frequency in air). When compared to transversely vibrating beams, the predicted characteristics (i.e. the resonant frequency, quality factor, and mass sensitivity) are shown to be higher. Considering the resonant frequency and mass sensitivity, this increase is larger for media with higher dynamic viscosities. These improvements result in an almost two orders of magnitude higher chemical sensitivity in viscous solutions. Besides for chemical sensing, this is ideal for biosensor applications where biofluids may have higher viscosities than water. It is also shown that shorter and wider beams will have higher quality factors and larger improvements in their mass sensitivity compared to transversely vibrating microcantilevers. This indicates that the limit of detection of microcantilever bio-chemical sensors operating in the in-plane flexural mode will be lower than that of microcantilevers operating in the out-of-plane flexural mode in liquid-phase sensing applications.

***Abstract*— A phononic crystal device is investigated as a sensor platform combining bandgap engineering with resonant transmission. Here we apply a regular phononic crystal with a solid matrix and liquid filled holes, fully immersed into the liquid with incidence direction of sound normal to the plate.**

I. INTRODUCTION

Phononic crystals are periodic composite materials with spatial modulation of acoustically relevant parameters like elasticity, mass density and longitudinal and transverse velocities of elastic waves. When applied as sensor, the material of interest constitutes one component of the phononic crystal, e.g., a fluid in the holes of a regular phononic crystal having a solid matrix. If the value of interest, here the concentration of one component in a liquid binary mixture, changes acoustic properties of this mixture, the acoustic properties of the phononic crystal will also change. Transmission or reflection coefficients are appropriate parameters for measurement and used to localize a characteristic feature of the phononic crystal. For a sensor application, a transmission peak within the band is the most favorable feature since the respective frequency of maximum/minimum transmission is easy to determine. The sensor scheme therefore relies on the determination of the frequency dependence of maximum transmission on the physical or chemical value of interest.

The sensitivity of the sensor, S_f can be defined as the ratio of frequency shift, Δf, and change of the input parameter, Δx:

$$S_f = \frac{\Delta f}{\Delta x} \tag{1}$$

Similar to acoustic microsensors the sensitivity has been found to be dependent on the probing frequency, f_0. We furthermore consider a certain frequency measurement resolution by taking the peak half band width, f_{HBW}, into account. We define therefore a reduced sensitivity, S_{fr}, which gives much better insights to the sensor capabilities:

$$S_f = \frac{\Delta f}{\Delta x \; f_0 \; \Delta f_{HBW}} \tag{2}$$

We recently have applied the one-dimensional concept for the first time with an arrangement of parallel solid plates and a liquid-filled gap in-between to determine the concentration of propanol in water [1,2]. This kind of realization is a reduction of a phononic crystal to one dimension in its most simple form. The difference of the acoustic impedance between aluminum, the material the solid plates are made of, and the liquid, the water-propanol mixture in the gap and pure water surrounding the phononic crystal is large enough to create a band gap sufficiently large for sensing purposes. We have designed the phononic band gap that a broad transmission window appears at the resonance frequency of the ultrasonic transducers used for generation and detection of ultrasonic waves. The narrow transmission peak sensitive to the composition of the liquid mixture in the gap emerges in the fist band gap below. The sensitivity $\Delta f/\Delta x_2$ in the concentration range between x_2 = 0–0.035 of 1-propanol (0–10%) is about 1.086 MHz, the reduced sensitivity is about 0.19 kHz^{-1}. One can estimate a limit of detection of propanol of about 0.1%, which has good practical relevance.

Although the one-dimensional approach can be reduced by size, one always has to realize a certain aspect ratio between radius of the plates/gaps and thickness of the plate/gaps. Moreover, the sensor only probes bulk properties since only longitudinal waves are useful.

We therefore go the next step and apply a two-dimensional regular phononic crystal keeping the incidence of sound normal to the plate. Still, a certain diameter of the plate is required, however, more opportunities exist in miniaturization. In addition, this realization features rich physics which can be applied in different sensing schemes based on different modes which are excited in the plate by the incoming longitudinal wave. Here we concentrate on the most apparent feature, the so-called extraordinary acoustic transmission phenomenon [3].

II. THEORY

Extraordinary acoustic transmission through plates has been found for several geometries, e.g., through metal plates with narrow gratings [4], sub-wavelength hole arrays [5-10] and through plates coupled by pillars [11,12] or a plate having linear gratings on both sides [13]. There are no generally recognized theory or conceptual framework concerning EAT, though the behavior of acoustic waves propagating through these structures has been a subject of intensive research. Extraordinary transmission has been attributed to the coupling between the compositions of diffractive waves excited on the surfaces of the grating and the Fabry-Perot resonant modes inside the apertures [4]. Evanescent waves are assumed altering Fabry-Perot resonance conditions and resonance can occur in apertures less than half wavelength of the incident wave. Resonance is smoothly linked to the surface-wave-like modes induced by the periodic structure factor [5,6]. Several transmission mechanisms are involved which produce a complex interplay phenomena, specifically interaction among holes arranged in an array and direct transmission through the bulk material [7]. When varying the thickness of the plate, the transition from the Fabry-Perot resonances (thick plate limit) to the structure-factor-induced surface modes resonance (thin plate limit) will take place. We have chosen a thin plate whose thickness is smaller than the minimum half wavelength of the scanned frequency range. The structure we have used consists of a steel plate with liquid-filled holes in square arrays. The lattice distance is 1.5 mm, the thickness of the plate is 0.5 mm and the diameter of the hole is 0.5 mm.

The three-dimensional finite-difference time-domain (FDTD) method has been applied to calculate the transmission spectrum through the plate. The elastic wave equation in homogeneous solids is given by equation (3) and (4):

$$\rho\frac{\partial^2\mu_x}{\partial t^2}=\frac{\partial T_{xx}}{\partial x}+\frac{\partial T_{xy}}{\partial y}+\frac{\partial T_{zx}}{\partial z} \tag{3a}$$

$$\rho\frac{\partial^2\mu_y}{\partial t^2}=\frac{\partial T_{xy}}{\partial x}+\frac{\partial T_{yy}}{\partial y}+\frac{\partial T_{yz}}{\partial z} \tag{3b}$$

$$\rho\frac{\partial^2\mu_z}{\partial t^2}=\frac{\partial T_{zx}}{\partial x}+\frac{\partial T_{yz}}{\partial y}+\frac{\partial T_{zz}}{\partial z} \tag{3c}$$

$$T_{xx}=(\lambda+2\mu)\frac{\partial\mu_x}{\partial x}+\lambda(\frac{\partial\mu_y}{\partial y}+\frac{\partial\mu_z}{\partial z}) \tag{4a}$$

$$T_{xy}=\mu(\frac{\partial\mu_x}{\partial y}+\frac{\partial\mu_y}{\partial x}) \tag{4b}$$

$$T_{yy}=(\lambda+2\mu)\frac{\partial\mu_y}{\partial y}+\lambda(\frac{\partial\mu_x}{\partial x}+\frac{\partial\mu_z}{\partial z}) \tag{4c}$$

$$T_{yz}=\mu(\frac{\partial\mu_y}{\partial z}+\frac{\partial\mu_z}{\partial y}) \tag{4d}$$

$$T_{zz}=(\lambda+2\mu)\frac{\partial\mu_z}{\partial z}+\lambda(\frac{\partial\mu_y}{\partial y}+\frac{\partial\mu_x}{\partial x}) \tag{4e}$$

$$T_{zx}=\mu(\frac{\partial\mu_z}{\partial x}+\frac{\partial\mu_x}{\partial z}) \tag{4f}$$

$\vec{u}(\vec{r})$ is the displacement vector, $\lambda(\vec{r})$ and $\mu(\vec{r})$ are the Lame coefficients, and $\rho(\vec{r})$ is the mass density. One obtains the relation equations of stress (T) and the velocity (v) by using discretization of the equations in both space and time domains. In the FDTD calculations, we have chosen a computational cell with dimension 30×30×300 grid points, corresponding to 30 grid points per lattice constant. A spatial grid with mesh size $\Delta x = \Delta y = \Delta z = 0.05$ mm has been used. The faces of the computational cell normal to x and y axes are chosen to have Bloch boundary conditions, while the faces normal to z axis (the top and bottom ones) have Mur's absorbing boundary conditions. For transmission spectrum calculations, a broad band wave packet is launched to illuminate the plate with a normal incidence. The transmitted signal is recorded as a function of time. The frequency dependence of the field at a particular point can be obtained by fast Fourier transforming the time results. The transmission coefficient is calculated by dividing the transmitted energy flux by the energy flux of the incident wave.

COMSOL™ simulations have been performed revealing further insights. We especially have been concentrating on coupled elements: liquid confined in the holes, regular set of portions of the plate surrounded by the holes and regular set of holes with adjacent portions of the plate. Each of these elements has their own set of modes and each of these modes can support either transmission or reflection. Eigenfrequencies of each of these elements depend on the boundary conditions including rheological properties of the liquid, which may lead to sensing schemes not considered so far.

III. EXPERIMENTAL

Different liquid properties are obtained by gradually changing the liquid in the holes and the surrounding from pure DI-water to a series of liquid mixture with different molar concentration of 1-propanol similar to [1,2]. Density and sound velocity have been taken from [3]. Whereas density decreases monotone with molar ratio of 1-propanol from 998 kg m^{-3} for pure DI-water to 804 kg m^{-3} (about 20 %) speed of sound increases from 1483 m s^{-1} to a maximum of 1588 m s^{-1} at $x_2 = 0.056$ (7 %) and decreases to 1220 m s^{-1} (for pure 1-propanol (-25 %; with respect to water).

The transmission curves have been obtained using a network analyzer (Agilent 4395A) together with an S-parameter test set (Agilent 87511A). Transmission S21 has been measured with and without sample in place respectively. The transmission amplitude is obtained by normalizing with the amplitude of the equivalent setup without the sample.

Several stages have been used to fix and align the sample parallel between two piezoelectric transducers with a central frequency of 1 MHz having a half bandwidth of 45 kHz, Fig. 1. Although the signal amplitude reduces considerably off the resonance, the amplitude is still sufficiently above the noise floor. The distance between the transducers and metal plate is large enough to avoid the near field effect and multiple reflections. A small tank contains the liquid. Porous plastic discs have been placed in the container to reduce unwanted reflection of the acoustic waves at the container walls.

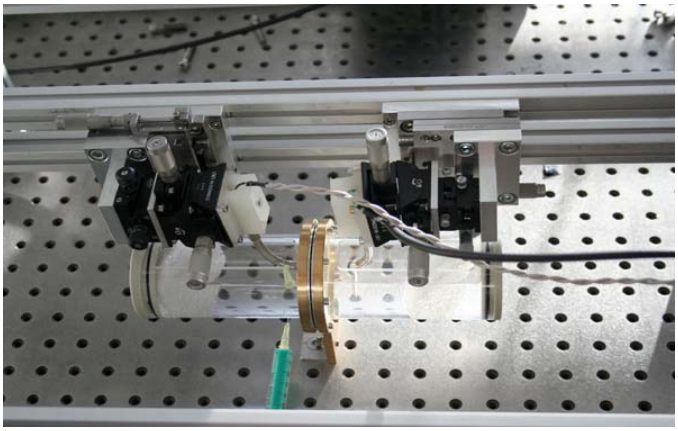

Figure 1. Photo of the experimental setup

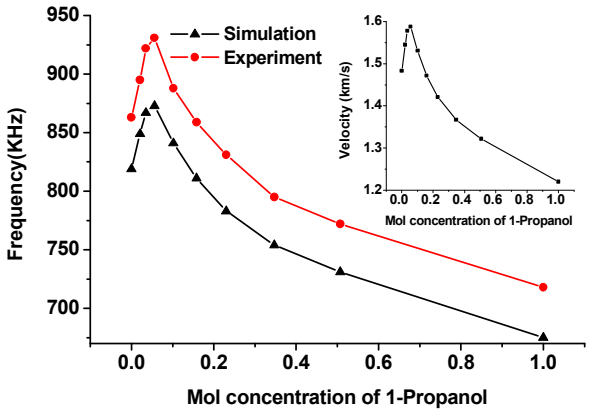

Figure 2. Results of resonant frequency *vs.* molar concentration of 1-propanol in the liquid mixture. The black curve with triangular symbols reflects the FDTD simulation and the red curve with circular symbols summarizes the experimental results. The maximum transmission peak frequency corresponds to the extreme in speed of sound at molar ratio $x_2 = 0.056$. The inset reflects speed of sound of the liquid mixture.

IV. Results

We observed both in FDTD simulation and in experiment that the frequency of resonant transmission peak significantly changes with the molar ratio of 1-propanol in the liquid mixture, Fig. 2. This finding resembles the results of measurement and simulation of the one-dimensional arrangement [1,2]. Specifically, the shift of the maximum transmission peak frequency again reflects the difference in speed of sound. The highest resonance frequency appears at a molar ratio $x_2 = 0.056$, corresponding to the maximum acoustic velocity of the mixture. The sensitivity $\Delta f/\Delta x_2$ in the concentration range between $x_2 = 0$–0.035 is about 3 MHz and three times larger, the reduced sensitivity is about 0.065 kHz^{-1} and hence only 3 times smaller than in the one-dimensional case. The major contribution for this decline in the reduced sensitivity is the 8 times larger half band width of the extraordinary transmission peak. Figs. 4 a-d (next page) reveal another effect not yet understood, the decline of the peak maximum. Viscosity changes of the liquid mixture are not very likely, since this value has also passes an extreme whereas the peak amplitude decreases monotone. Finally, Fig. 4 exhibits also a systematic frequency difference between simulation and experiment. Further analyzes reveal the reason for the difference. We have found that only a slight difference in the lattice constant between the fabricated sample and the design can cause this shift whereas the peak frequency is much less sensitive to similar deviations in the hole diameter as well as in the acoustic velocity of steel.

Fig. 3 exemplarily shows acoustic wave propagation through the device at the frequency of extraordinary transmission. First of all, the calculations confirm earlier findings, the sound pressure before and after the phononic crystal is the same. The value is much higher in the hole, an effect which does not appear having only one hole in the plate. Fig. 3 also demonstrates the excitation of several modes in the plate by the incoming longitudinal wave which very much depend on the frequency. The extraordinary acoustic transmission peak must therefore be attributed to 'collective' resonances of the liquid inside the holes.

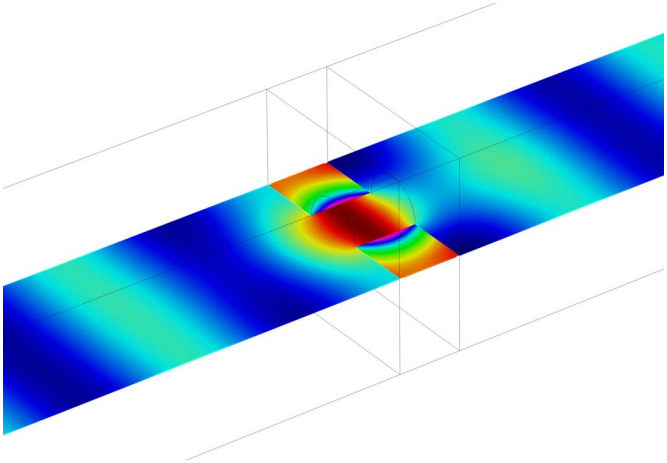

Figure 3. Comsol Simulation of the extraordinary transmission of sound through an array of sub-wavelenth holes

V. Conclusions

Regular 2-dimensional phononic crystals in an arrangement with normal incidence of sound can be used as sensor to determine acoustic properties of liquids like speed of sound concentration of a component in a mixture with sensitivities comparable to ultrasonic sensors. The sensing effect is based on collective resonances inside the holes, hence the principle can be used for very small volumes.

***Abstract*—This work addresses the importance of ambient conditions in the design of a sensor system for real-time monitoring of contaminated water sites and groundwater *in situ* for fuel and oil spills. The sensor system is based on shear-horizontal surface acoustic wave devices with chemically sensitive polymer coatings for analyte sorption. In addition to the use of a sensor array, evaluation of response time (absorption time constant) is discussed as a tool for analyte identification. The influence of relevant ambient parameters (temperature, pH, salinity) on the sensor response is described, and resulting requirements for the design of the sensor system are discussed.**

I. INTRODUCTION

Various types of chemical compounds are known to pose a demonstrable or potential health hazard through contamination of groundwater. This has resulted in the introduction of legal limits for a broad range of these compounds both for industrial effluent and for drinking water [1]. Current methods for monitoring contaminants include gas/liquid chromatography and mass spectroscopy. Although these methods can be very accurate, they often require samples to be taken to laboratories for analysis, are very time consuming, and relatively expensive. Moreover, vital information can be lost during sample collection, transportation, and storage. Therefore, there is a need to develop *in-situ* monitoring systems for rapid analysis and characterization of samples. An ideal solution would be a compact, portable sensor system that permits real-time monitoring of critical sites for contamination. Various types of sensor systems have been proposed for this application, including acoustic wave sensor devices [1]. It has been demonstrated that shear-horizontal surface acoustic wave (SH-SAW) sensor devices can be used to detect small concentrations of chemical and biochemical analytes *in situ* in liquid phase [2]–[4]. In addition, SH-SAW sensor systems can be made small and portable [1]. This permits real-time, distributed monitoring of groundwater or contaminated sites without the need to collect samples and analyze them off-site in a laboratory. Consequently, such sensor systems show the potential to reduce analysis time and cost. In addition, they can be used to gain a more detailed and comprehensive understanding of the distribution and dispersion pathways of chemicals in contaminated sites.

In contrast to a controlled laboratory environment, this approach requires a very thorough understanding of the ways a changing environment will affect the sensor system. For example, it has been shown that the responses of absorption-based vapor sensors can be significantly influenced by environmental parameters such as ambient temperature, which affects the partitioning of analyte vapor into polymer sensing films [5]–[7]. For *in-situ* measurements where ambient parameters cannot always be controlled, it is crucial to understand such effects and to compensate or correct for them by appropriate system design.

In this work, the investigation of a SH-SAW sensor system to detect aromatic hydrocarbons at trace levels in contaminated water *in situ* and in real time is reported. Aromatic hydrocarbons such as benzene, toluene, ethylbenzene, and xylenes (the BTEX compounds) are major components of gasoline and diesel fuels [8] and therefore are important targets in groundwater and contaminated site monitoring. In this application, temperature, pH, and salt concentration of a particular monitoring site depend significantly on various factors including geographic location. Active control of the environmental variables would require unacceptable increases in system complexity, size, and power consumption. Therefore, the influence of temperature and other ambient parameters such as pH or salt concentration on the sensor response must be determined. Results can then be used to develop a system for accurate *in situ* measurement of

trace concentrations of aromatic hydrocarbons such as BTEX in contaminated water.

II. Experimental

A. Sensor Design

The sensor platform used in this work consists of a piezoelectric substrate (36° rotated Y-cut, X-propagation $LiTaO_3$) supporting a SH-SAW, and electrodes (interdigital transducers, IDTs) with a periodicity of 40 µm. This corresponds to a frequency of operation of about 103 MHz. The entire device (including the IDTs) is coated with a chemically sensitive polymer and immersed in the liquid to be monitored. A schematic of the sensor device is shown in Fig. 1. For simplicity, Fig. 1 shows only a single SH-SAW sensing channel; the actual device consists of a dual delay line design where the second SH-SAW channel is coated with poly(methyl methacrylate) (PMMA) baked for 120 min at 180 °C and serves as a reference line. It is noted that the treatment of the PMMA, which results in a glassy polymer layer, prevents analyte absorption. The purpose of the reference channel is to compensate for signal drift due to secondary effects such as changes in temperature.

Various polymers have been investigated as chemically sensitive coatings. In this work, poly(ethyl acrylate) (PEA), poly(epichlorohydrin) (PECH), and poly(isobutylene) (PIB) have been used. The polymers were deposited from solution by spin coating and baked for 15 min at 60 °C, resulting in thicknesses ranging from 0.5 to 1.0 µm as indicated below. The design of the SH-SAW sensor platform has been described in detail in previous work [2], [4].

B. Materials and Instrumentation

Among the polymers used in this study, only PEA was obtained as a solution (20% w/v in toluene, Sigma-Aldrich). The other polymers were obtained in undissolved form from Sigma-Aldrich (PECH, PIB) and Scientific Polymer Products (PMMA), respectively. PECH and PIB were dissolved in chloroform (99.8%, Sigma-Aldrich), and PMMA was dissolved in 2-ethoxyethyl acetate (98%, Sigma-Aldrich). Spin coating of the polymers was performed using a Specialty Coating Systems 6708D spin coater. All chemicals were used as received.

The BTEX compounds were obtained from Sigma-Aldrich and had the following purities: 99.8% (benzene and toluene), 99% (ethylbenzene), and 98.5% (xylenes, mixture of isomers), respectively. Only filtered and degassed DI water (Milli-Q) was used throughout this study. For pH-dependent measurements, pH was adjusted using potassium phosphate dibasic and potassium phosphate monobasic (both 98%, Sigma-Aldrich); all pH values were verified using a pH meter (Corning 220). NaCl (99%) was obtained from Sigma-Aldrich as well.

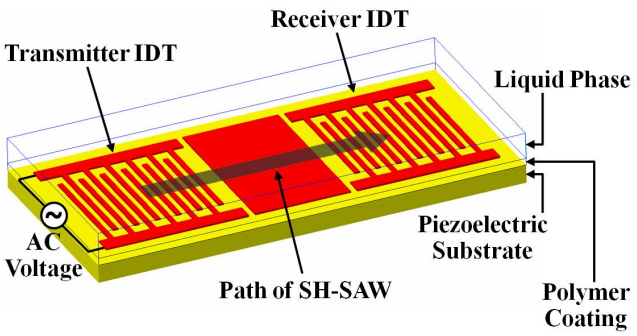

Fig. 1: Schematic of the SH-SAW sensor device.

The experimental set-up consisted of a network analyzer (Agilent 8753ES) and a switch/control system (Agilent 3499A) to switch between the two SH-SAW channels. The sensor was placed inside a flow cell made in-house, and the pump (Eppendorf EVA) was set to a sample flow rate of 0.4 mL/min. Temperature was held constant at 22.0 ± 0.1 °C; for the temperature-dependent measurements, the temperature of the flow cell and sensor device was varied using a Peltier element (Custom Thermoelectric TEC module).

III. Theoretical Considerations

Generally, the absorption of an analyte by a polymer coating on an acoustic wave sensor device affects both the velocity and the attenuation of the acoustic wave. For this study, priority is given to the change in acoustic wave velocity which is measured by a network analyzer as a proportional change in frequency. Acoustic wave loss (attenuation) has sometimes been investigated only for the purpose of interpreting the observed frequency changes.

Absorption of the analyte into the polymer coating will not only increase the mass loading on the sensor surface but will also lead to swelling of the polymer, accompanied by changes in its shear modulus. Both mechanisms will affect the characteristics of the acoustic wave. The resulting change in frequency, Δf, can be expressed as [4]:

$$\Delta f = \Delta f_C \, C_{Amb} \, K_{P\text{-}L} \, (1 / (\rho_P + C_W) + \beta). \qquad (1)$$

In this equation, Δf_C is the frequency shift due to the coating (including water absorbed by the coating), C_{Amb} is the ambient concentration of the analyte, $K_{P\text{-}L}$ is the partition coefficient of the analyte between polymer and liquid phase, ρ_P is the density of the polymer, C_W is the concentration of water in the polymer, and β is a sensitivity coefficient which is a function of device, polymer, and medium properties and contains the viscoelastic contributions to the sensor signal. Equation (1) implies that viscoelastic contributions in Δf are linear with Δf_C and C_{Amb}. Note that this applies only for small coating thicknesses and low analyte concentrations.

For some polymers, partition coefficients have been calculated for the liquid phase [9], [10]. For the BTEX compounds, liquid-phase partition coefficients for PECH and PIB are summarized in Table I.

Various groups have performed calculations to determine the effect of the viscoelastic parameters of a sensor coating on both frequency and loss of an acoustic wave [3], [11], [12]. Li *et al.* investigated the effect of the complex shear modulus of a polymer coating, $G = G' + jG''$, and determined the influence of a variation in G' and G'' on acoustic wave velocity, v, and

Table I: Calculated partition coefficients in aqueous phase, $K_{P\text{-}L}$, for two polymers, PECH and PIB [9], [10].

acoustic wave loss of a coated sensor device in liquid phase [3], [12]. Results of these calculations are shown in Fig. 2.

While the exact dependence of the shear moduli of the polymers used in this study as a function of temperature and analyte concentration is not known, such calculations can nevertheless serve as a guideline to the interpretation of experimental observations. As Fig. 2b indicates, the influence of shear modulus on acoustic loss is generally small for glassy or moderately rubbery polymers but can rapidly increase as the polymer gets softer. It is well known that the shear modulus of a polymer depends on temperature in a complex way [13], undergoing a rapid decrease around the glass transition temperature, T_g, and changing at a lower rate in the rubbery regime above T_g. The exact behavior of the shear modulus in the rubbery regime depends on the type of polymer [13]. The chemically sensitive polymers used in this study have glass transition temperatures below the freezing point of water (see Table II), and thus will be in the rubbery state in groundwater monitoring applications.

While exact data on the mechanical properties of our chemically sensitive polymers in the rubbery regime are not available from the literature, experimental observation shows an increase in acoustic loss with temperature for all three polymers around room temperature (data not shown). This observation implies a further softening of the polymers as the temperature is increased beyond T_g.

IV. Results and Discussion

Coated sensor devices were exposed to various concentrations of BTEX compounds in water to evaluate the performance of the various coating materials in the liquid phase. Sample results are shown in Fig. 3 for the detection of ethylbenzene using a 1.0-µm-thick PEA coating.

Assuming non-specific sorption of the analytes into the polymer, Henry's law should be valid at low concentrations [15], and the measured frequency shift should be linear with concentration. For the coating, type of analyte, and concentration range investigated in Fig. 3, this assumption appears to be valid. Measurements were conducted for a larger concentration range to test the limits of Henry's law. Fig. 4 shows the result for benzene and a PEA-coated device.

In Fig. 4, no systematic deviation from a linear fit can be observed (only a small and random scatter of the data due to manual pipetting in sample preparation is noticeable). For this example, as well as for other analytes and sensor coatings, Henry's law was always observed to be valid for

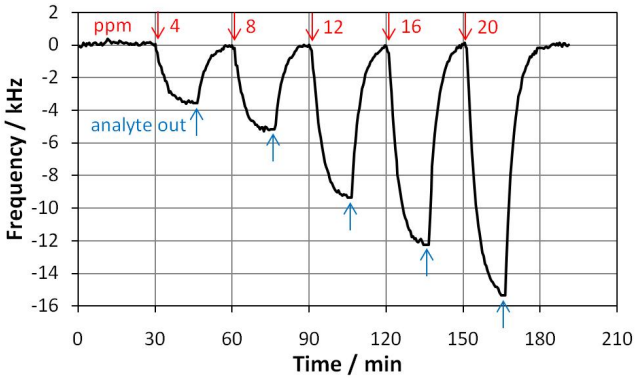

Fig. 3: Frequency response of a SH-SAW device coated with 1.0 µm PEA to various concentrations of ethylbenzene in water; concentrations are indicated on the graph (1 ppm = 1 mg/L). The analyte was flushed out with water between individual samples. The signal was corrected for baseline drift.

concentrations below 50 mg/L.

The ultimate goal of the design of the SH-SAW sensor system is to identify and quantify a given analyte in the presence of other contaminants. Therefore, the system needs a certain degree of selectivity. Non-specific analyte sorption is associated with partial selectivity, permitting analyte identification using an array of sensors with different coatings [16], [17]. An example of partial selectivity is reflected in the data presented in Table I. However, it should be noted that the partition coefficients depend on thermodynamic driving forces based on two input variables: the affinity of the coating for the analyte, and the solubility of the analyte in the liquid phase. In order to judge the partial selectivity of a given coating for an analyte, the measured frequency shift has to be divided by analyte solubility. In addition, since the sensor response is predominantly based on mass loading, the data should also be normalized with respect to analyte molar mass in order to compare data in terms of the number of molecules absorbed into a coating. If both normalization procedures are applied, a parameter is obtained which permits a thermodynamically more meaningful comparison of different coating materials:

$$\Delta f\,(\text{normalized}) \;=\; (\Delta f / M_W) \,/\, (\Delta C_{Amb} / C_S). \qquad (2)$$

In this equation, M_W is the analyte molar mass, and C_S is the analyte solubility; the other variables are defined as in Equation (1). Data for solubilities and molar masses of organic hydrocarbons have been taken from the literature [18].

Experimental results have been collected for the detection of 20 mg/L of the BTEX compounds and the three chemically sensitive polymers investigated. The data have been normalized according to Equation (2) and are presented in Fig. 5. Of the BTEX compounds, benzene is the most hazardous to human health. Therefore, coating materials have been selected with a focus on maximum partial selectivity for benzene, and the data in Fig. 5 have been normalized to the respective value for benzene for each coating material.

A useful concept to understand the interaction between two substances is the Hildebrand solubility parameter [19], which measures the cohesive energy density of a given substance, i.e. the amount of energy needed to remove a unit volume of molecules of this substance from their neighbors to infinite distance. The cohesive energy contains various contributions from polarity, polarizability, hydrogen bonding, etc. Chemical substances with similar solubility parameters will usually show good solubility in each other. Fig. 5 indicates that PEA shows the strongest partial selectivity for benzene. This is in agreement with the fact that PEA and benzene have almost identical Hildebrand solubility parameters [19].

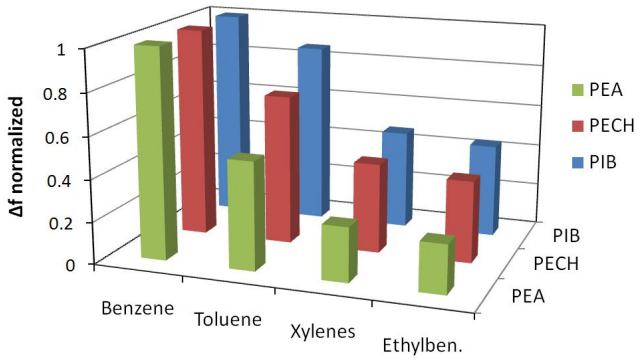

Fig. 5: Normalized frequency shifts for the BTEX compounds for sensors coated with 1.0 µm PEA, 0.6 µm PECH and 0.5 µm PIB, respectively. Data have been normalized as described in the text to extract the effect of partial selectivity of the polymers.

Fig. 5 also shows slightly different response patterns for the investigated polymers, a fact that can be exploited for pattern recognition. However, since this effect is not pronounced, this study also investigates the potential of the sensor response time to be an additional tool to identify a given analyte. To use response time as an input parameter for pattern recognition, an appropriate mathematical procedure must be identified to extract this parameter from experimental data. This has been done by modeling experimental response curves with an exponential fit using a state-space model [4]:

$$y(t) \;=\; y_0\,(1 - \exp(-t / \tau)). \qquad (3)$$

In this equation, $y(t)$ is the frequency change as a function of time, starting at the moment the analyte is added. The response time, τ, has been determined for 20 mg/L of each BTEX compound. Results are given in Table III for two polymer coatings.

Note that the coating thickness has to be known because it affects the value of τ. On the other hand, it was observed that τ is independent of analyte concentration within experimental error. Also note that benzene has a very short response time, a fact that might be useful for rapid extraction of benzene concentration from the sensor array response in the presence of other contaminants. In light of these findings, both equilibrium frequency change and response time were evaluated for their dependence on ambient parameters.

Fig. 6 shows an example of the influence of ambient temperature on the frequency response of a device coated with 0.5 µm PIB. The change in device loss is also presented, as it will be helpful in the interpretation of the results. The equilibrium frequency change is not much affected by ambient temperature; however, the latter does affect both the response time and the change in device loss. Fig. 6b shows that the change in loss increases with temperature, a result which is in agreement with the assumption that the polymer gets softer with increasing temperature as discussed in section III. The increase in softness is also expected to facilitate analyte diffusion into the polymer, thereby reducing response time.

Table III: Response times, τ, extracted from experimental data for the detection of 20 mg/L of the BTEX analytes with two polymer coatings, 1.0 µm PEA and 0.6 µm PECH, respectively.

Analyte	τ_{PEA} **(s)**	τ_{PECH} **(s)**
Benzene	63	52
Toluene	98	92
Xylenes	262	241
Ethylbenzene	265	216

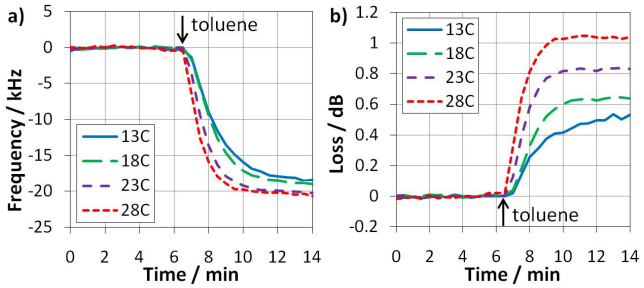

Fig. 6: Frequency shift (a) and change in device loss (b) for detection of 200 mg/L toluene for a sensor coated with 0.5 µm PIB, measured at four different temperatures as indicated on the graphs (in °C). The signal was corrected for baseline drift.

In order to quantify the effect of temperature on both frequency shift and response time, response curves measured at different temperatures were modeled with exponential fits according to Equation (3), and data for equilibrium frequency shift, y_0, and τ were extracted. Results for the detection of 10 mg/L toluene using a device coated with 0.6 µm PECH are shown in Fig. 7; the extracted fitting parameters are listed in Table IV.

Table IV shows that while y_0 is only slightly affected by temperature, τ varies by more than a factor of two in the temperature range investigated. Similar findings were made for the other investigated chemically sensitive polymers.

An additional set of experiments was conducted where the pH value of the aqueous phase was varied between 5.5 and 8, and the BTEX compounds were detected at each respective pH value. It was shown that pH had no significant impact on either frequency shift or response time (results not shown). In another set of experiments, the salinity of the aqueous phase was varied by adding NaCl in concentrations of 0 to 3%. Again, it was found that salinity has no significant influence on either frequency shift or response time in BTEX analyte detection. This is important if the device is to be used for detection in contaminated ocean or brackish water sites.

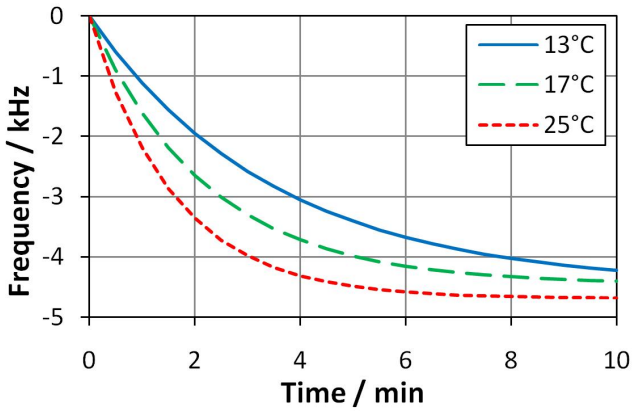

Fig. 7: Exponential fits for the frequency-vs.-time responses measured for detection of 10 mg/L toluene using a device coated with 0.6 µm PECH, measured at three different temperatures as indicated on the graph.

Table IV: Response times, τ, and equilibrium frequency shifts, y_0, extracted from the exponential fits shown in Fig. 7 for detection of 10 mg/L toluene using a device coated with 0.6 µm PECH.

17	133	-4.45
25	95	-4.69

V. Conclusion

A system using polymer-coated SH-SAW sensor devices was presented, which is under investigation for the detection and monitoring of BTEX compounds in groundwater or contaminated sites. It was shown that in addition to using the partial selectivity of the polymer coatings, it will be useful to evaluate the response time as an additional sensor parameter for pattern recognition. Since the sensor system is going to be used *in situ*, the influence of various ambient parameters on both the frequency shift and response time of the sensors has been investigated.

It is known that the temperature of groundwater and contaminated water sites depends on geographic location. In the US (Alaska and Hawaii not included), near-surface groundwater temperatures vary between about 5 °C and 25 °C [20]. In addition, the acidity and salinity of groundwater and contaminated water can vary significantly. It was shown that the influence of all three ambient parameters investigated on the equilibrium frequency shift is small. Therefore, the latter is regarded as a robust parameter under field conditions. Within the relevant range, groundwater acidity and salinity also have little influence on response time for the polymers investigated. In contrast, it was shown that ambient temperature significantly affects the response time of polymer-coated sensors.

It was observed that both the baseline acoustic wave loss and the change in loss upon analyte sorption increase with temperature for the investigated chemically sensitive polymers, indicating a softening of these polymers with increasing temperature. Theoretical calculations [12] show that a decrease in shear modulus of a polymer can under certain conditions lead to a large change in acoustic loss but only a minor change in frequency, in agreement with experimental observations in this study. The softening of the polymer is also consistent with the faster response times observed for higher temperatures [21], [22].

The above findings suggest two alternative routes for the design of a sensor system for monitoring of groundwater or contaminated sites. A sensor array with pattern recognition based solely on using equilibrium frequency shift data would be the more straightforward approach because the influence of all the investigated ambient parameters on frequency shift is insignificant. However, such a system would have to rely on the limited partial selectivity of the polymer coatings for analyte identification. This might result in a decrease both in reliability in analyte identification and in accuracy in analyte quantification, and likely would preclude accurate analysis of analyte mixtures.

Therefore, a second approach is proposed that uses both equilibrium frequency shift and response time as sensor parameters for pattern recognition. It has been shown that response time is a powerful parameter in analyte identification (see Table III). In this case, the design of the sensor system requires that ambient temperature be monitored and used as an input parameter to compensate for the dependence of response time on temperature. This could be achieved by adding a small thermal sensor to the sensor array, and by modifying the pattern recognition software to take into account this additional parameter. It is expected that this approach will lead to better performance of the sensor system in analyte identification and ultimately will facilitate mixture analysis.

Abstract—**A novel surface acoustic wave flow sensor is studied in this paper. ST-X cut quartz SAW delay line device is chosen for its ultra-high temperature stability. Test chamber is designed and built using acrylic plate and the SAW device is mounted on the chamber wall. Test Results show that SAW flow sensor has a linear relationship between the passing flow rate and system phase delay. The system has a response resolution of 4.24Deg / kPa in terms of pressure or 1 degree phase change for flow rate change of every 11.8ml/min. The change of resonant frequency is found to be not as obvious as phase change. The system can be further integrated with wireless system for remote on site monitoring.**

I. INTRODUCTION

Fluid flow sensor has broad applications in various industrial and research operation monitoring and control. It's especially important to have accurate flow measurement in some aero-space technology applications and some of the cutting edge research projects.

There has been numerous flow sensors, some of them already commercialized. Traditional mechanical flow sensors, such as venturi flow meters [1] and pitot tube flow meters [2], do not require power supply, and have simple structures. However, the readouts of these traditional flow sensors are not compatible with electronic system, making them unsuitable for modern applications.

Modern electronic flow sensors can be divided into several categories based on operation principles. One of the most important types of flow sensor is thermal flow sensor [3], including hot-wires anemometers, calorimetric flow sensors. They usually have a heater and at least one temperature sensing element to measure, e.g. the heat transfer from the heater to the thermometer. These flow sensors can have broad measurement range, from micro fluid measurement to macroscopic petroleum transport pipes. It's also convenient to integrate these sensors into CMOS circuit same chip control. The other important type of flow sensor is ultrasonic flow sensor [4]. The sensing structure is clamped to the outside wall of the pipe, where ultrasonic wave travels through the flow and is reflected back through the flow and intercepted by the receiver.

Sponsored by NSF grant #0925716 and DOE grant #0002138.

The response of the ultrasonic wave, including resonant frequency, magnitude and phase change depends on the flow rate through the pipe. However, the power consumption of these sensors makes them hard to be used in portable devices or remote areas where power supply is a challenge.

For pressure driven laminar flow, as shown in Fig. 1, the pipe wall is subject to pressure along the flow direction. The pressure on the wall decreases linearly towards the exit.

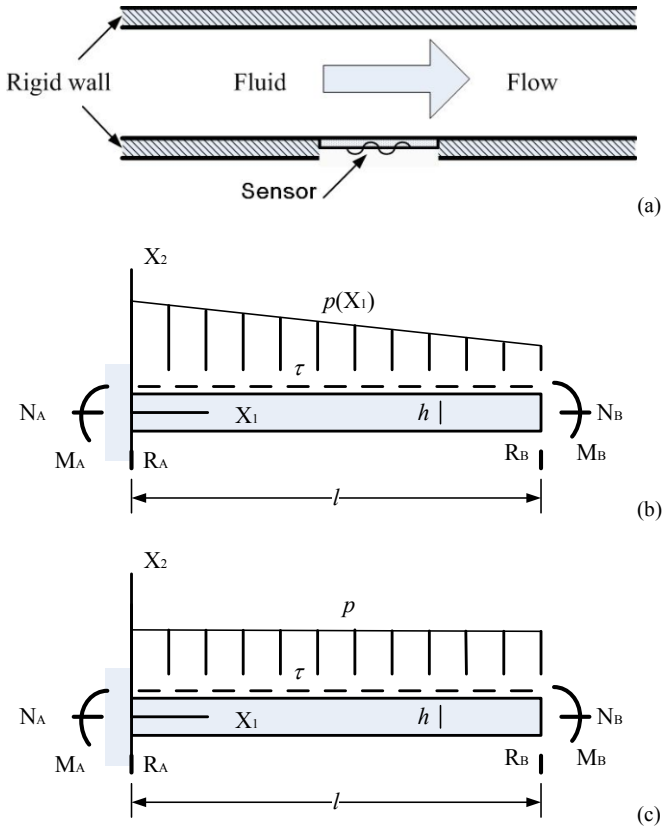

Fig. 1. Schematic view and Physics model of flow sensor. (a) schematic view of the pipe and sensor. (b) Sensor is subject to linearly decreased pressure. (c) Normal pressure can be simplified as uniform for small sensor surface area.

When a sensor is mounted on the pipe wall, the sensor will also be subject to linearly decreased pressure. For sensor with small surface area compared to pipe dimension, the pressure can be assumed to be uniform as shown in Fig. 1(c).

Previous research [5] showed that, for laminar flow, the pressure difference between specific point on pipe wall and flow exit depended linearly on flow rate. The normal pressure and shear stress on the pipe wall can be calculated as equation (1) and (2).

$$\Delta P = \int_{L/2}^{0} \frac{dp}{dx} dx + \frac{8\mu L_p}{\pi R_p^4} Q = \frac{6Q\mu L}{h^3 w \left(1 - \frac{192h}{\pi^5 w} \sum_{n=1,3,5\ldots}^{\infty} \frac{1}{n^5} \tanh\left(\frac{n\pi w}{2h}\right)\right)} + \frac{8\mu L_p}{\pi R_p^4} Q, \quad (1)$$

$$\tau_r = \frac{h}{2}\left(-\frac{dp}{dx}\right)\left[1 - \frac{8}{\pi^2} \sum_{n=1,3,5\ldots}^{\infty} \frac{1}{n^2} \frac{\cosh\left(\frac{n\pi z}{h}\right)}{\cosh\left(\frac{n\pi w}{2h}\right)}\right]_{z=0} = \frac{6\mu Q}{h^2 w} \frac{\left[1 - \frac{8}{\pi^2} \sum_{n=1,3,5\ldots}^{\infty} \frac{1}{n^2 \cosh\left(\frac{n\pi w}{2h}\right)}\right]}{\left[1 - \frac{192h}{\pi^5 w} \sum_{n=1,3,5\ldots}^{\infty} \frac{1}{n^5} \tanh\left(\frac{n\pi w}{2h}\right)\right]}. \quad (2)$$

The calculated shear stress on the pipe wall is three order magnitudes less than the normal stress thus can be ignored.

Since flow rate depends linearly on pressure, the flow meter essentially functions as a pressure sensor.

To facilitate the integration of wireless module, surface acoustic wave (SAW) is chosen as the sensing method. SAW sensor has been widely used for its low power consumption and easy operation and compatibility with wireless.

There has been some research on SAW pressure sensor design and fabrication [6]. However, the fabricated sensor is based on $LiNbO_3$ and has two-layer chamber structure. Since $LiNbO_3$ is temperature dependant, the pressure sensor is unstable without proper temperature compensation. The two-layer structure also makes it unsuitable for flow sensor application.

ST-X cut quartz is selected for flow sensor due to its excellent temperature stability. Plate structure is used for fabrication simplicity.

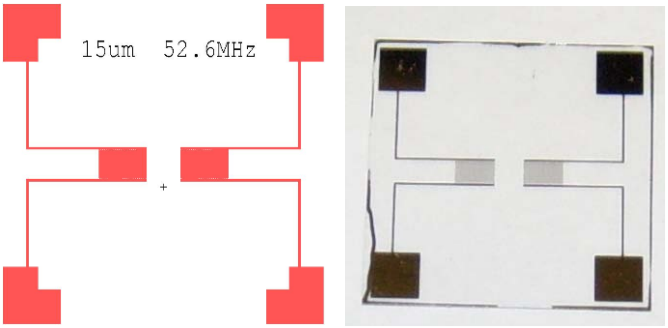
II. DEVICE DESIGN AND ANALYSIS

A. Sensor Design

Traditional two port SAW sensor structure is used in this study. As shown in Fig. 2, the excitation inter-digital-transducer (IDT) generate SAW under alternate current, the wave travels along the surface of the substrate and intercepted by the receiving IDTs. Under normal pressure, the substrate will bend and elongate. The elongation of the substrate will cause the increase of the wave travel time. The travel time change can be measured using network analyzer, and the travel time change will be further interpreted into phase change. So phase change will be shown for different normal pressure, i.e. different flow rate.



(a) (b)

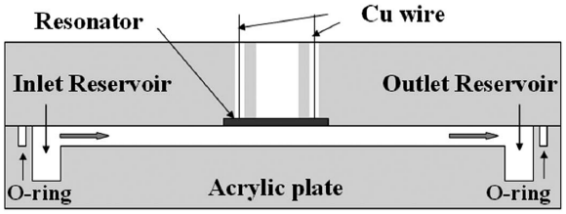
Fig. 4. Designed and fabricated Sensor top view

To determine the location of the IDTs and space between the input and output IDTs, it's necessary to simulate the deformation under pressure by finite element method (FEM). Ansys® is used to simulate the response of the substrate. As shown in Fig. 3, the plate will bend under pressure.

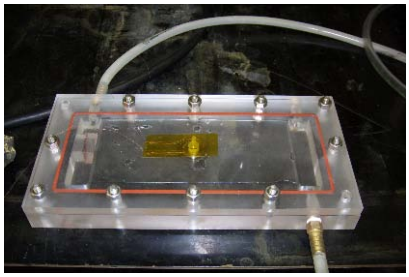
Since SAW signal will damp significantly in water and other liquids, it's natural that IDTs are located on the back of the substrate, thus SAW can propagate on the back of substrate. As shown in Fig. 3(a), along the symmetrical line of the substrate, the area close to the clamped end will be subject to compression and the area on the center will be subject to tension. The IDTs are finally selected in the manner that they will have minimal deformation under pressure and the SAW propagation path is entirely located on tension area. The designed sensor has 70 pair of input and output IDTs and 3mm apart. The resonant frequency is calculated as 52.63MHz assuming SAW velocity on ST-X cut quartz is 3158m/s. The substrate under pressure is 2cm by 2cm. Fig. 4(a) shows the sensor design over view.

B. Sensor Fabrication

A 50nm thick Cr layer was deposited on the Quartz wafer. Then a 150nm thick Au layer was sputtered on top of Cr layer. After that a 3um thick AZ4210 was coated on Au surface by spin-coating at 3000rpm for 30 seconds. After patterning, the Au and Cr on IDT area were kept and others were removed by Au etchant and Cr etchant. The remaining photoresist is then removed by acetone. Finally the wafer is cleaned using IPA and DI water and then dehydrated for 30min at 120℃. Silver paste is used to connect the IDT electrodes to the measurement instrument. Fig. 4(b) shows the fabricated sensors.



(a)



(b)

Fig. 5. Designed and completed test setup.

C. Test Setup

A rectangular flow chamber is designed with dimension of 165.10 mm × 69.85 mm × 0.51 mm (L × W × H) and is composed of 2 parallel acrylic plates. The schematic view of the chamber, which includes a rectangular flow channel and an inlet and outlet reservoir, a sensor mounting port, and an inlet port and an outlet port, is shown as Fig. 5(a). Fig. 5(b) shows the completed setup.

III. EXPERIMENT RESULT AND DISCUSSION

The SAW flow sensor is tested under different flow rates from 0ml/min up to 3500ml/min, which corresponds to normal pressure of 0Pa up to 60kPa. Using the group delay measurement function from network analyzer, the delay time and the corresponding resonant frequency of the sensor can be recorded simultaneously. When the flow rate increases from stagnant, the delay time changes accordingly. This increase of delay time is then converted into phase change after dividing by the period of the SAW. From this aspect, the phase change is linearly dependant on delay time change.

From Fig. 6, it can be seen that the phase change of the sensor is linearly depending on the fluid flow rate at 1Deg/11.8ml/min, while the resonant frequency does not show obvious change along flow rate change, probably because the choice of IDT locations minimize the deformation of IDTs.

IV. CONCLUSION

SAW flow sensor was built on ST-X cut quartz substrate. FEM simulation was done to determine the deformation of the crystal plate under flow pressure and guide the fabrication of the IDTs. Test results show linear relationship between the flow rate and delay time change, i.e. phase change.

***Abstract*— The work reported here shows a direct experimental comparison of the sensitivities of AlN solidly mounted resonators (SMR)-based biosensors fabricated with standard metal electrodes and with carbon nanotube electrodes. SMRs resonating at frequencies around 1.75 GHz have been fabricated, some devices using a thin film of multi-wall carbon nanotubes (CNTs) as the top electrode material and some identical devices using a chromium/gold electrode. Protein solutions with different concentrations were loaded on the top of the resonators and their responses to mass-load from physically adsorbed coatings were investigated. Results show that resonators using CNTs as the top electrode material exhibited higher frequency change for a given load due to the higher active surface area of a thin film of interconnecting CNTs compared to that of a metal thin film electrode and hence exhibited greater mass loading sensitivity. It is therefore concluded that the use of CNT electrodes on resonators for their use as gravimetric biosensors is viable and worthwhile.**

I. INTRODUCTION

Gravimetric sensing is a well known technique utilised to detect the variation in a measurable parameter as a function of the deposited mass on an active sensing area [1-3]. Quartz crystal microbalances (QCM) resonating in the range of 5-20 MHz are one of the earliest, most successful examples of gravimetric sensors. Historically, the emergence of the Quartz crystal as a microbalance can be traced back to Sauerbrey, who realised that a resonating quartz crystal could be used for the microgravimetric measurement of sputtered thin films [4]. A few years later, King chemically sensitised a QCM to make selective chemical mass measurements of 10^{-9}g [5]. Since then, there has been an increased interest in developing gravimetric sensors with higher sensitivities for their use as biosensors. Mass loading sensitivity is proportional to the square of the operating frequency [4]; hence the emergence of bulk acoustic wave resonator (BAW) technology, a nanoscale version QCM with an operating frequency in the range of a few GHz, offered great potential to improve the sensitivity and detection limitation of gravimetric sensors. BAW resonators offer the additional advantage of lower fabrication cost due to the employment of microfabrication technologies and small dimensions, which makes them suitable for the fabrication of array of sensors for parallel or multi detection.

However, higher frequency and smaller dimensions cause all environmental and boundary conditions to affect the operation of the BAW resonators more strongly than the QCMs, resulting in a higher noise level and lower quality factors. It is for this reason that up to now, mass sensitivity of BAW resonators is not significantly better than that of QCMs [6-8].

Work has been carried out in the last few years towards the improvement of the structural and electrical properties of piezoelectric thin films for their use as the active material in these devices [9-12], with the aim of improving the electrical response of the resonators through the achievement of materials with improved piezoelectric properties. Recently, it has also been understood that the electrode material also plays an important role in the resonator's electrical response [13-16]. Electrodes not only affect the growth of the piezoelectric thin film but also provide the shape of the resonant area and, if designed properly, can confine the acoustic energy between the facets of the resonator thereby minimising losses and maximising electro-mechanical transduction (hence *Q*). Ideally, the electrode material should have low mass (in order to minimise mass-loading effects) but high acoustic impedance (in order to confine the acoustic waves within the piezoelectric layer) and high conductivity (in order to minimising the series resistance in the transmission of the excitation signal). Aluminium (Al), molybdenum (Mo)

The work reported here was supported by the EPSRC, grants number EP/F063865/1, EP/F06294X/1, EP/F062966/1 and EP/E023614/1. Iborra, Clemet and Olivares acknowledge financial support from the Ministerio de Ciencia e Innovación of Spain through project MAT2010-18933, and from the European Union through the European Regional Development Fund (FEDER).

tungsten (W), gold (Au) and platinum (Pt) are the most common metals utilised as the electrode materials. However the low acoustic impedance of Al and high weight of Mo, W, Au and Pt make them less ideal for their use as the electrode materials.

Carbon nanotubes (CNTs) have been shown to be an excellent material choice for BAW resonators [15-16]. They possess low densities in the range of 1-2 g·cm^{-3}, electrical conductivities of up to 10^6 S·m^{-1} and exceptionally high elastic moduli (hence high acoustic impedance), usually higher than 1 TPa [17]. Fig. 1 shows a comparison of densities and acoustic impedances of some of the commonly used metals for electrodes, and highlights that CNTs posses the highest acoustic impedance and lowest density allowing simultaneously low mass electrodes with high acoustic impedance and low series resistance.

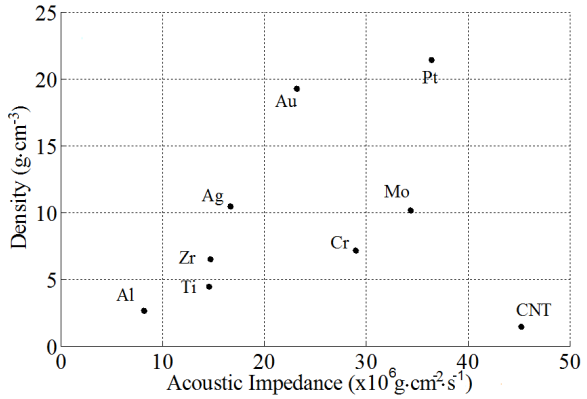

Figure 1. Density and acoustic impedance of commonly used electrode metals

Biosensors with CNT electrodes will offer an additional benefit compared to those with metal electrodes as it is possible to post-growth functionalise them for direct bonding to targeted molecules, thereby preventing non-specific binding or the need of additional bonding layers. Hence the potential exists to use chemically modified CNTs which would double both as the electrode and the sensing layer. Recent advances in chemical functionalisation of CNTs in sensing systems have been reported in [18-23]. Furthermore, the surface area of a thin film of interconnecting CNTs is significantly higher than the surface area of a metal thin film electrode; hence the binding area is increased without physically increasing the size of the devices. Consequently, for the same concentration of biological samples, a greater number of targeted molecules can be bound onto the resonator's surface compared to devices with metal electrodes, and hence devices with higher sensitivity can be realised.

The work reported here shows a direct experimental comparison of the sensitivity of AlN SMRs biosensors with standard metal electrodes and with CNT electrodes. SMRs resonating at frequencies around 1.75 GHz have been fabricated, some devices using a thin film of multi-wall CNTs as the top electrode material, and some identical devices using a top chromium/gold electrode. The CNTs were directly grown on the AlN film from an iron seed layer at 650°C in a NH_3 and C_2H_2 atmosphere, and possess very low density (<2 g cm^{-3}), high electrical conductivities (>10^5 S/m), and exhibited excellent definition and adhesion to the surface. Bovine Serum Albumin (BSA) solutions with different concentrations were loaded on the top of the resonators and their responses to mass-load from physically adsorbed protein coatings were investigated.

II. Experimental Methods

A. AlN SMR fabrication

SMRs were fabricated by growing Ir/AlN/CNT stacks on top of acoustic mirrors centred at a frequency of around 2 GHz and formed by five alternating low and high acoustic impedance layers of porous SiO_2, with an acoustic impedance of 9.5×10^6 kg·m^{-2}·s^{-1} [24], and Ir, with an acoustic impedance of 138.0×10^6 kg·m^{-2}·s^{-1} [25]. A seed layer of Ti/Mo (15-20 nm thick) was used to improve the adhesion and crystal quality of the Ir bottom electrode to the acoustic reflector. Ir slugs (99.98% pure) were electron-beam evaporated at a base pressure of less than 1×10^{-6} Torr to form bottom electrodes 120 nm thick. The AlN piezoelectric films were then reactively sputtered from a 150 mm in diameter Al target in a Leybold Z-550 sputtering system. Before AlN deposition, a 60 s soft-etch in an Ar discharge was performed to condition the Ir bottom electrode. AlN films were sputtered with a 3:7 Ar/N_2 admixture at a total pressure of 1.2 mTorr, a pulsed DC power level of 1.2 kW, and a substrate temperature of 400º C. An RF bias was applied to the substrates to tune the stress in the AlN films and to improve their crystal structure and orientation. These conditions yielded a deposition rate of 40 nm·min^{-1}. The thickness of the AlN layer was set to 1550 nm.

The crystal structure of the AlN and Ir films was assessed by X-ray diffraction (XRD) through the measurement of the θ/2θ patterns and the rocking-curves (RC) around the most intense reflections, i.e. the AlN 00·2 at 18.02º (θ) and the Ir (111) at 20.35º (θ). The surface of the different layers was inspected by atomic force microscopy (AFM), which provided the measurement of the surface roughness. Additional information on the polar orientation was obtained by wet chemical etching of the AlN layers.

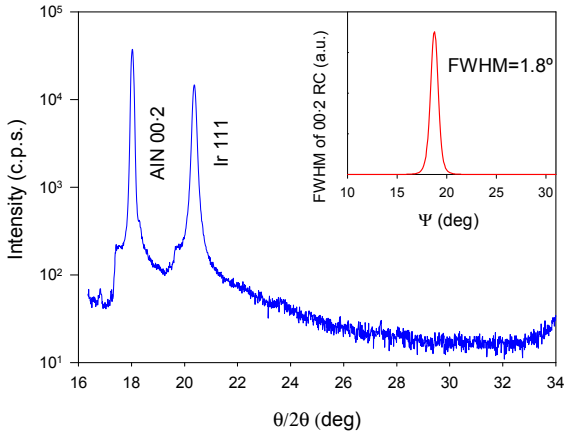

Figure 2. XRD patterns of AlN on Ir. The inset show the rocking curve (RC) of the 00·2 AlN peak.

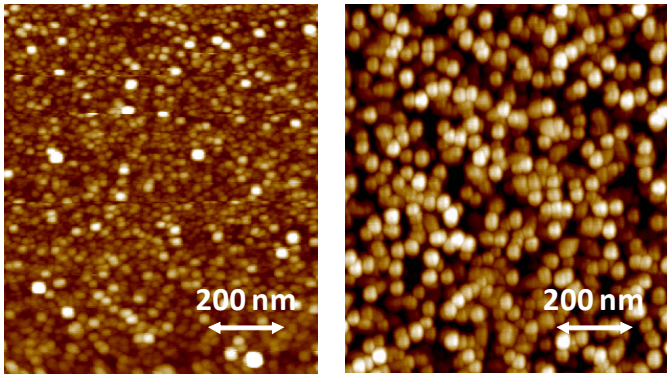
XRD characterisation showed that highly *c*-axis-oriented AlN films were successfully grown on (111)-oriented Ir layers, provided these surfaces were etched with Ar+ ions immediately before AlN deposition (see Fig. 2). The pre-treatment of the Ir surface was essential to avoid the growth of tilted microcrystals related to the degradation of the piezoelectric response; AlN films with pure 00·2 orientation and RC ranging from 1.8º to 3º, almost independent of the texture and roughness of the Ir bottom electrode, were obtained. No degradation of the piezoelectric quality of AlN films with the texture was observed in the mentioned range.

Fig. 3 shows atomic force microscopy (AFM) images of the surface of Ir electrode (before AlN deposition) and AlN films. The roughness of the Ir electrode is around 4 nm and that of AlN films is around 7 nm. The structure of the AlN surface indicates a *c*-axis orientation of the microcrystals with a basal plane diameter of around 50 nm.



(a) (b)

Figure 3. AFM images of the surfaces of : (a) Ir bottom electrode before AlN deposition and (b) AlN film.

After AlN deposition, vias were formed through the AlN for electrical connection to the bottom electrode by wet etching the AlN in a warm (40°C) KOH solution through a Mo mask. The top electrode was then patterned with a lift-off photolithography process. At this point, a 10 nm of Cr layer followed by a 90 nm of Au layer was evaporated on one set of devices. A 7 nm of Fe layer, which acts as a catalyst layer for the CNTs growth, was evaporated on another set of devices. The CNTs were directly grown on the second set of the devices, as explained in the following section.

Fig. 4 shows the top view of one of the devices fabricated with top CNTs electrode. It can be seen that the definition of the electrodes is excellent.

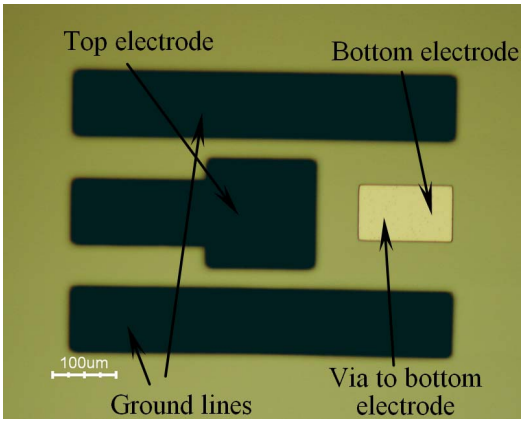


Figure 4. Image of a fabricated SMR with CNT top electrode

B. *CNT growth and characterisation*

CNT growth was carried out by thermal CVD. The substrate was loaded into the chamber and heated up to 650 °C at a rate of 4°C/min. Ammonia (NH_3) was introduced into the chamber to raise the pressure up to 5 mbar. It also helped to maintain the catalyst metal surface activity by reacting with the amorphous carbon. The system was maintained for several minutes so as to break the catalyst layer into nanoislands, after which acetylene (C_2H_2) was introduced into the chamber to commence the growth. C_2H_2 is the source of carbon necessary for CNT growth, and was introduced into the chamber through a large, flat, stainless steel plate 'showerhead' configuration, which ensures a uniform flow of gas over the whole area of growth. Once the growth is finished, the gases were evacuated and the system was left to cool down. This type of growth produces a forest of interconnecting nanotubes that should possess optimal electromechanical properties [17]. However if no particular care is taken, CVD generally produces CNTs with numerous defects. A high density of defects are favoured when the growth occurs at low temperatures, dopants such as N_2 or B are present or a residual growth process continues when the power is shutdown, but the gases are not turned off.

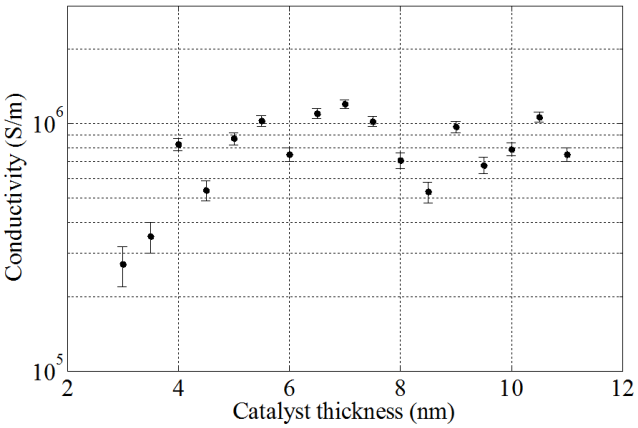

Figure 5. Conductivity of the CNTs layer *vs*. catalyst layer thickness for growth temperature of 750 ºC

The gas ratio C_2H_2 / NH_3 and growth temperature were optimised so as to avoid the presence of amorphous carbon, which would decrease significantly the conductivity. The catalyst layer thickness was varied in order to clarify its effect on the conductivity of the CNT layer. It was found that the conductivity increases with the catalyst thickness up to ~5nm, and become less thickness dependent afterwards as shown in Fig. 5.

The growth temperature was also changed in order to maximise the conductivity. A higher growth temperature produces CNT layers with a higher conductivity, as shown in Fig. 6, due to lower number of defects. However when growing the CNTs on top of an acoustic mirror, the Ir layers on the reflector stack delaminate, damaging a large number of devices. For this reason, when the growth temperature is 750 ºC, the yield is only around ~10%. Lowering the growth temperature to 650 ºC decreases slightly the conductivity but increases the yield to around ~20%. Growth does not occur at temperatures below ~600 ºC under these experimental conditions.

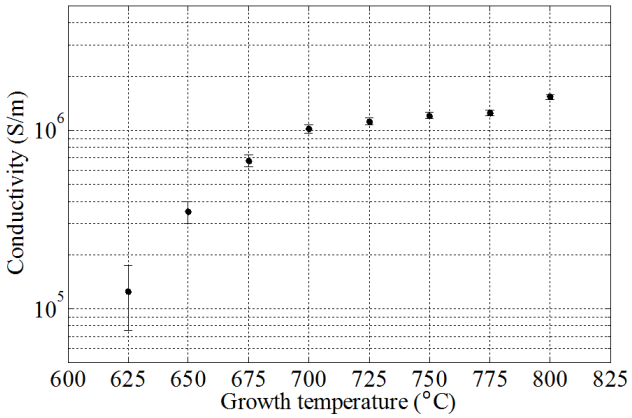

Figure 6. Conductivity of the CNTs layer vs. growth temperature

In this work CNTs were grown at 650 ºC with a catalyst thickness of 7 nm. CNT layers obtained possess an electrical conductivity of ~3.5×10^5 S/m.

III. FBAR Electrical Characterisation

Electrical characterisation of the SMR devices was carried out using an Agilent E5061B network analyser. An automation measurement routine was written with LabView to continuously monitor and record the resonance spectrum of the SMRs. Devices resonating at around 1.75 GHz, with resonance spectra that were free from significant spurious modes, were achieved and a typical response of the devices with CNT electrodes is shown in Fig. 7. It was also found that the resonant frequency of the devices covered with CNT electrodes is slightly higher due to the lower mass of the CNT electrodes compared to the Cr/Au electrodes.

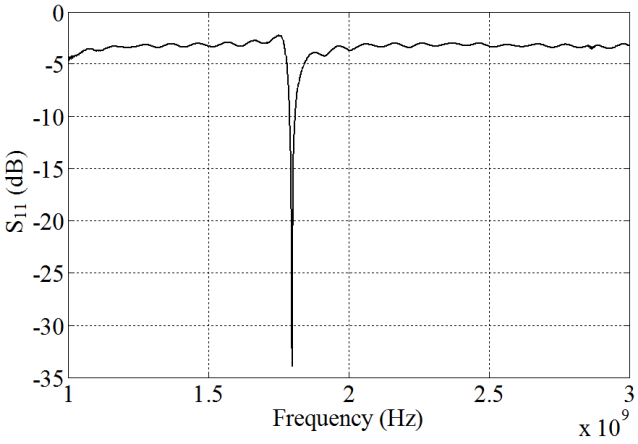

Figure 7. Typical frequency response of fabricated devices with CNT top electrode, showing the main resonance at f_0 ~ 1.75 GHz.

The quality factor of the resonance peak was calculated using the 3-dB method [26] from the equation:

$$Q_{3dB} = \frac{f_r}{|f_2 - f_1|} \tag{3}$$

where f_r is the resonant frequency taken from the S-parameter and f_1 and f_2 are the frequencies at which the insertion/return loss are +3 dB compared to the insertion/return loss at f_r.

Q was found to be higher than 2000 for the devices with CNT electrodes and around 1000 for the devices with metal electrodes. Generally devices with higher Q exhibit sharper resonance peaks that allow tracking a smaller frequency shift. Therefore, CNT electrode BAW resonators have the potential to measure smaller frequency shifts, increasing the sensitivity compared to the metal electrode devices.

IV. Preparation of Bio Targets on Devices and Biosensing Results

The resonant frequency of unloaded resonators was tracked over 30 min and was found to be stable with changes of less than 2 kHz. Bovine Serum Albumin (BSA) solutions with different concentrations (62.5, 125, 250, 500 and 1000 µg/ml) were then placed on the top of different sets of identical SMRs both with metals and CNT electrodes, and allowed them to physically adsorb onto the SMRs' surface for 15 min, after which they were rinsed by buffer and dried with N_2. Measurements were subsequently carried out on loaded devices when they are completely dried to monitor the frequency shift (compared to unloaded devices), and results are shown in Fig. 8 as a function of BSA concentration. The frequency shift was of the order of hundreds of kHz, and has a distinct linear relation with the solution concentration over the range measured. The absolute frequency changes observed on the SMRs with CNT electrodes are significantly greater than

those with metal electrodes, demonstrating its high performance and great potential for use.

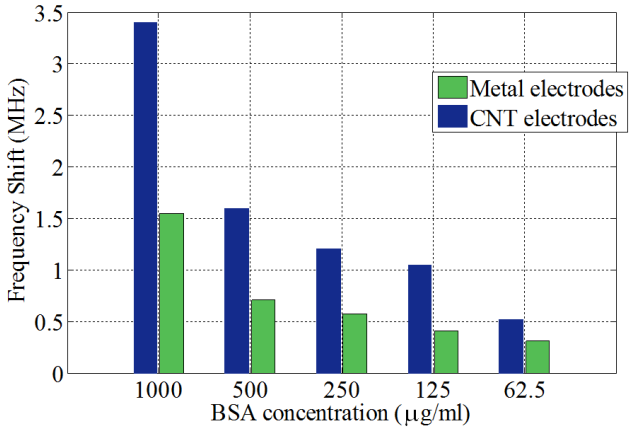

Figure 8. Frequency shift observed as a function of protein concentrations

V. CONCLUSIONS

BAW resonators with CNT electrodes have been shown to have many advantages for the development of acoustic wave based biosensors. AlN SMRs with a top CNT electrode resonating at around 1.75 GHz were microfabricated and exhibited a significantly large unloaded quality factor Q>2000, much greater than the identical devices fabricated with metal electrodes, which is a direct consequence of the low density and high acoustic impedance of the CNT electrodes. Devices with higher *Q* possess higher sensitivity due to sharper resonance peaks which facilitates tracking smaller frequency shifts. Furthermore, protein solutions with different concentrations were loaded on the top of the resonators and their responses to mass-load from physically adsorbed coatings were investigated. It was found that resonators using CNTs as the electrode material exhibited higher frequency change for a given load due to the higher surface area of a thin film of interconnecting CNTs compared to that of a metal thin film electrode.

***Abstract*—Microelectronic technologies developed over the past decade to replace quartz crystal resonators (XTALs) and oscillators (XOs) are discussed. A new figure-of-merit (FOM) is proposed to compare these emerging technologies. It is shown that CMOS oscillators (COs) have been an underestimated technology amidst these efforts as the performance of COs is comparable to existing and emerging technologies and continues to scale. Motivations and concepts behind COs are presented along with native and package-induced frequency drift mechanisms. Design and packaging approaches that minimize drift are demonstrated. A brief history of CO product embodiments is presented. State-of-art CO performance is reported where better than ±25ppm frequency drift is achieved over 0 to 70°C and less than 950fs$_{RMS}$ phase jitter integrated from 12kHz to 20MHz is realized.**

I. Introduction

Quartz crystal resonators (XTALs) and oscillators (XOs) serve as the de facto frequency reference in nearly all electronic platforms. Yet quartz cannot be integrated into microelectronic form. Achieving that goal would likely enable frequency control devices with a smaller form-factor, lower cost, greater flexibility, higher reliability and a myriad of unforeseen potential benefits. Consequently, efforts to replace quartz with such a technology date back to the 1960's. In 1967, a transistor was presented with a mechanically resonant gate [1]. Similarly, the frequency stability of solid-state oscillators, such as that in [2], was also explored. Those efforts were limited as the net performance of frequency control devices based on these technologies was inferior to that which could be achieved with quartz.

In 1980, silicon was presented as a viable mechanical material [3]. Since then, and particularly in the 1990's to the present, several researchers have aimed to develop technologies leveraging silicon microelectromechanical systems (MEMS) to replace quartz. In [4], one of the first MEMS oscillators (MOs) was presented. These results spawned a variety of academic and commercial efforts in the field. However, as these efforts captured the limelight, radio frequency (RF) CMOS became mainstream [5]. With this development, the possibility of high-performance, self-referenced, *LC* CMOS oscillators (COs) became a reality. As opposed to XOs and MOs, COs are electrically resonant and entirely solid-state. In this manuscript, a brief history of the development of this technology will be presented up to the state-of-the-art. It will be shown that COs now achieve performance that rivals both MEMS and quartz technology on several dimensions.

II. Performance Benchmarking and a Proposed FOM

MEMS resonators can be fabricated in a batch silicon process and typically exhibit a high quality (Q) factor, which is what makes the technology interesting for frequency control [4]. In [6] and [7], efforts to benchmark the performance of XO, MOs and COs were presented. Several performance metrics were reported including frequency stability, timing and phase jitter, single sideband (SSB) phase noise power spectral density (PSD) and power dissipation. In that work, it became clear that the native high-Q of MEMS resonators was not realized in the complete device. This is due, predominantly, to the fractional-N phase-locked loop required for frequency-trimming and temperature-compensation of the resonator. Additionally, other work has shown that non-linear transduction of the resonator results in upconversion of flicker noise in MOs [8]. Nevertheless, the native high-Q of MEMS resonators continues to be cited as a critical performance metric despite the fact that frequency control devices referenced to MEMS resonators do not exhibit performance consistent with high-Q.

Addressing these efforts to benchmark different technologies while avoiding use of less relevant metrics, the authors propose a figure-of-merit (FOM) to capture the multi-dimensional nature and aggregate performance of frequency control devices. The radar plot in Fig. 1, adapted from that in [9], illustrates the concept that the best-performing frequency con-

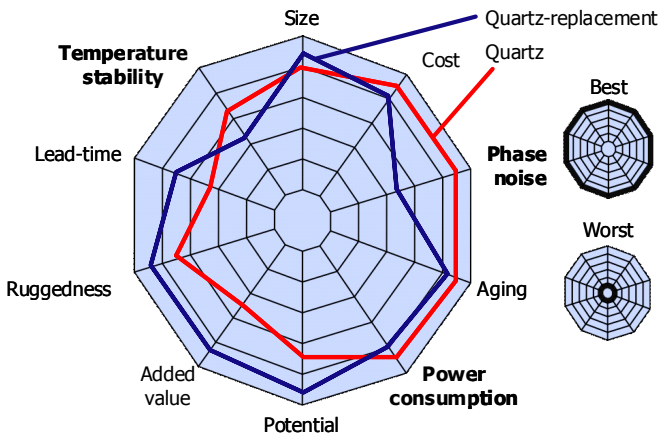

Figure 1. Radar plot illustrating the performance dimensions of a complete frequency control device. Dimensions in bold are considered significant and technology-dependent. The figure is adapted from [9].

trol device achieves high-performance across all dimensions simultaneously. As shown, XOs typically achieve high-stability, low-noise and low-power. Emerging technologies for quartz replacement are generally inferior along these dimensions, but performance continues to scale and these technologies are positioned to offer benefits over quartz including smaller size and shorter lead-times.

In this work, the authors consider the three most significant and technology-dependent performance metrics: frequency stability, phase jitter (integrated from 12kHz to 20MHz) and power dissipation. The goal is to define a measure that is frequency and technology-independent while capturing trade-offs in the embodiment of the device. To begin with, frequency stability is frequency-independent by definition. Similarly, phase jitter over the bandwidth presented is approximately frequency-independent. In emerging technologies, high frequency stability is often achieved through active temperature-compensation due to the fact that the native temperature coefficient of frequency (TC_f) of the reference resonator is high, particularly compared to quartz. Consequently, power is often a penalty in achieving high stability.

Considering these factors, the proposed FOM is computed by plotting the value of each metric along mutually-orthogonal axes and solving for the volume (V_{FOM}) of the irregular tetrahedron defined by these points. The volume is then normalized to 1ppm-ps_{RMS}-mW and taken in dB. Thus, lower FOM indicates better performance. Such an approach equally-weights all three metrics. Fig. 2(a) illustrates ideal performance, which is a single point at 0ppm-ps_{RMS}-mW. COs have traditionally demonstrated performance similar to that in Fig. 2(b) where low-power is achieved, but with poor stability and phase jitter. Fig. 2(c) illustrates the opposite case where high-stability and low-noise are achieved through increased power.

The proposed FOM is particularly useful in benchmarking various technologies. Table I presents the performance of a TCXO, XO and several generations of MOs and COs. Consistent with Fig. 1, the FOM shows that the TCXO and XO achieve performance superior to the emerging technologies. Further, it is interesting to note that the performance of several MOs and COs are comparable. One of the MOs achieves stability and phase jitter that is comparable to the TCXO, but at the expense of power, which is captured by the FOM.

III. CMOS Oscillator Technology

A. Motivations and Concepts

A high-accuracy, low-noise and low-power CO would enable frequency control devices to be migrated to a standard and batch silicon manufacturing process with nearly infinite capacity. This would enable the lowest possible cost structure while introducing the possibility of complete microelectronic integration of the frequency source. However, CMOS technology does not include high-Q components. For example, and despite the advent of RF-CMOS, the Q-factor of an integrated inductor is in the range of 10-20. However, CMOS technology supports the design of high-frequency oscillators. Thus, the Q-frequency (Q-f) product in COs is high. Consequently, COs can achieve low-noise, despite the low-Q of the resonator compared to MOs and XOs [10]. The remaining challenge involves minimizing frequency drift and achieving high frequency stability.

B. Native Frequency Drift Mechanisms

Native frequency drift mechanisms in COs have been presented and discussed in [10]. The natural resonant frequency of an LCO is $\omega_o = \sqrt{1/(LC)}$ where L is the net tank inductance and C is the net tank capacitance. Due to resistive losses in both the inductor and capacitor, the actual resonant is given by,

$$\omega_1 = \omega_o \sqrt{\frac{CR_L^2 - L}{CR_C^2 - L}}, \quad (1)$$

Table I. Benchmarking the performance of various frequency control devices based on different technologies

Metric	TCXO (TCF4)	XO (SG-210)	MEMS (SiT8002)	MEMS (SiT5002)	MEMS (DSC1121)	CMOS (Si500)	CMOS (IDT3CP02)	CMOS (IDT3LV04)
Stability (ppm)	2	50	50	2.5	10	150	100	50
Phase jitter (ps_{RMS})	0.25	0.25	250	0.6	1.7	2	2	1
Power (mW)	3.6	3	73	58	50	25.2	3.6	10.8
FOM (dB)	**2.6**	**15.6**	**59.6**	**19.4**	**29.3**	**38.8**	**28.6**	**27.3**

where R_L and R_C are the losses in the coil and the capacitor respectively. Typically, R_L is significantly larger than R_C. Consequently, (1) can be simplified to,

$$\omega_1(T) \approx \omega_o \sqrt{1 - CR_L^2(T)/L}, \quad (2)$$

where it is clear that the native TC_f is negative and concave-down.

In [10], additional drift mechanisms were presented and include harmonic work imbalance and the TC_f of both the fixed capacitance and the variable capacitance presented by the transistors in the sustaining amplifier. A closed-form solution for drift arising from HWI was presented in [10] and is dependent on the spectral content of the current delivered to the tank by the sustaining amplifier. These additional drift mechanisms are small compared to the drift induce by loss in the tank. However, these mechanisms can introduce non-linearity in the temperature-compensated response of the CO.

C. Design Approaches

In [10], an orthogonal frequency-trimming and temperature-compensation approach was presented. Referring to Fig. 3, an array of switched thin-film capacitors, C_f[X:0], serves to trim the nominal frequency against process variation. Temperature-compensation is achieved with an active approach. Here, either the power-supply or a temperature-dependent voltage, $v_{ctrl}(T)$, is applied to a switched array of varactors, C_v[Y:0]. When the varactor is biased to the power supply, it does not vary whereas when switched $v_{ctrl}(T)$, the TC_f is compensated. The number of active varactors sets the amount of compensation.

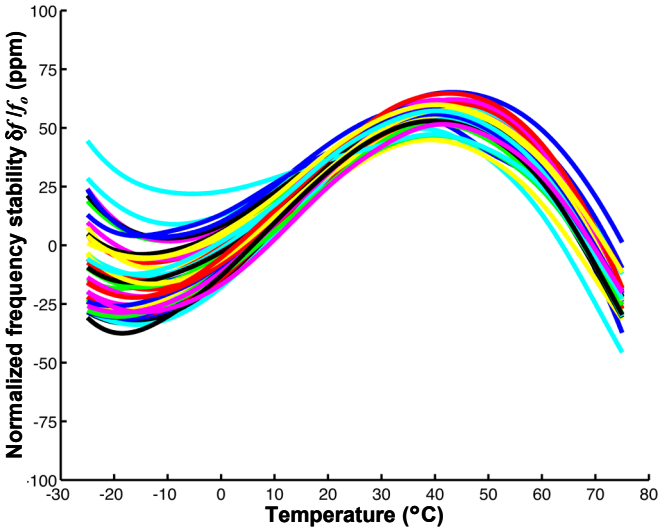

Figure 4. Measured absolute frequency stability of 40 randomly selected COs from production test. No device exceeds ±75ppm error from -20 to 70°C.

Referring to (1), it is clear that if a loss, R_C, is deliberately introduced to the tank capacitance, C, the drift due to the loss in the coil, R_L, can be cancelled. This observation led to the development of the passive compensation approach in [11], which is illustrated in Fig. 3. This approach has enabled COs to achieve total frequency stability under ±100ppm over -20 to 70°C, all operating conditions and lifetime while dissipating less than 4mW. Fig. 4 presents the TC_f of 40 devices which were selected randomly from the production test flow. No device exceeds ±75ppm frequency error against temperature.

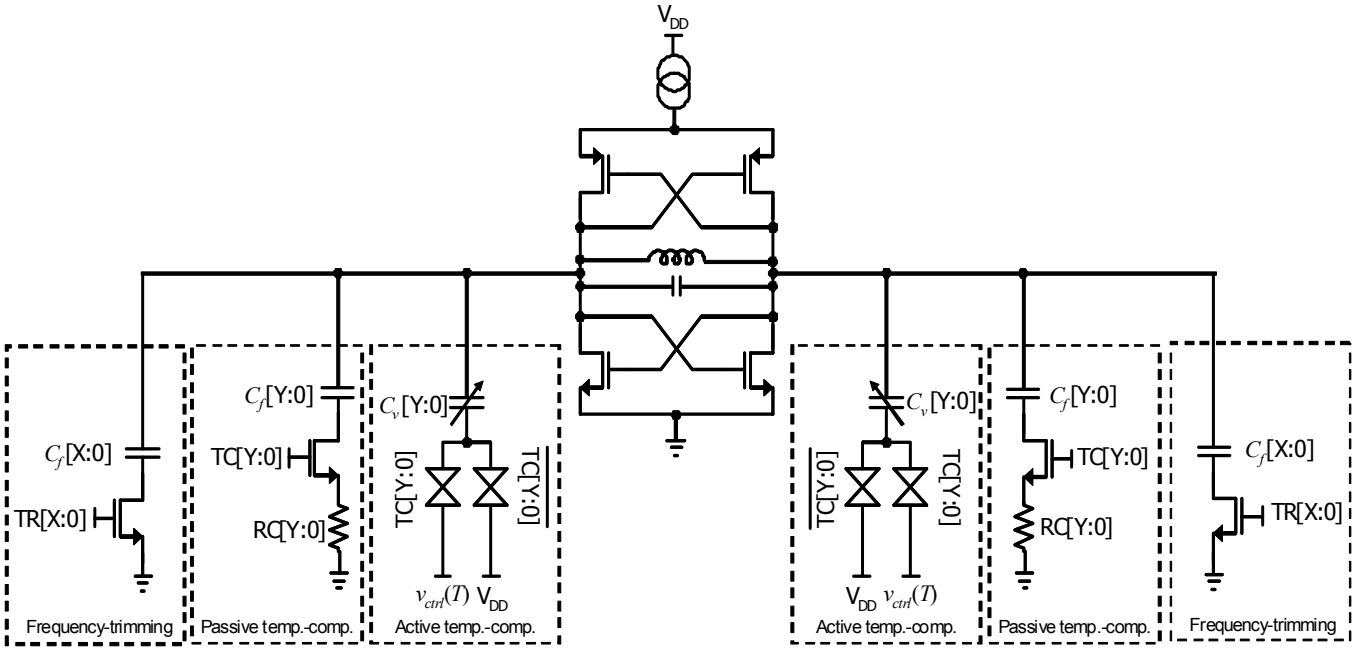

Figure 3. Simplified schematic illustrating frequency-trimming and active and passive approaches to temperature-compensation of the CO.

D. Package-Induced Frequency Drift

The work in [10] and [11], among other work, presented different design approaches to contain the native frequency drift of the CO. However, in [11], it was shown that fringing electromagnetic fields emanating from the die can be perturbed by the surrounding package or environment and induce frequency drift. Referring to Fig. 5(a), the *B*-field that radiates from the coil can extend beyond the boundary of the package. Consequently, if the field is modulated by a permeable material or terminated with a metal, the frequency will drift. Similarly, a parasitic capacitance is created by the stray *E*-field from the device. Any changes in the permittivity of the molding compound of the package can induce frequency drift. Left uncontained, each mechanism can induce frequency drift exceeding hundreds of ppm.

A post-processed wafer-scale Faraday shield was developed in [11] to contain these package-induced frequency drift mechanisms. Fig. 5(b) illustrates the latest rendition of this shield. A thick dielectric mesa is photo-patterned on top of the die, excluding the bond pad windows. Next, metal is electroplated over the mesa. The metal is patterned such that it encapsulates the mesa and contacts the over-glass layer of the die which creates a hermetic seal. Additionally, the backside of the die is metallized. Metal thicknesses are selected to contain the known strength of the fields. As illustrated in Fig. 5(b), the shield terminates the fringing *B*-field on both sides of the die. Additionally, the hermetically-sealed dielectric material presents a constant permittivity to the fringing *E*-field. This approach enabled the devices in [11] to achieve ±300ppm stability over all operating conditions including a panel of industry-standard stress and reliability tests. This latest generation of the Faraday shield, pictured in Fig. 6, enables COs to achieve ±100ppm frequency stability over the same tests.

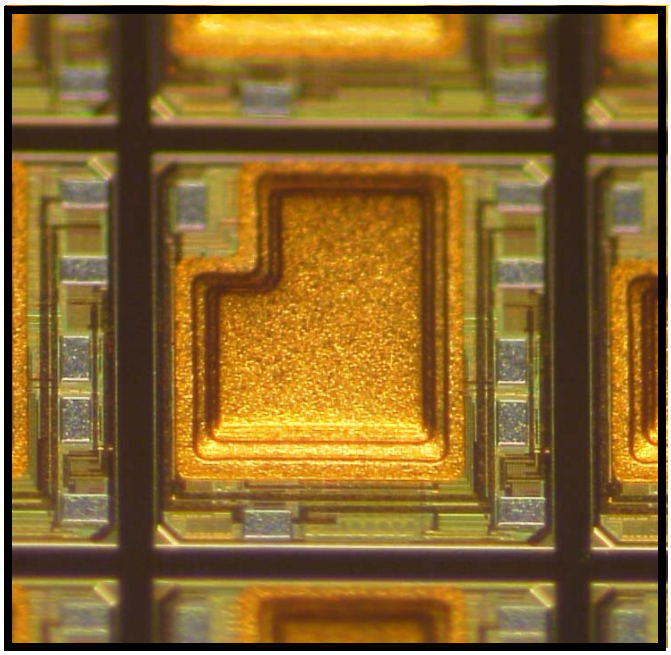

Figure 6. Micrograph of the post-processed Faraday shield at the wafer-level.

IV. Commercialization of CMOS Oscillators

A. Hard Intellectual Property Macro

In [10], a hard intellectual property (IP) macro of a CO was presented. The macro was embedded in a USB bridge controller and was fabricated in a 0.35µm 2P4M CMOS process. The CO occupied 0.22mm^2, dissipated 31mW and maintained ±400ppm stability from -10 to 85°C. The device was a commercial success where tens of millions of units have shipped in production. However, and as discussed in [11], IP is difficult and expensive to support due to costly re-targeting of the macro to various foundries and technology nodes.

B. A Silicon Die as a Frequency Source

In [11], a silicon die as a frequency source was presented for XTAL resonator replacement and in an effort to address the challenges associated with IP while also demonstrating significant differentiation of COs when compared to MOs and XOs. As described in [11], this device utilized the passive temperature-compensation approach shown in Fig. 3. Further, the ability to deliver the device in unpackaged form was enabled by the development of the Faraday shield presented previously. The device achieved ±300ppm total frequency stability over all operating conditions including industry-standard stress and reliability tests. Further, it dissipated under 4mW while achieving 2ps$_{RMS}$ phase jitter integrated from 12kHz to 20MHz.

This device has achieved the greatest commercial success to date as it is well-suited to wireline applications such as USB, S-ATA and PCIe where stability requirements do not exceed ±300ppm. The die frequency source can be assembled

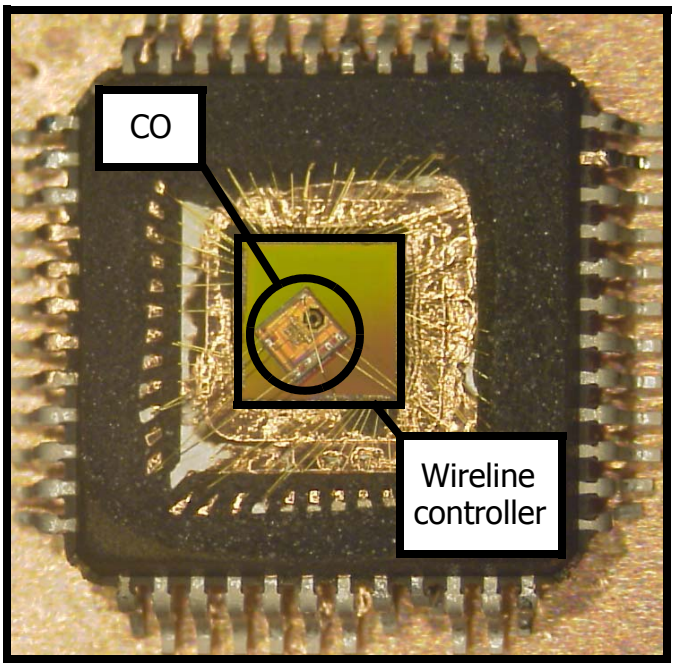

Figure 7. The CO presented in [11] assembled in a 48-pin QFP MCP atop a wireline controller. The MCP eliminates the need for an external XTAL. To the end-user, the device appears to include a hard IP macro. The Faraday shield has been dissolved with the package. The CO die was fabricated in a 1P6M 0.13µm CMOS technology and measures 920µm × 880µm × 250µm.

with a chip-on-board (CoB) process, as shown in [11], or it can be stacked in a multi-chip package (MCP) as shown in Fig. 7. In the latter case, the final assembled device appears as if it contains the hard IP macro in [10]. However, the die frequency source is fabricated in a fixed technology node, thus overcoming the challenges associated with IP development while achieving the same goals of IP integration.

C. Standard Components

Though COs can be integrated as IP and assembled in an MCP or with a CoB process, that does not preclude the device from being assembled as a standard component. COs have been assembled in standard plastic packages that are pin-compatible with XOs and MOs. The frequency stability data shown in Fig. 4 were captured from these standard devices. Historically, these devices have had modest commercial success due to the fact that frequency stability was inferior to that of quartz. However, as Fig. 4 shows, the stability of these devices now rivals XOs. Consequently, commercial traction has increased substantially and is growing exponentially.

D. Reliability

Initial reliability data for COs was presented in [11]. Since then, several enhancements have improved the performance of COs markedly. For example, Fig. 8 shows the measured frequency stability of a population of over 200 COs. It is shown

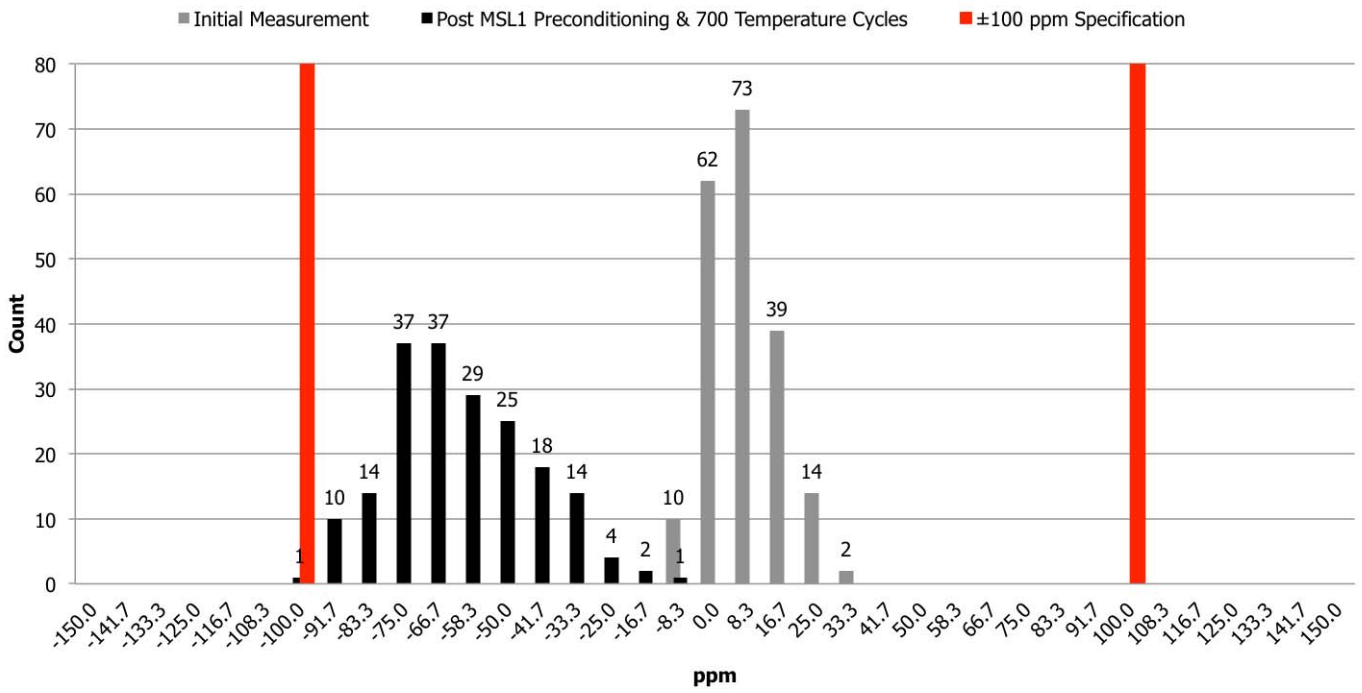

Figure 8. Measured frequency accuracy of COs assembled in standard plastic packages before and after JEDEC MSL1 preconditioning and 700 temperature cycles from -55 to 125°C. All devices maintain ±100ppm frequency stability after stress. The corresponding lifetime is 29 years. Other industry-standard stress tests yield similar results.

that ±100ppm frequency stability is maintained for the entire population after MSL1 pre-conditioning and 700 temperature cycles from -55 to 125°C, which corresponds to a lifetime of 29 years. Other stress and reliability tests yield similar results.

E. State-of-the-Art Performance

The latest generation of COs leverages a frequency-trimming and temperature-compensation approach that is a hybrid of the approaches presented in Fig. 3. Further, a next-generation Faraday shield has also been developed, though it is not shown here. With these advances, state-of-the art performance has improved significantly. In Fig. 9, the temperature-stability of 40 devices selected at random is less than ±25ppm from 0 to 70°C. Further, referring to Fig. 10, the phase jitter integrated from 12kHz to 20MHz is less than $1ps_{RMS}$, which is a significant achievement because this meets the requirement for optical networking.

V. Future Directions and Conclusion

Significant efforts continue in developing frequency control technologies to replace quartz. Given these various technologies, a new FOM was proposed to facilitate benchmarking. As shown, the performance of COs continues to improve to the point that the technology now rivals the performance of XOs and MOs. The temperature-stability of state-of-the art COs is under ±25ppm while phase jitter is less than $1ps_{RMS}$ integrated from 12kHz to 20MHz. Additionally, CO technology has enabled several new embodiments of frequency control devices including IP, singulated die and standard components in plastic packages. Many of these devices have achieved significant commercial success. It is expected that further enhancements to CMOS process technology, new design approaches and new post-process technology will enable CO performance to continue to scale into the future.

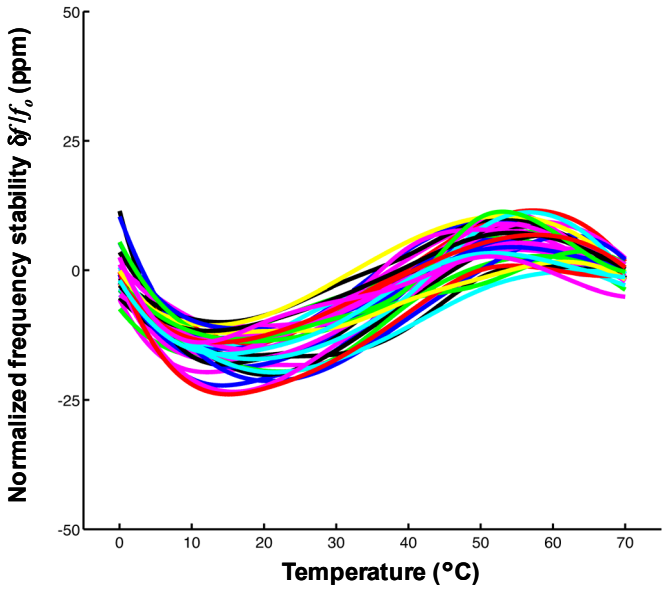

Figure 9. Measured absolute frequency stability of 40 randomly selected next-generation COs against temperature. No device exceeds ±25ppm frequency error from 0 to 70°C.

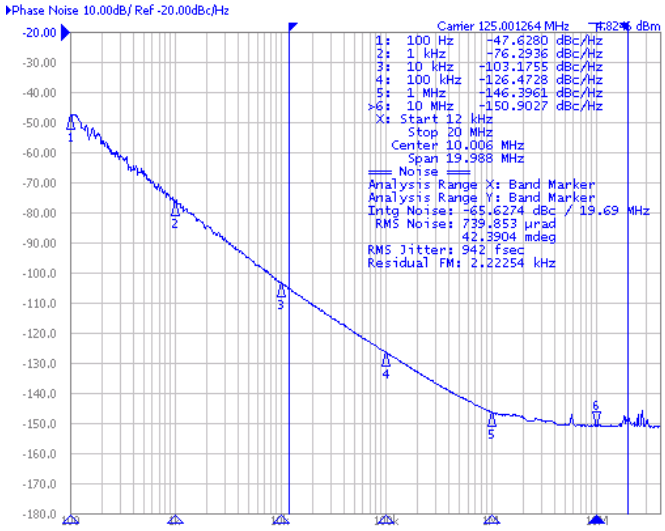

Figure 10. Measured SSB phase noise PSD of the a next-generation CO. Phase jitter, integrated from 12kHz to 20MHz, is $942fs_{RMS}$. The device maintains $<1ps_{RMS}$ phase jitter over the same bandwidth over all process corners.

A Highly Stable CMOS Self-Compensated Oscillator (SCO) Based on an LC Tank Temperature Null Concept

A. Ahmed, B. Hanafi, S. Hosny, N. Sinoussi, A. Hamed, M. Samir, M. Essam, A. El-Kholy, M. Weheiba, A. Helmy
Timing Products Division, Si-Ware Systems, Cairo, Egypt

***Abstract*—A highly stable all silicon Self-Compensated Oscillator (SCO) reference source is presented. Self compensation across temperature is achieved using a newly discovered phenomenon in LC-tanks named the Temperature Null (TNULL) which has been described and briefly analyzed. A quadrature oscillator architecture has been used to implement the SCO in a 0.18μm CMOS technology. The SCO has on-chip infrastructure facilitating low cost trimming and frequency calibration at room temperature. Excellent frequency stability of ±50ppm has been measured across temperature (0 – 70°C), 3.0 – 3.6V supply and 1 – 15pF load. The SCO has a programmable frequency range of 1 – 133MHz, consumes 7.1mA at 25MHz and has an RMS period jitter of 2ps at 125MHz.**

I. INTRODUCTION

The demand for clocks has been continuously fueled by increased consumption of many feature rich consumer gadgets. A clock is generated from a reference frequency source which has to date been dominantly based on a quartz crystal. This industry de-facto of quartz crystals has been rightfully earned through reliable performance of quartz crystal oscillators (XO) in terms of excellent frequency stability across temperature, low power consumption and low noise. Moreover, quartz crystals enjoy very high manufacturing maturity that has been gained over the past decades which has helped sustain a steady, yet slow, decrease in the price of quartz crystal-based products. As new applications emerge, a need for new reference frequencies arise which unfortunately require long lead times of up to 14 weeks to be developed in quartz crystals leading to longer development cycles and slower market deployment. There has been always a need, thus great value, in decreasing the size of any solution through higher levels of integration while adding more features and functionality. The initial trend of decreasing package footprint and thickness has gained acceptance and interest. However, the benefits of having a monolithic CMOS timing solution are unbeatable. Such a solution will benefit from the continuously decreasing price of CMOS technologies that can produce thousands of reference clocks from a single wafer in comparison to hundreds of quartz crystals from a panel. This is directly translated into lower cost and very high volume capability.

The dominant deterring factor in clock selection for very high volume consumer products will be price as long as the required performance is secured. The most important performance metric is frequency stability across temperature, supply, load and aging. A total frequency stability of ±100ppm across a temperature range of 0 – 70°C and -20 – 70°C is considered the critical threshold that gives access to a large percentage of the market with heavy emphasis on very high volume consumer applications. Aggressive price reduction can only be achieved through a quantum reduction in the cost structure of clocks which requires the search for alternative technologies to quartz. The cost of an XO is composed of: Quartz Crystal, CMOS die, Ceramic Package, Assembly and Test. A programmable reference clock based on a silicon micro-electro mechanical system (MEMS) resonator, [1], [2] has merits in lowering the lead time but fails to address higher integration levels. The cost of a MEMS resonator is lower than a quartz one owing to very high number of resonators on a single MEMS wafer yet still requires wafer level packaging to conserve its performance and reliability. Expensive ceramic packaging is also dropped to low cost plastic packaging [3], [4]. However, the assembly cost of a MEMS-based solution requires stacking of the wafer level packaged MEMS die and CMOS die. In addition, the CMOS die in a MEMS-based solution is larger, compared to the die in an XO, thus more expensive. Furthermore elaborate production testing is required to trim each part to the required performance. Overall, the cost benefits of a MEMS-based solution is not evident thus cannot easily compete in the price sensitive lower performance consumer market.

Another alternative technology is an all silicon CMOS reference clock using an on-chip LC-tank. Recently several solutions have been reported [5], [6], [7] and commercialized. Such solutions are by definition highly integrated and have short lead times due to their programmability. Furthermore, the cost structure is very promising since it has been reduced to: CMOS die, low cost plastic package, simple assembly and production testing. The die in this case is still larger than the one found in an XO yet smaller than the die in a MEMS-based solution. It is then obvious that such a solution is conceptually of lowest cost as long as the production test cost is low. This work presents a new all silicon CMOS reference clock that uses an on-chip LC-tank designed to operate at a very specific low temperature-sensitivity phase operating point thus self compensating across temperature. The part is trimmed using a low cost single insertion at room temperature test procedure. Such a solution is promising very low cost and has achieved a total frequency stability of ±50ppm that can address a large

This work was partially sponsored by ITIDA through the ITAC program, PDP project grant.

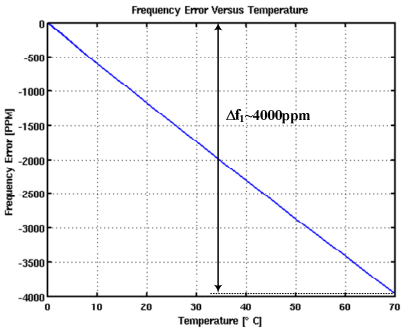

Figure 1. Temperature dependence of an LC-tank resonance frequency.

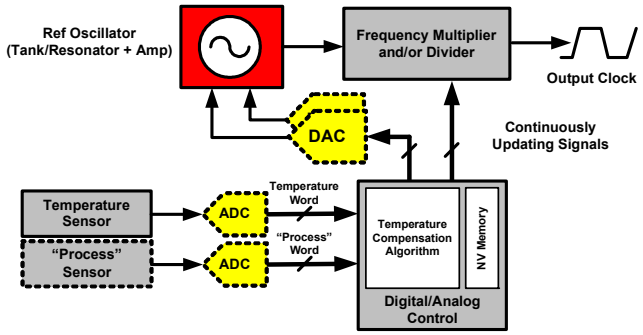

Figure 2. Generic block diagram of open loop temperature compensation.

percentage of high volume consumer applications such as SATA, PCI-E, HDD, LCD TV, printers and many others.

II. Temperature Compensation Techniques

The frequency stability of classical LC-tank based oscillators is highly dependent on temperature and typically may have a temperature coefficient ranging from -50ppm/^{o}C to 100ppm/^{o}C. The main source of temperature dependence comes from the LC-tank and in particular the inductive part. Fig. 1 shows simulation results of the frequency variation of an LC-tank across a 0 – 70^{o}C temperature range of ~4000ppm which is not acceptable as a reference source. This large temperature dependence of LC-tanks has been the main challenge in designing an LC-tank based reference which requires sophisticated compensation techniques to neutralize the frequency variation. There are two main types of compensation techniques; either an open loop technique or a closed loop technique. Closed loop techniques are commonly used in oven-compensated oscillators where the ultimate objective is to tightly control the oscillator temperature by placing it in a temperature controlled oven and in turn stabilizing its frequency. Alternatively, one may opt to design the frequency determining element of the oscillator, the resonator mainly, to be temperature insensitive thus the oscillator becomes self-compensated.

A. Open Loop Compensation

An open loop temperature compensation technique aims to negate the temperature generated frequency shift of the oscillator by imposing a frequency shift in the opposite direction of equal magnitude. To achieve this one can modify the oscillation frequency using one or more frequency tuning controls of the oscillator. Alternatively one can follow the oscillator with a frequency multiplier and control the multiplication factor such that the output frequency is temperature independent. In all cases one must measure the temperature accurately using a suitable sensor and use it to generate the temperature dependent control(s) of the oscillator or frequency multiplier. To successfully achieve the required accuracy in compensation it is imperative not just to have an accurate temperature measurement but to also have precise knowledge of the oscillator frequency across temperature and its frequency tuning control(s). Fig. 2 shows a generic block diagram of an open loop compensation system indicating different variations of where the temperature sensor analog output may be directly used or converted to a digital word. Similarly the temperature compensation algorithm may be implemented using analog or digital circuitry and can generate analog or digital controls which may be converted back to analog signals to control the oscillator.

Clearly this is a knowledge based process since exact cancellation of the temperature dependence will require deterministic knowledge of the complete system behavior to build an effective compensation algorithm. Otherwise one must rely on characterization of the system performance across temperature for every oscillator unit to generate the required data. However, this may still not provide perfect cancellation of frequency shifts unless the system has the ability of synthesizing controls with high accuracy. Inevitably this adds to the overall system complexity that may be translated into cost due to a large die size and/or long production test times using two or more temperature insertions. Nonetheless, open loop compensation has been used to compensate MEMS-based clocks [3] which uses a fractional-N Σ-Δ PLL frequency multiplier that is digitally temperature controlled. On the other hand, a CMOS LC-tank based reference oscillator reported in [6] uses a digital open loop compensation technique that utilizes an integrated microprocessor and [5] uses analog temperature dependent circuitry to control the behavior of the oscillator across temperature. All open loop techniques will require the storage of calibration coefficients on-chip during the calibration process for future retrieval during the lifetime of the oscillator.

B. Self Compensated Oscillator

A self-compensated oscillator across temperature has intrinsically low temperature sensitivity. Such oscillators do not require any real time compensation and temperature sensors and are thus simpler. Usually self compensated oscillators have a specific temperature range where the oscillation frequency has tolerable variation. An excellent example of a self compensated oscillator is an XO built using a quartz crystal. An AT-cut quartz crystal if designed and manufactured correctly can exhibit low temperature sensitivity. This is achieved by selecting the exact cutting angle that achieves lowest temperature sensitivity. This was made possible by excellent control on the manufacturing process of quartz crystals which is today a very mature and stable technology. Similarly there have been trials for producing MEMS resonators that are self compensated by designing stiffness compensated and geometric compensated resonators as noted by [1] and summarized in Fig. 3. Such

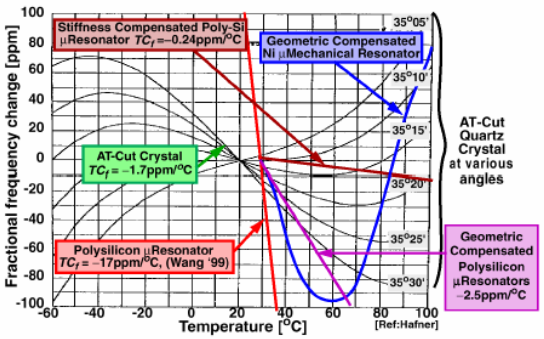

Figure 3. Frequency stability over temperature of self-compensated AT-cut quartz crystal and MEMS resonators.

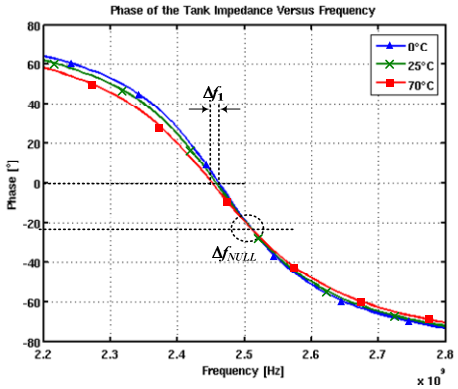
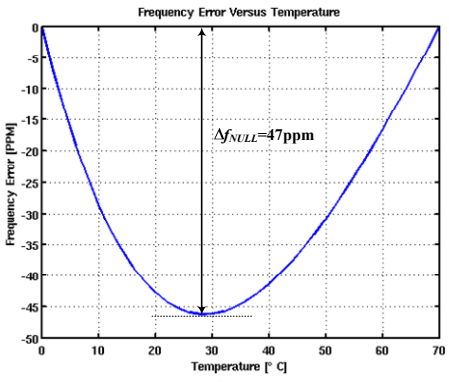
designs depend on materials with opposite temperature coefficients to cancel. However, the manufacturing accuracy and purity of the materials may impact the overall temperature dependence resulting in a wide variation in performance that is not industrially accepted. Such resonators end up with very non-linear temperature dependence of wide variation that make the use of open loop compensation techniques to correct them very challenging. In effect commercially viable self compensated MEMS resonators up to date are not available.

III. LC-Tank Temperature Null Concept

Building an oscillator operating at the LC-tank resonance frequency with variation over temperature shown in Fig. 1

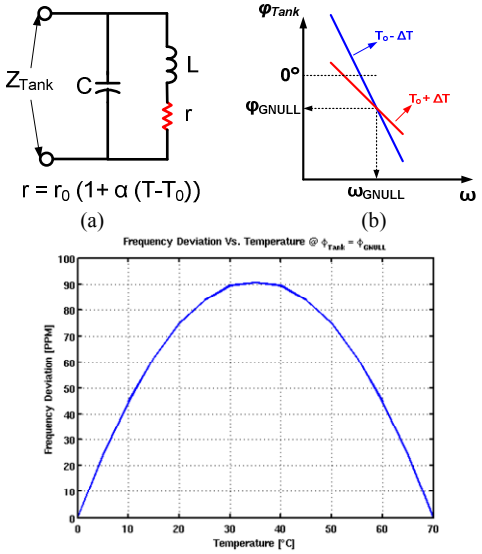


(a)



(b)

Figure 4. (a) LC-Tank impedance phase versus frequency for different temperatures and (b) frequency variation at TNULL.



(a) (b) (c)

Figure 5. (a) Simple first order model of an LC-tank, (b) Global Null of an LC-tank and (c) Frequency deviation at GNULL phase.

would result in very poor frequency stability. This may be easily understood by studying the tank impedance Z_{Tank} phase versus frequency at different temperatures shown in Fig. 4(a). A classical oscillator operates with almost zero phase across the tank. A zero phase intersection with the tank phase curves over temperature results in a large frequency variation Δf_1. However, studying the tank impedance phase curves carefully one can notice that tank phase curves across temperature intersect at a negative phase where frequency variation across temperature is minimized by a factor of ~100 to be Δf_{NULL}=47ppm as shown in Fig. 4(b). This phenomenon of minimum temperature sensitivity of frequency will be named as the LC-tank Temperature Null (TNULL) and the phase across the tank as φ_{NULL}. This non-traditional phase operating point is very desirable since it is an example of a Self Compensated Oscillator (SCO) across temperature. The challenge is to design an LC-tank with a TNULL that exhibits good frequency stability and to successfully oscillate at φ_{NULL}.

The TNULL phenomenon may be mathematically derived using a simple first order model of an LC-tank shown in Fig. 5(a) where the only temperature dependent element is r, the ohmic losses of the inductor with a first order temperature coefficient α. The tank impedance phase φ_{Tank} is given by:

$$\varphi_{Tank} = \angle Z_{Tank} = \tan^{-1}\left(\frac{\omega L}{r}\right) - \tan^{-1}\left(\frac{\omega r C}{1-\omega^2 LC}\right) \quad (1)$$

The Global Null (GNULL) is defined across a temperature range of interest as the intersection of the tank phase curves at the temperature extremes as shown in Fig. 5(b). The operating phase φ_{GNULL} is the point of minimum temperature sensitivity across this temperature range. For a temperature range of $2\Delta T$ around T_0 using the simple first order tank model GNULL phase and frequency are given by:

$$\omega_{GNULL} = \frac{1}{\sqrt{LC}}\sqrt{1+\left(\frac{1-\alpha^2\Delta T^2}{L/Cr_o^2}\right)}, \quad \varphi_{GNULL} = -\tan^{-1}(2r_0 C\omega_{GNULL}) \quad (2)$$

Fig. 5(c) shows the frequency deviation across temperature at the GNULL phase. Since the simple first order model does not take into consideration many second order affects one can note the difference between plots in Fig. 4(b) and Fig. 5(c) yet the TNULL concept is evident.

IV. SCO Implementation Based on TNULL

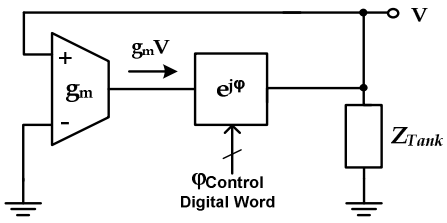
This section illustrates the architecture of the SCO based on the aforementioned LC-tank TNULL concept. The SCO functional block diagram is shown in Fig. 6. The main objective of the architecture is to operate the LC-tank at precisely the TNULL phase. The oscillator is formed of a transconductor stage and a phase shift stage. At steady state, the transconductor and phase shifter provide a phase that is the negative of the required TNULL phase. Thus, at steady state, the LC-tank is forced to oscillate at the required non-zero TNULL phase. One of the most important design aspects of the phase shift circuitry is to provide a phase that is accurate and temperature independent, otherwise frequency deviation will increase. Phase magnitude is controlled via a digital phase control signal ($\varphi_{Control}$) the accuracy of which will determine how close the final operating point to the GNULL will be. The value of $\varphi_{Control}$ is trimmed to tune the phase operating point and is stored on chip.

Fig.7 illustrates one of the methods of injecting a positive phase into the oscillator loop using a quadrature oscillator architecture with variable coupling m between the two oscillators in quadrature. Two identical LC oscillator tanks are forced to oscillate at the same frequency but in quadrature phase with respect to one another. Transconductor stages a and c inject two quadrature currents g_m*V and $g_m*V\angle 90$ into their respective tanks I and Q while stages b and d couple the oscillators together by injecting $m*g_m*V\angle 90$ and $-m*g_m*V$ currents into tanks I and Q respectively. The value of the coupling factor m is variable and is controlled via a digital control word. A gain block produces a 180 degrees phase shift to force both oscillators to be in quadrature. Therefore, the tank total current phase shift φ is a simple function of the coupling ratio m and is given by:

$$\varphi = \tan^{-1}(m) = -\varphi_{GNULL} \qquad (3)$$

The value of m is varied by scaling the bias current of the transconductor stages and the dimensions of the active devices. This guarantees producing a stable temperature independent coupling ratio and phase across both tanks.

The architecture includes an automatic amplitude control (AAC) block. The AAC block senses the oscillation amplitude of both tanks and compares it to a reference voltage (V_{REF}). The amplitude level is adjusted such that at steady state oscillator amplifiers or transconductor stages operate at a fairly linear region. This minimizes the oscillation harmonic content and the impact of this harmonic content on frequency stability. The AAC block controls all four amplifier stages to ensure that all stages have a tracking gain and a constant coupling ratio m during operation.



$$Z_{Tank} = \frac{1}{g_m} e^{-j\varphi}$$

Figure 6. SCO functional block diagram.

The SCO is trimmed using a low cost room temperature only (RTO) trimming and frequency calibration algorithm. The algorithm modulates the temperature of the LC tank using on-chip resistors, varies the value of m and detects the phase with minimum oscillator temperature sensitivity (zero slope) which may be related to the required GNULL phase. The trimming and calibration routines are done only once during production testing and the value of m is stored on chip. At power-up, the value of m is loaded to operate the oscillator at the TNULL to become a self-compensated oscillator.

V. Measured Performance

The SCO architecture described has been fabricated in a 0.18µm CMOS process with thick aluminum top metal. A set of programmable dividers produce a CMOS output frequency from 1 to 133MHz. The chip has been packaged in a standard 4-pin package. A large number of parts have been tested and characterized. Tests include total frequency stability across temperature, supply and load, single side band (SSB) phase noise, current consumption and period jitter.

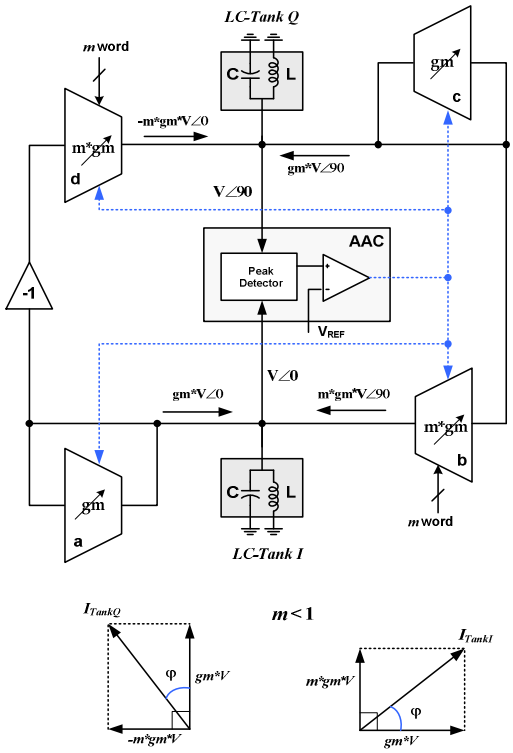


Figure 7. Block diagram of an SCO implemented using a quadrature oscillator architecture.

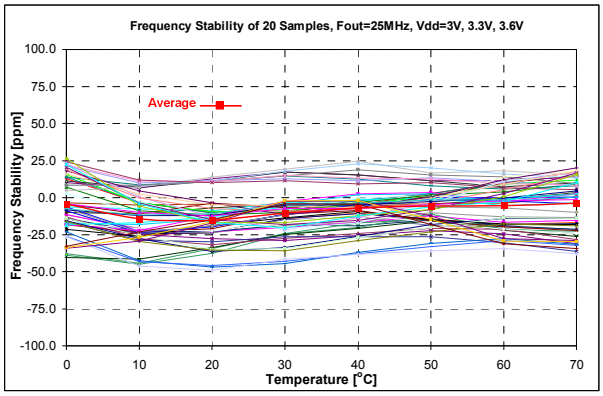

Figure 8. Frequency stability of 20 randomly selected samples.

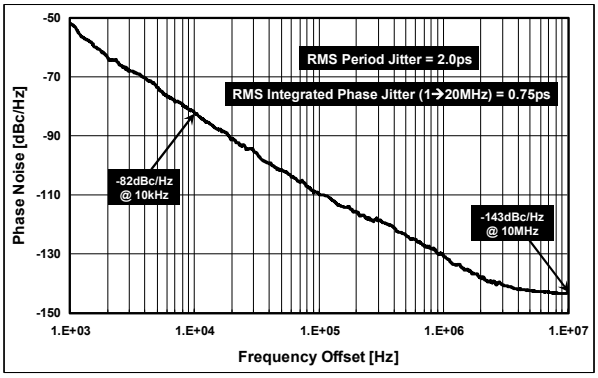

Figure 9. Phase noise measurement of a 125MHz output clock

Parts were randomly selected from a single wafer, trimmed and calibrated to a frequency of 25MHz at the CMOS output. Parts were inserted in a temperature chamber where the frequency was measured from 0 to 70°C in steps of 10°C. The power supply was varied by ±10% relative to a nominal 3.3V value. The measured total frequency stability for 20 parts is plotted in Fig. 8. Results show very good correlation between measurements and simulations indicating the robustness of the architecture and validity of the TNULL concept. Frequency stability across a capacitive load varying from 1pF to 15pF was tested and showed a maximum frequency variation across temperature of <10ppm. Frequency stability measurements illustrate clearly a very tight performance spread across the measured parts with an overall frequency stability of better than ±50ppm. It is to be noted that further improvements in the trimming and calibration routines can improve the initial accuracy to achieve an overall tighter frequency error of ±25ppm. The no load current consumption of the oscillator is 7.1mA at a 25MHz output frequency. The phase noise of a 125MHz output frequency was measured and is shown in Fig. 9 indicating a phase noise of -82dB/Hz at an offset of 10kHz. Processing the phase noise measurements yields 0.75ps RMS integrated phase jitter from 1MHz to 20MHz and a period jitter of 2ps. The performance of the SCO performance is compared to other all silicon CMOS LC-tank based commercially available oscillators in Table I. It is to be noted that the reported SCO frequency stability does not include aging while the other clocks include aging. It is expected that aging would increase the frequency stability by ±25ppm. Overall SCO performance is very competitive in terms of frequency stability and period jitter. Current consumption may be lowered by migrating to a smaller feature size technology such as a CMOS 0.13µm and use of higher quality factor copper integrated inductors will help decrease current and improve phase noise.

TABLE I. SCO PERFORMANCE COMPARISON

Specification	3CP0C02[8]	Si500S[6]	This work
CMOS Technology	0.13µm, Cu	0.13µm, Cu	0.18µm, Al
Frequency Range	4 – 133MHz	0.9 – 200MHz	1 – 133MHz
Total Freq Stability 0 – 70°C	±100ppm	±150ppm	±50ppm
No Load Current	2.2mA	9.7mA @ tri state o/p	7.1mA @ 25MHz
RMS Period Jitter	5ps @ 75MHz	1ps @ 200MHz	2ps @ 125MHz

VI. CONCLUSION

Self-compensation found in quartz crystals through precise selection of a mechanical cutting angle is analogous to the electrical TNULL phase. The LC-Tank TNULL concept has been analyzed, verified in simulation and validated by measurements. A Self Compensated Oscillator (SCO) has been successfully implemented based on the TNULL concept using a quadrature oscillator architecture which facilitated accurate temperature independent tank phase control and successful low cost trimming and calibration. The overall achieved frequency stability of ±50ppm across temperature (0 – 70°C), supply and load is very competitive with reported performance of all CMOS oscillators and may be further improved to achieve ±25ppm. Period jitter, phase noise and current consumption are reasonable and there is room for improvement by going to a smaller feature size technology such as a CMOS 0.13µm process with copper metal layers.

***Abstract*—In this paper, a 4.6 GHz frequency synthesizer integrated circuit for Cesium-based miniature atomic clocks is presented. Based on a fractional-N phase-locked loop (PLL) with sigma-delta modulator, the chip features a frequency resolution below 10^{-3} Hz at its output, allowing a tuning resolution of 10^{-13}. This value was measured on the circuit which is integrated into a 130 nm CMOS process. It consumes 15 mW, features an output phase noise of -76 dBc/Hz @ 1 kHz offset from the 4.6 GHz carrier, and provides a programmable output power from -10 to 0 dBm.**

I. INTRODUCTION

Modern wireless communication and navigation systems depend heavily on stable frequency references for synchronization and positioning. Atomic clocks are mostly used for this purpose, however they are large devices (~ 100 cm^3), power-hungry (~ several Watts) and too expensive to be deployed in a large scale or used in portable applications, such as GNSS receivers and future mobile communication devices. Recent efforts for miniaturization have led to the so-called miniature atomic clocks, offering reduced dimensions (~ 10 cm^3) and power consumptions (~ hundreds of mW) [1] as well as high precisions and capabilities of low-cost mass productions.

A low phase noise, high resolution frequency synthesizer is a needed block to implement atomic interrogation. For miniature systems, low power operation is also required. Previously, several papers discussed about different topologies of frequency synthesis for atomic interrogation. One traditional technique is depicted in [2], employing frequency multiplication with step recovery diodes (SRD). Ref. [3] describes a topology realized by a frequency chain using sampling mixers to avoid narrow-band filtering, while [4] and [5] utilize non-linear transmission line (NLTL) circuits instead of SRD during the frequency multiplication. However, the disadvantage of frequency multiplication is the large energy dissipation during the operation, leading to very low energy efficiency and high power consumption.

Fractional-N phase-locked loop (PLL) integrated frequency synthesizers are widely used in communication, and have proven high frequency tuning resolution and low phase noise ([6]-[8]). With the objectives of miniaturization, low-power operation as well as low phase noise level, this paper presents the design and realization of a 4.596 GHz frequency synthesizer integrated circuit, fabricated into a 130 nm CMOS process. Compared to [9] and [10], the chip features an un-common frequency resolution of about 10^{-13}, which allows its use in high-performance Cesium-based atomic clocks.

The paper is organized as follows: in Section II, the circuit general architecture is presented, as well as the detailed design of the main blocks. Section III highlights the realization and experimental results of the chip, while Section IV concludes the paper.

II. CIRCUIT DESIGN

Fig. 1 illustrates the general architecture of the frequency synthesizer, which includes the PLL blocks (a phase and fre-

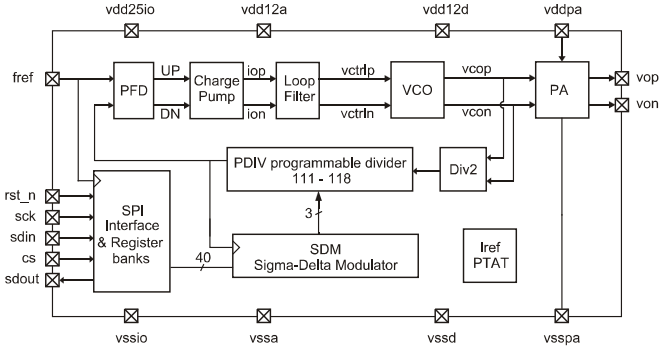

Figure 1. Systematic diagram of the frequency synthesizer.

This work was funded by the EU 7th framework program FP7, under contract no. 224132.

quency detector, a charge pump and a loop filter), a voltage controlled oscillator (VCO), a power amplifier (PA), a divide by two prescaler, a programmable divider controlled by a sigma-delta modulator, a PTAT reference for generating the bias currents, and a serial peripheral interface (SPI) to access a register bank for controlling the chip.

A. Voltage Controlled Oscillator

The VCO is a challenging block in the design of frequency synthesizers because its phase noise has a big impact on the performance of the whole chip. A LC tank VCO is naturally selected for its relatively good quality factor and low power operation. However, to improve the noise immunity of this sensitive structure, a fully-differential scheme is chosen for all elements, including the varactor, permitting to reduce the common-mode noise and to maintain a symmetrical topology of the circuit as shown in Fig. 2.

The VCO LC tank consists of a fully differential inductor with a varactor load for frequency fine tuning, and a 5-bit capacitor bank for coarse tuning. NMOS transistors form the cross-coupled pair to feature the function as a negative impedance convertor for sustaining the oscillation. PMOS transistors are used to construct the current biasing block. In comparison to NMOS transistors, they can provide lower flicker noise. Filtering capacitors are connected between the PMOS gate and VDD to stabilize V_{GS} in order to reduce the noise influence from the voltage supply.

Several other measures are taken to improve the VCO performance. The symmetry in the varactor allows to improve its linearity. For the switches of the capacitor bank, bias resistors are added to control the DC voltage at the switch terminals to ensure a minimal and constant parasitic capacitance of both the source and drain diffusions.

The varactor dimensioning is the result of a trade-off: on one side, it should be large enough to ensure continuous frequency tuning between successive coarse tuning codes and to allow an operation in the middle of its dynamic range, where the linearity is optimal. On the other side, the varactor value should be minimized to reduce phase noise degradation due to circuit noise (substrate, etc.) coupling into it. A compromise is selected with a varactor tuning range corresponding to three coarse tuning steps.

Concerning the cross-coupled transistors, the minimal length is chosen to reduce the parasitic capacitance, while the width is calculated to get sufficient transconductance g_m for sustaining the oscillation, according to Barkhausen's criterion. For the current biasing transistor MS, its size is selected to limit the flicker noise as well as to mitigate the layout mismatch influence.

B. Frequency Prescaler

The divide-by-2 prescaler, shown in Fig. 3, is directly connected to the RF output of the VCO; therefore, it requires a high frequency operation and symmetrical structure. To meet these constraints, a current-mode logic (CML) D-flip-flop is used since its reduced switching amplitude allows the circuit to be operated in high-speed conditions.

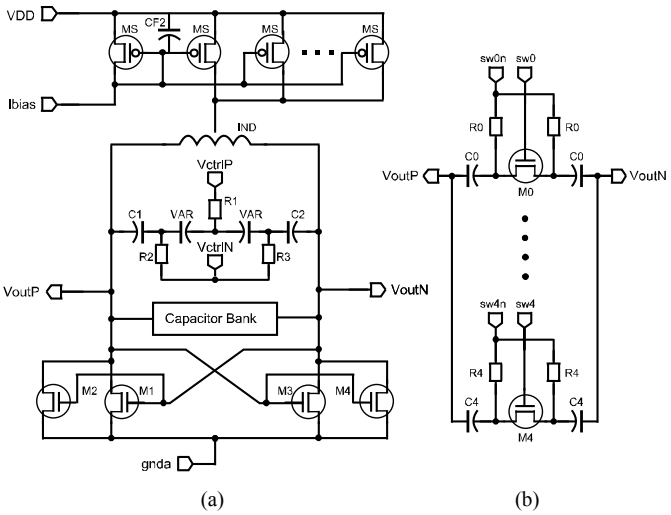

Figure 2. Schematics of (a) the fully differential VCO and (b) the coarse tuning capacitor bank.

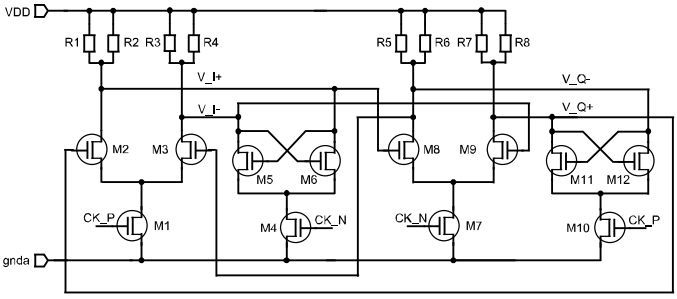

Figure 3. Schematic of the divide-by-2 prescaler.

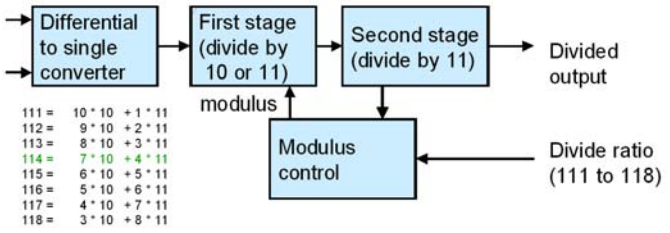

Figure 4. Circuit diagram of the programmable divider.

The two complementary outputs of each D-flip-flop are used to drive a CML-to-CMOS converter so that the power of these four quadrature signals is exploited, thus enhancing the power efficiency. This also provides an equal load to both D-flip-flop outputs that improves the symmetry of the circuit.

To improve the output dynamic swing, the tail current transistor which is normally found in this circuit is suppressed. Instead, a bias current is applied to a single transistor which provides the two functions of switching and biasing.

C. Programmable Divider

A programmable divider is needed for the design of a fractional-N synthesizer. Fig. 4 shows the architecture of the circuit which comprises three stages: a dual-modulus divider 10/11, a programmable counter (divide-by-11) and a modulus

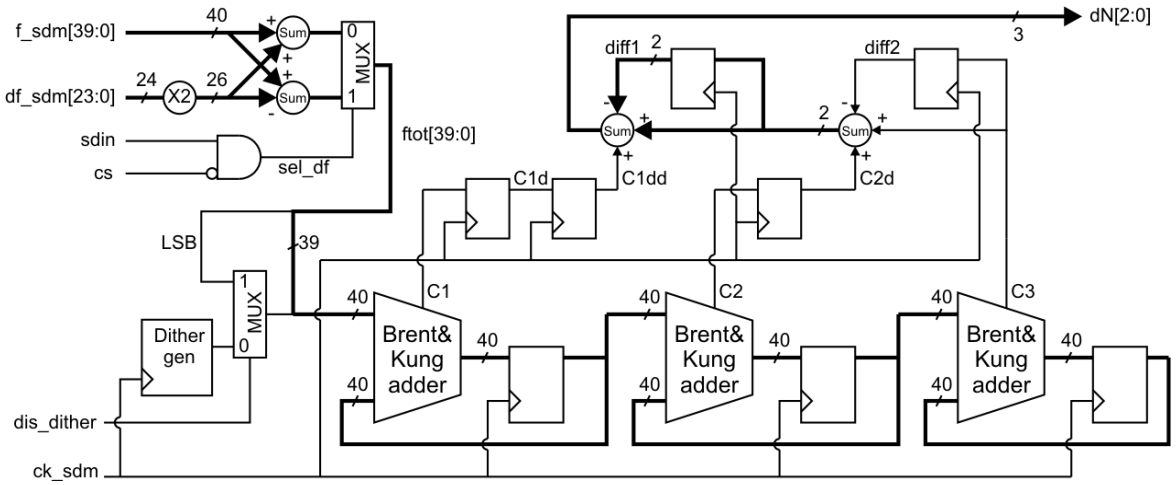

Figure 5. Schematic of the sigma-delta modulator structure.

control (A-counter). The dual-modulus divider divides the RF signal either by 10 or 11 depending on the modulus control input from the A-counter. Its output signal is divided by certain ratio (<11) again after passing the programmable counter to obtain the wanted output frequency, which is also used to reset the A-counter for restart. The A-counter is reduced by 1 each time it is triggered by the clock and sends different modulus signals to control the division ratio of the dual-modulus divider. Considering the high operating frequency of 2.3 GHz, the circuit of this block is realized with dynamic logic.

In this chip, the programmable divider takes the 2.3 GHz signal from the divide-by-2 prescaler and further divides it with an average ratio of about 114.9 to get the desired 20 MHz feedback frequency. Its integer division ratio varies from 111 to 118, controlled by a 3-bit word provided from the sigma-delta modulator.

D. Sigma-Delta Modulator

The sigma-delta modulator (SDM) is used to modulate the programmable divider to achieve a fractional division ratio. Fig. 5 shows the schematic of a 3rd-order, MASH SDM structure made with three 40-bit accumulators, which are built of a Brent & Kung adder and a 40-bit register for each. The 3-bit carry outputs C1, C2 and C3 are combined to calculate the SDM output dN[2:0].

The designed SDM is simulated and provides a low power spectrum density within the PLL bandwidth (up to 250 kHz). Above, the noise rises rapidly but can be filtered out by the PLL loop filter.

III. CIRCUIT REALIZATION AND EXPERIMENTAL RESULTS

The frequency synthesizer integrated circuit is implemented into a 130 nm RF CMOS process. It occupies an active area of about 2 mm^2. The chip microphotograph is shown in Fig. 6. The total power consumption of the chip is 15 mW at the nominal supply voltage of 1.2 Volt.

The tuning range of the RF signal is measured to be from 4.07 GHz to 5.17 GHz, well centered on the 4.6 GHz nominal frequency. The K_{VCO} is measured from 113 MHz/V to 203 MHz/V, which is around three times larger than the expected

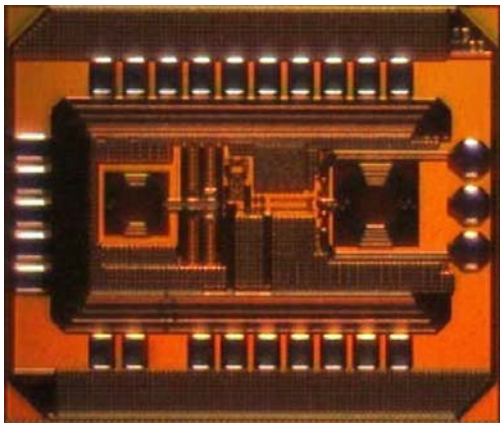

Figure 6. Microphotograph of the die with an active area of about 2 mm^2.

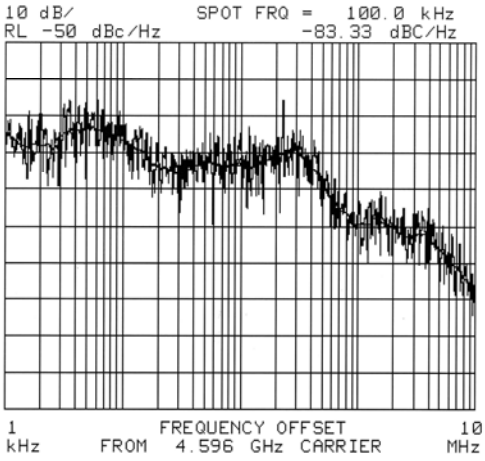

Figure 7. Curve of the synthesizer phase noise.

value. The reason is due to an over-estimation of the varactor value (no model available).

The phase noise curve is shown in Fig. 7, giving a noise level of -76 dBc/Hz @ 1 kHz offset and -83 dBc/Hz @ 100 kHz offset from the carrier. This noise is higher than the ex-

TABLE I. CRITICAL EXPERIMENTAL RESULTS OF THE CHIP COMPARED TO THEIR EXPECTED VALUES.

	Expected Values	**Experimental Results**
PLL BW	120 kHz ~ 300 kHz	100 kHz ~ 400 kHz
Freqency Resolution	10^{-13}	10^{-13}
Power Consumption	15 mW	15 mW
Phase Noise at 1 kHz offset	-77 dBc/Hz	-76 dBc/Hz
Phase Noise at 100 kHz offset	-89 dBc/Hz	-83 dBc/Hz

pected value of -89 dBc/Hz @ 100 kHz offset. It has been verified that the excess of phase noise inside the PLL bandwidth is generated by digital switching noise coming from the on-chip logic and the input level shifter on the 20 MHz reference clock. Indeed, lower phase noise is found when the sigma-delta modulator is switched off. Furthermore, measurements of the VCO alone give a phase noise of -92 dBc/Hz @ 200 kHz offset from the carrier, which is much lower than the closed-loop noise at the same offset position in Fig. 7. This shows that the limited performance comes from the PLL sys-tem, especially from digital switching noise instead of the VCO.

The frequency resolution of the synthesizer is measured by means of a self-down-mixing system. Since the specified frequency resolution value is about 10^{13} times smaller than the 4.596 GHz signal (<1 mHz) it is difficult to make a direct measurement for such a tiny frequency variation to be observed at the RF output. Therefore, down-mixing the 4.596 GHz into the baseband frequency regime can lead to a much easier measurement procedure. In order to eliminate the need for an accurate reference frequency generator, two ASICs using the same input reference clock are used to generate two slightly different RF frequency signals, which are mixed together. The resulting beat frequency is measured in function of the change in the sigma-delta modulator input register. Frequency differences of less than 0.5 mHz are measured, corresponding to a resolution of 10^{-13}, which meets the specifications. The critical experimental results of the full chip measurement are summed up in Table I.

IV. CONCLUSION

A 4.6 GHz frequency synthesizer implemented into a 130 nm RF CMOS process for Cesium-based miniature atomic clocks application is presented. A 3rd-order, 40-bit sigma-delta modulator is used to provide the fractional ratio for the synthesizer to generate the 4.596 GHz signal with a frequency resolution higher than 10^{-13}. The power consumption of the circuit is less than 15 mW and the chip occupies an active area of 2 mm^2. The measured phase noise is -76 dBc/Hz @ 1 kHz offset and -83 dBc/Hz @ 100 kHz offset. These performances allow using this chip in chip-scale atomic clocks with stabilities in the order of 5×10^{-11}. For better stabilities, the phase noise needs further improvements. This can be done by using a smaller varactor and decreasing the on-chip digital noise.

Abstract— **Injection mode-coupled voltage-controlled SAW oscillators (VCSOs) are versatile performers in low-noise frequency synthesizers, both as high-frequency sources and as reference oscillators. A novel high frequency digital synthesizer is reported with the intent of lowering following: size, cost, power-consumption, phase noise, jitter, and vibration sensitivity. The measured phase noise is typically better than -100 dBc/Hz, -115 dBc/Hz, -129 dBc/Hz, -133 dBc/Hz at 100 Hz, 1 kHz, 10 kHz, and 100 kHz offset frequencies respectively from the carrier frequency of 5200 MHz. The reported synthesizer can generate frequencies from 5 GHz to 5.3 GHz in steps of 100 kHz with typical spurious of -65 dBc and the power consumption is less than 300 mill watt for a given 5 dBm output power.**

I. INTRODUCTION

Frequency synthesizers come in many shapes and sizes. They range from tiny system-on-a-chip (SoC) devices and modules to rugged military-grade rack mount systems and bench-top instruments [1]-[20]. They are also based on a wide array of technologies, from analog to digital in nature, starting with many different signal sources, including voltage-controlled oscillators (VCOs) and surface-acoustic-wave (SAW) resonators. One of the more novel approaches combines both analog and digital techniques: a frequency synthesizer based on an injection mode-coupled voltage-controlled saw oscillator (VCSO) circuits. The novel VCSO using injection mode-coupling approach is part of a frequency synthesizer capable of typical measured phase noise of -152 dBc/Hz offset 10 kHz from a 1-GHz carrier, with less than 6 fs RMS jitter for a given power consumption of 60 mill watt (DC bias operating condition: 5V, 12 mA).

Historically synthesizer designers have relied on crystal based multiplied reference oscillator featuring excellent phase noise performance at 1GHz and above frequencies. Although, frequency multiplier crystal oscillator can offer low phase noise performance at 1 GHz and above frequencies but at the cost of large size, high noise floor and high power-consumptions. The most dramatic change will occur when optimum loop bandwidth extends to a few megahertz, where adaptive injection mode mode-coupled VCSO's phase noise performance becomes competitive or supersede the performance of the conventional multiplied crystal oscillator at 1GHz and above. Furthermore, these characteristics, accompanied with the low cost, low power consumption and compact size inherent to the VCSO topologies, are likely to secure their domination in the foreseeable future at higher frequency synthesizers and reference frequency standards.

II. STATE-OF-THE-ART SYNTHESIZER TOPOLOGIES

A typical phase-lock-loop (PLL) synthesizer consists of a reference phase detector, loop filter, VCO and VCO divider (N divider) as shown in Fig. 1. The PLL is typically available as an integrated circuit (IC) with a reference divider, phase detector or phase frequency detector (PFD) with charge pump, and the VCO divider. The relationship between the output frequency 'f_{out}' and reference frequency 'f_{ref}' can be described by [14]

$$f_{out} = N\left[\frac{f_{ref}}{R}\right] \quad (1)$$

As shown in Fig.1, the PFD compares the two input signals (f_{ref} /R) and (f_{out} /N) produces an error voltage proportional to the phase difference between them. The loop filter attenuates the high-frequency noise components from the PFD output and limits the bandwidth of the error signal. The filtered error voltage is applied to the tuning port of the VCO; the error signal drives the VCO frequency, f_{out} higher or lower in frequency until the error voltage at the PFD output is zero.

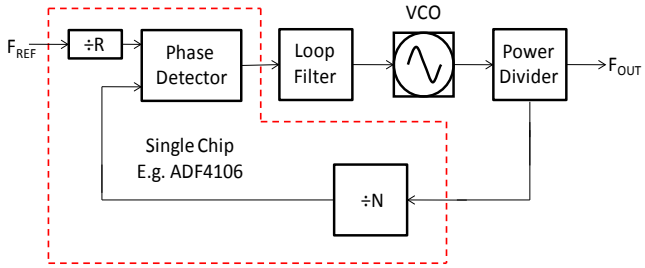

Fig.1. This simplified block diagram shows a simple, single-loop integer-N PLL module.

Typically, the VCO divider is implemented as a dual-modulus counter to obtain large continuous division of the VCO output. To vary the output frequency f_{out} of the synthesizer, the value of N is changed, and it can be seen from (1) that the minimum frequency step (defined as the step size) obtained at the output is given by f_{ref}/R.

Smaller step size can be obtained by operating the PFD at low frequency - i.e., by increasing the R value (and thus increasing N). The problem with increasing the N value is the noise of the PFD increases. The close in phase noise of the synthesizer is estimated by noise of the synthesizer itself (provided by the manufacturer), PN_{SYN} and adding 20logN (where N is the N divider value) and 10log (f_{PFD}) [14]:

$$PN_{TOT} = PN_{SYN} + 10log(f_{PFD}) + 20\log(N)$$

$$= PN_{SYN} + 10\log\left(\frac{f_{REF}}{R}\right) + 20\log(N) \qquad (2)$$

From (2), to minimize the phase noise, the value of N should be kept small. But for fine tuning resolution, the PFD must operate at low frequency, requiring a high value for N and resulting poor noise performances.

The conflict eliminates the conventional PLL design for use in low-noise, high-resolution applications. The loop filter in a PLL synthesizer design also limits switching speed. A higher loop bandwidth yields faster switching speed but with excessive noise. A narrow loop bandwidth lowers phase noise but sacrifices switching speed. The tradeoff is between phase noise and switching speed. Typical phase noise for a conventional PLL synthesizer operating from 500 to 1200 MHz in 500-kHz steps includes switching time of less than 5 ms and better than -70 dBc spurious levels with a 10-MHz reference (Fig. 2).

To improve the performance of an integer-based PLL (as shown in Fig. 1) the 'N' divider can be implemented as a fractional divider instead, rather than an integer divider. This enables the use of higher PFD frequency and lower N values, thus improving the phase noise performance of the synthesizer.

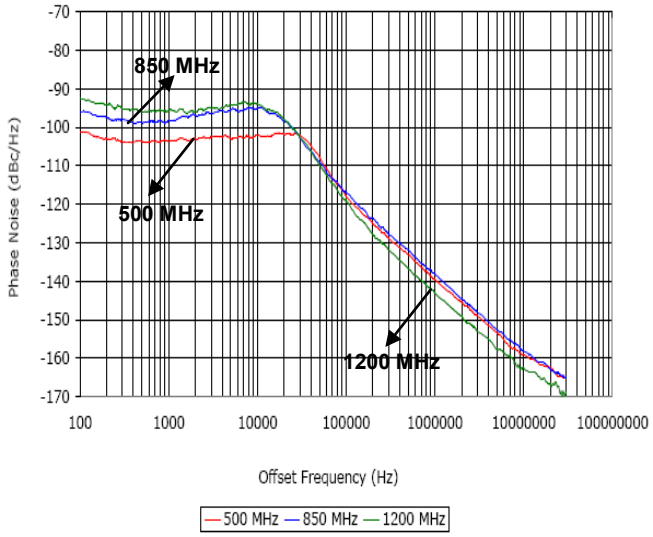

Fig.2. This plot shows the typical measured phase noise for an integer-N frequency synthesizer.

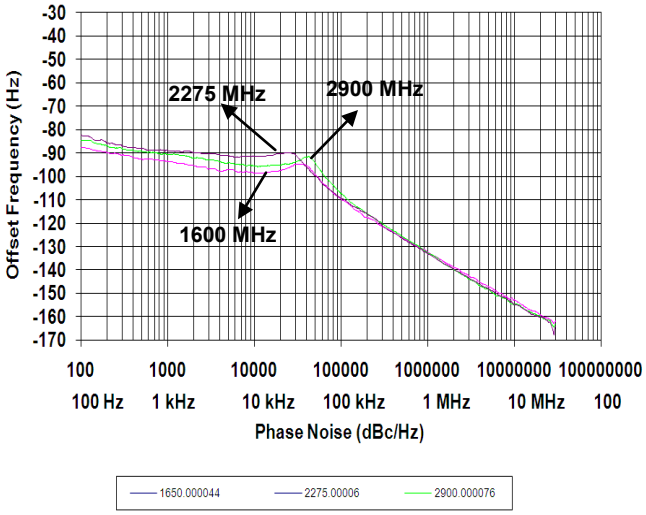

Fig.3. This plot shows the typical measured phase noise for a fractional-N frequency synthesizer,

But a fractional-N divider also introduces spurious at the output of the synthesizer. In addition to this, even with the fractional N the step-size of the synthesizer cannot go below 1 Hz. Typical fractional-N synthesizer performance from 1600 to 2900 MHz with a 10-MHz includes better than 1-ms settling time and spurious levels of -60 dBc or better (Fig. 3).

Multiloop synthesizer architectures with direct-digital synthesizers (DDSs) have been used for tuning resolution better than 1 Hz. Figure 4 shows a typical dual-loop synthesizer where a DDS module combines with a conventional PLL synthesizer. The DDS clock is fed by a selectable frequency synthesizer which provides a fixed set of frequencies based on the parallel select lines.

Unfortunately, the DDS approach can generate high spurious output levels. But these spurs can also be predicted and shifted by proper choice of clock frequency. If spurious products fall within the loop bandwidth, by switching the clock frequency, the spurs can be shifted to a band where they can be attenuated. In this dual-loop approach, the output synthesizer's PFD can be high to improve phase noise while still delivering 1-Hz resolution with a 10-MHz reference. Spurious levels are typically better than -70 dBc from 1100 to 2500 MHz with 1-Hz step size, better than 1-ms switching speed, and low phase noise characteristics (Fig. 5).

As briefly discussed above, designers have often relied on multiplying a low-noise crystal oscillator based VCO to achieve higher-frequency (1 GHz and higher) output signals.

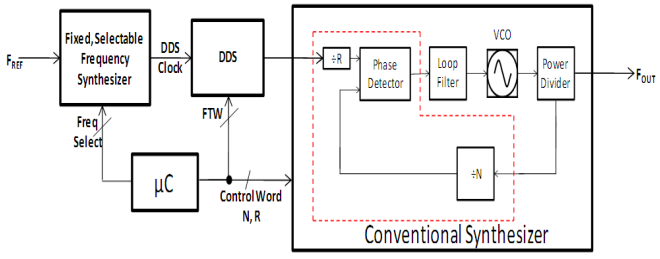

Fig.4. This simplified block diagram shows a DDS-based dual-loop frequency synthesizer.

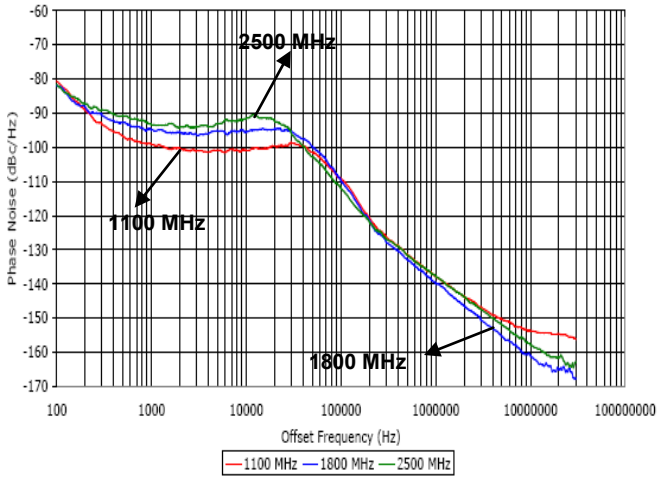

Fig.5. This is typical measured phase noise for a DDS-based dual-loop frequency synthesizer

The crystal oscillator multiplier VCO approach can provide excellent phase noise, but such synthesizers tend to consume a great deal of power, generate high levels of noise, and are large in size. Commercially available crystal oscillators at 100 MHz and below are available with phase noise of -160 to -176 dBc/Hz offset 20 to 100 kHz from a 100-MHz output. When multiplied, the phase noise translates to -140 to -156 dBc/Hz offset 20 to 100 kHz from 1 GHz but degrades the noise floor by as much of 20 dB.

The availability of low-cost, low-noise VCSOs clears the way for small, low-noise synthesizers. Part of using these sources involves modeling the surface acoustic wave resonators under large signal drive conditions for the better insights about noise dynamics at close-in phase noise, then developing manufacturable methods for producing high-purity and temperature stable oscillators in chip form.

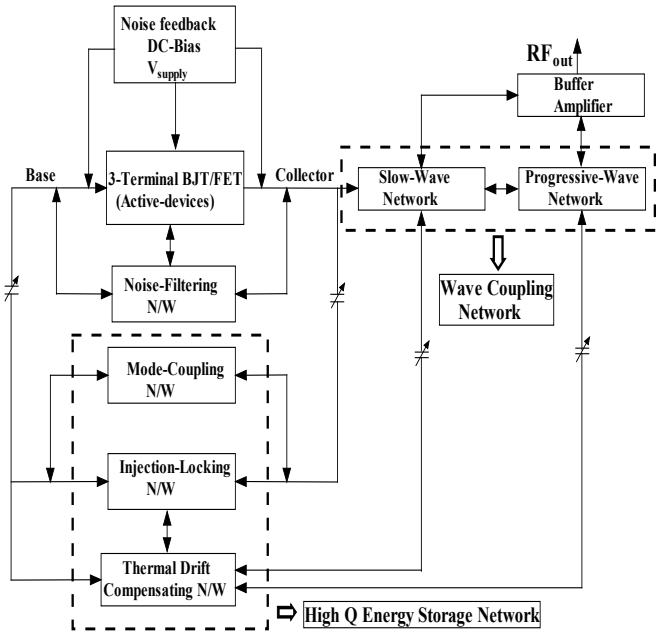

Fig.6. This block diagram shows the functional parts of an adaptive injection mode-coupled VCSO for low cost high performance synthesizer circuit.

Fig. 6 shows a typical block diagram for an adaptive injection mode-coupled VCSO optimized for low phase and noise with 400 kHz tuning require for compensating the frequency drift due to temperature and ageing, while Fig. 7 compares its phase noise at 1 GHz to that of a commercially available multiplied crystal oscillator circuit.

An adaptive mode-coupled VCSO combined with a digital PFD can be used to form a low-cost, low-power synthesizer module. The digital PFD has a wide capture range, although with high noise floor. An analog PFD has lower noise floor, but narrow capture range. To create a low-noise synthesizer with a wide capture range, a digital PFD can be used in parallel with an analog phase detector. The digital PFD is used for initial acquisition, and the analog detector for final tuning.

For example, within a DDS architecture, the VCSO module can be used to create a synthesizer (Fig. 8) with fast switching speed (about 200 µs). The DDS is used as the feedback divider for high resolution and flexibility in choosing a reference frequency. From 530 to 630 MHz, spurious levels are better than -75 dBc with low phase noise (Fig. 9). Since the analog phase detector has a low noise floor, the synthesizer bandwidth was kept large for fast switching time with low phase noise.

III. Frequency Synthesizer Using Adaptive Injection Mode-Coupled VCSO Circuit

A high-performance synthesizer based on an adaptive mode injection-locked VCSO and multiple loops, including a sampling PLL, is shown in Fig. 10.

The main PLL (Fig. 10b) achieves a coarse lock to the desired output frequency using a 120-MHz reference signal, which can be derived from an internal OCXO or low-noise 800-MHz VCSO.

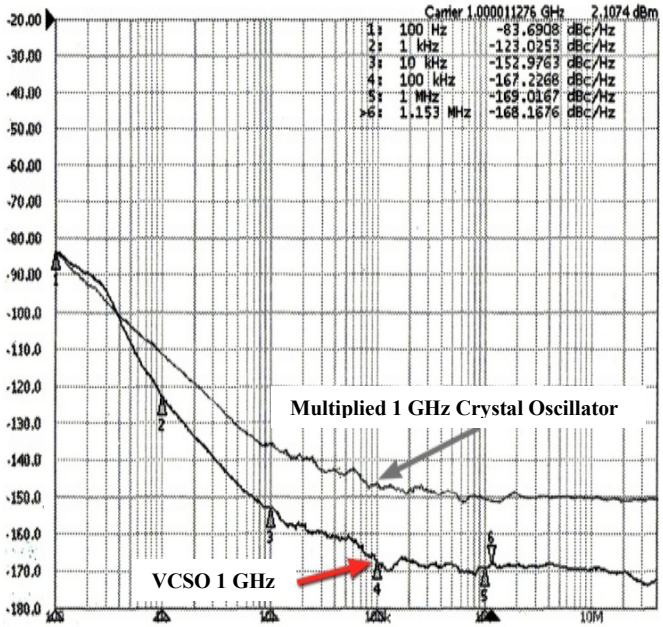

Fig.7. This phase noise plot compares the performance of a 1-GHz VCSO with 1-GHz achieved by multiplying a crystal oscillator.

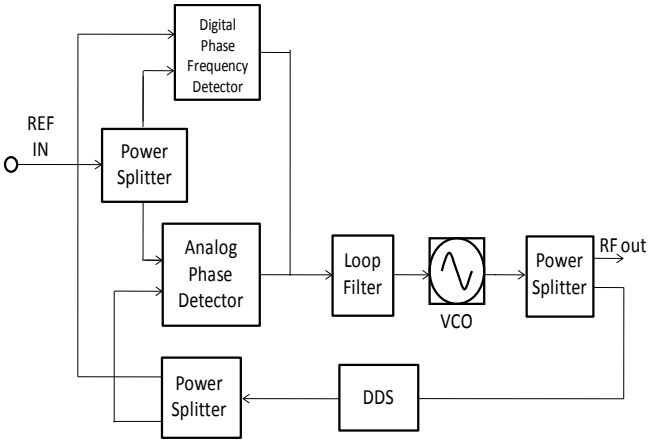

Fig.8. Shows the typical block diagram of DDS based high performance fast switching synthesizer.

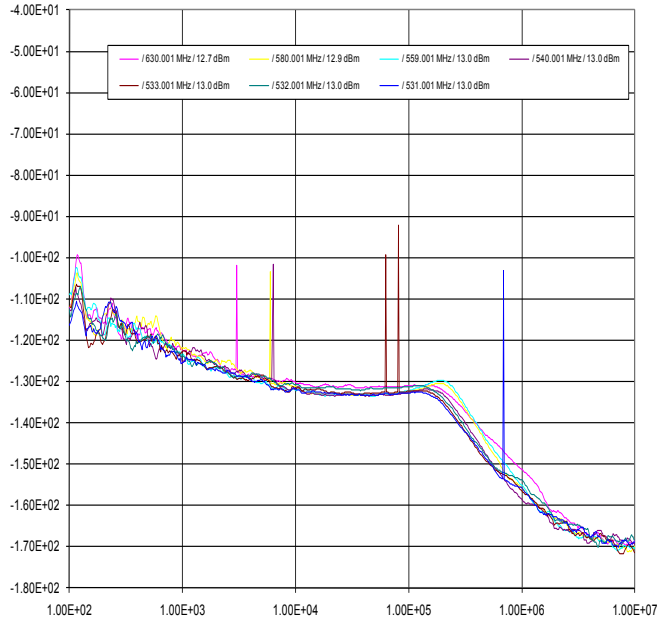

Fig.9. This plot shows the phase-noise of the DDS-based fast-switching frequency synthesizer.

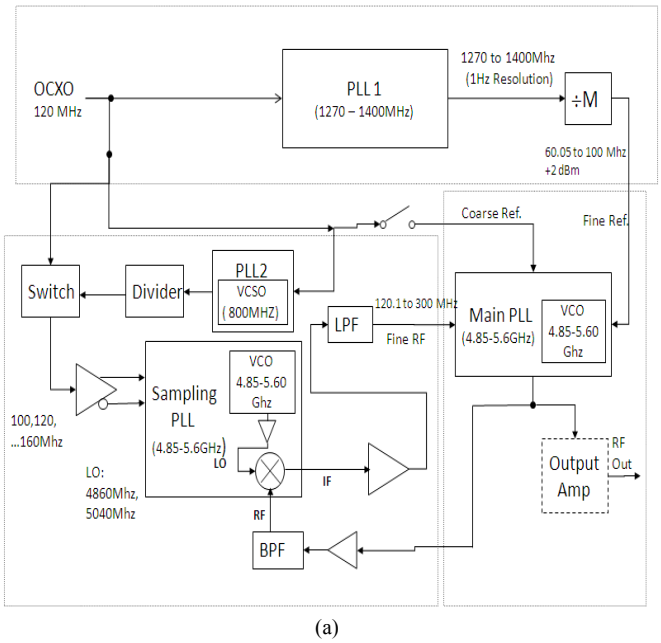
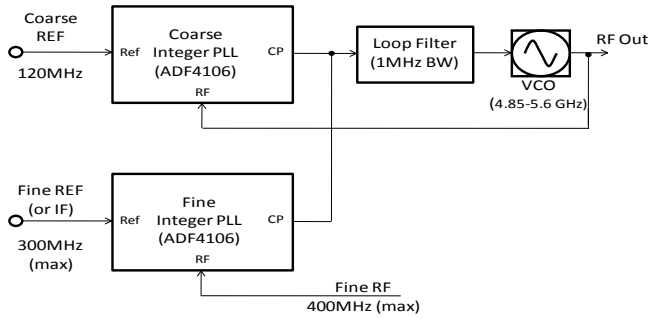
The fine lock is achieved by switching to a fine loop with a reference from PLL1 and fine RF signal from the sampling PLL (Fig. 10c). The sampling PLL features a sampling phase detector with low noise floor. It synthesizes frequencies 120 to 300 MHz away from a desired output frequency by multiplying a reference input signal (from the OCXO or VCSO).

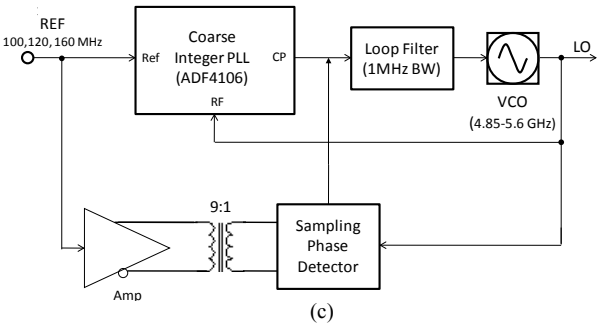
Software is used to choose the appropriate reference for best output spurious performance. The fine RF signal is the difference between RF output and the sampling PLL output (generated by mixing the two and filtering the difference). The fine reference to the main PLL is generated from PLL1. The software determines the PLL1 output frequency and appropriate division ratio (M divider) to achieve the desired output frequency. The synthesizer generates 5000 to 5300 MHz in 100-kHz steps (Fig. 10d) with better than -65 dBc spurious (Fig. 11) and exhibits low phase noise characteristics (Fig. 12).



(a)



(b)



(c)

(d)

Fig.10. This synthesizer architecture (a) uses a sampling PLL with a VCSO providing reference signals, with a (b) main PLL and (c) sampling PLL as part of the design (d) layout and package of the synthesizer module (1.2 x 0.9 inches).

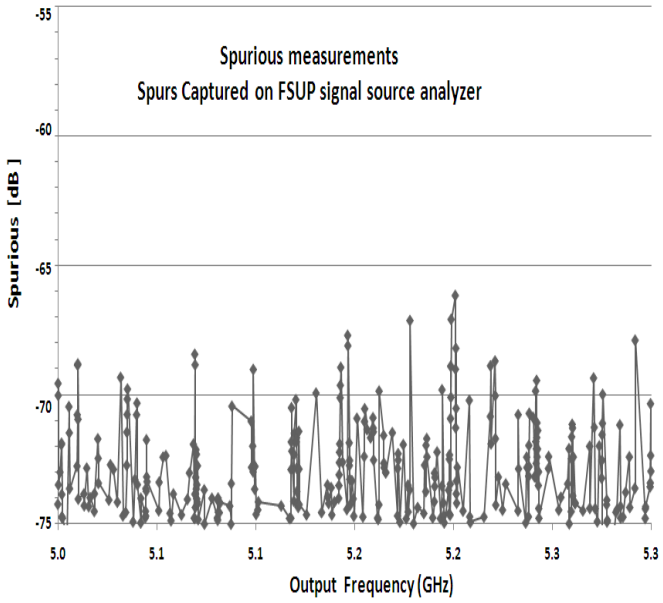


Fig.11. The spurious for the VCSO-based synthesizer with sampling PLL is specified better than -65dBc over the frequency bands (5000-5300MHz)

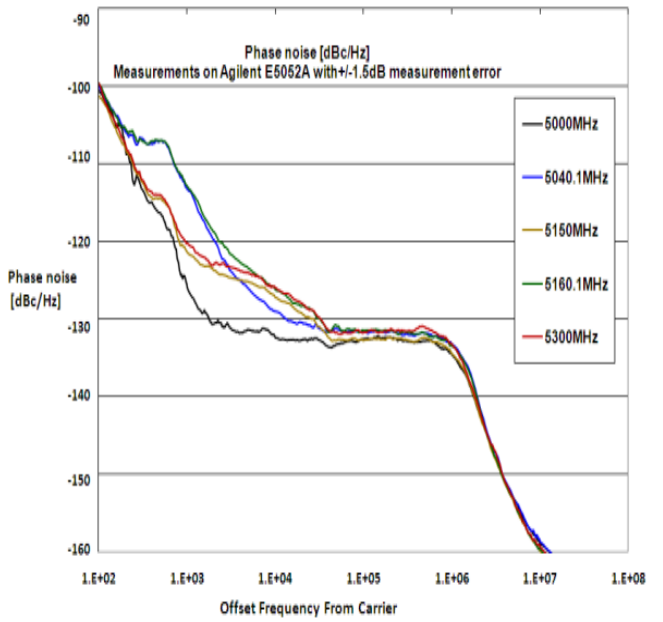

Fig.12. The phase noise for the VCSO-based synthesizer with sampling PLL is specified better than -130 dBc/Hz at 100 kHz from the carrier over the frequency bands (5000-5300 MHz).

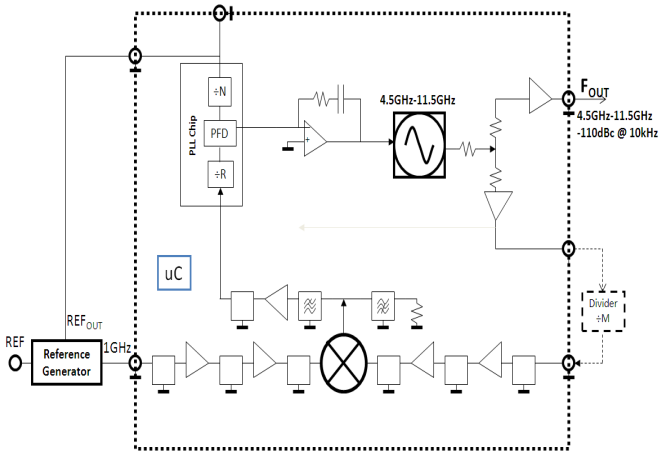
Adaptive mode-coupled VCSOs can also be used in low-spurious synthesizer designs for applications that may require stabilized signals with low levels of spurious noise (Fig. 13).

In such a frequency synthesizer design, the reference generator multiplies a reference frequency (such as 10 MHz) to 1 GHz through a 1-GHz VCSO-based PLL. This 1-GHz signal is mixed with a signal (20 to 150 MHz) from a DDS or flying-adder-based synthesizer to produce a reference signal for the main PLL from 1020 to 1150 MHz [7]-[11].

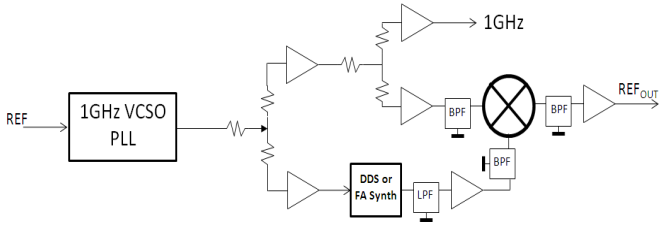
The main PLL is basically a loop that translates a low-noise reference to higher frequencies from 4.5 to 11.5 GHz. The programmable divider (divide-by-M or M-divider) can divide by 4, 5, 6, 7, 8, or 9 for frequencies ranging from DC to 15 GHz. The divider output is fed to the translational loop where this signal is mixed with the 1-GHz low-noise reference and fed as a reference to a PLL chip. The reference from the reference generator is applied to the RF port of the PLL chip. A required frequency is obtained at the output by means of proper reference (R) and divider (N) settings.

It can be seen from Table 1, the division ratios required to implement a high frequency output is low leading to very low phase noise performance of the synthesizer. The advantages of this topology are: design is simple and small enabling small size packaging, performance over size ratio delivered by the architecture is very high, and architecture uses comparatively low cost components.

The drawbacks of this topology are: phase noise is limited by the noise floor of the digital PFD, and even though the division ratios used in the design is low, the noise floor of the dividers degrades the phase noise characteristics.



(a)



(b)

Fig.13. (a) Shows the block diagram main PLL, and (b) the reference generator for the main PLL.

Table1. Describes various settings for different output frequencies

Output Frequency (GHz)	RF Divider (UXM15P)	DDS/FA output frequency (MHz)	R divider	N divider
4.5	4	62.5	2	17
5	4	83.33	3	13
8	7	71.428	2	15
9	8	62.5	2	17
10	8	83.33	3	13
11	9	111.11	3	15

IV. CONCLUSION

By the use of a high performance adaptive synthesis and injection mode-coupling mechanism, low cost, high frequency, and high performance digital frequency synthesizer module is reported in compact package without compromising the phase noise performance, jitter and vibration characteristics.

2-IDT Double-Mode SAW Filters with Decreased Insertion Loss and Advanced Functionalities

Doberstein S. A.,

Omsk Research Institute of Communications & Electronics (ONIIP), Omsk, Russia
e-mail: info@oniip.ru

Abstract— **This paper presents new 2-IDT double-mode SAW (DMS) filters with the decreased insertion loss and advanced functionalities: low input and output impedances, balanced operation and impedance conversion on 42º YX $LiTaO_3$, 64º YX and 41º YX $LiNbO_3$. To decrease the input and output impedances and resistive losses of the IDT electrodes the parallel connection of the 2-IDT DMS filters in the different acoustic tracks is used simultaneously reducing the aperture of each track. For an impedance conversion a series connection of the output IDTs in the 2 parallel acoustic tracks of the filters is used. To increase the selectivity of the filters the cascaded connection and phase weighting are employed. The constructional and topological optimization of the SAW filters is provided with a computer simulation using an equivalent circuit model. The 240-367 MHz samples of the balanced SAW filters have shown an insertion loss of about 1 dB, stopband attenuation of about 20 dB, impedance conversion from 50-75 Ω at the input to 200-300 Ω at the output in a wide fractional bandwidth of 2-6%. Two cascaded filter has provided an insertion loss of less than 2 dB and stopband attenuation of about 50 dB. The filters are housed in the 5x5x1.35 mm SMD packages.**

I. INTRODUCTION

The 3-IDT DMS filters become major as the RF filters for the telecommunication equipment [1]. In spite of the simpler design the 2-IDT DMS filters have not found wide application because they have the high input and output impedances of 130-200 Ω, large insertion loss and require the complex topologies for the impedance conversion [2-4]. This paper presents new 2-IDT DMS filters with the decreased insertion loss and advanced functionalities: low input and output impedances, balanced operation and impedance conversion on 42º YX $LiTaO_3$, 64º YX and 41º YX $LiNbO_3$. To decrease the input and output impedances and resistive losses of the IDT electrodes the parallel connection of the 2-IDT DMS filters in the different acoustic tracks is used simultaneously reducing the aperture of each track (Fig.1) [5]. The balanced operation of the filters is provided by symmetrical connection of the parallel input and output IDTs to the loads. In order for a low input impedance of the filters to be converted to a high output impedance a series connection of the output IDTs in the 2 parallel acoustic tracks of the filters is used (Fig.2). The strongly different impedances at the input and output are achieved with the use of this method of the impedance conversion without applying the complex topologies [4] and without disturbing the balanced operation at the output of the filter. In this case the natural symmetry of the output IDTs and the geometrical symmetry of the bus-bars and contact pads are used.

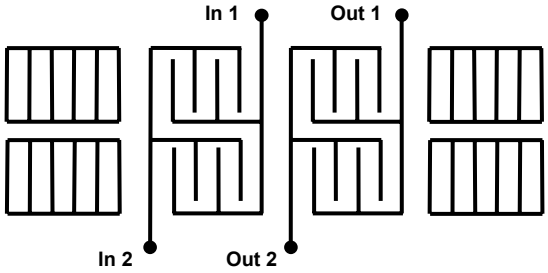

Figure 1. Balanced 2-IDT DMS filter with a parallel connection of the input and output IDTs

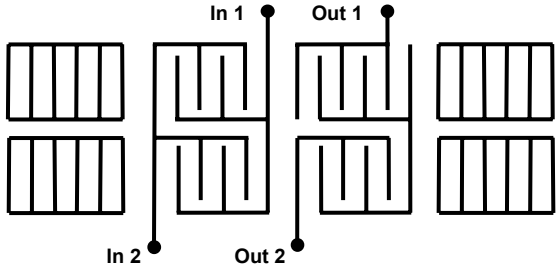

Figure 2. Balanced 2-IDT DMS filter with a parallel connection of the input IDTs and a series connection of the output IDTs

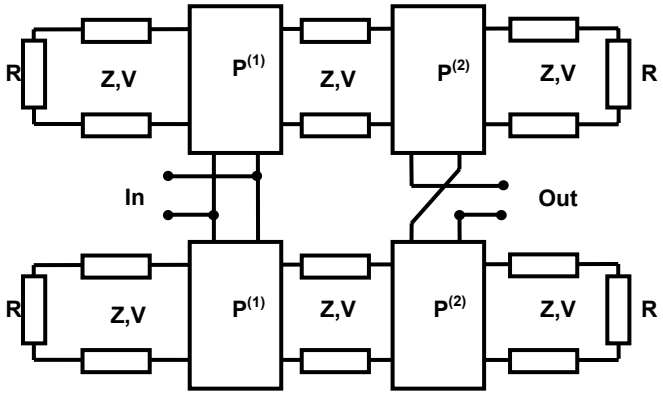

Figure 3. Equivalent circuit of the 2-IDT DMS filter with impedance conversion

II. Simulated and Experemental Results.

A theoretical analysis of the balanced 2-IDT DMS filter was provided using a computer simulation on a basis of an equivalent circuit model [4]. The equivalent circuit of the balanced 2-IDT DMS filter with a parallel connection of the input ITDs and a series connection of the output IDTs is shown on Fig. 3. Here $P^{(1)}$ is a mixed matrix of the input IDT, $P^{(2)}$ is a mixed matrix of output IDT, Z is characteristic impedance of the medium between IDTs and reflectors, V is a SAW velocity, R is an equivalent impedance for a reflector. Fig. 4 shows a simulated frequency response of the balanced 2-IDT DMS filter on 42° YX $LiTaO_3$ in a 50-Ω –200-Ω system. The filter has shown a 3-dB fractional bandwidth of 2% with minimal insertion loss and ripple, stopband attenuation around 20 dB at ±5% offset from a center frequency. The measured frequency response of the balanced 2-IDT DMS filter is shown in Fig. 5. The filter has been symmetrically connected to a 50-Ω input load and to a 200-Ω output load. Measurements were carried out by the network analyzer and balanced transformers.

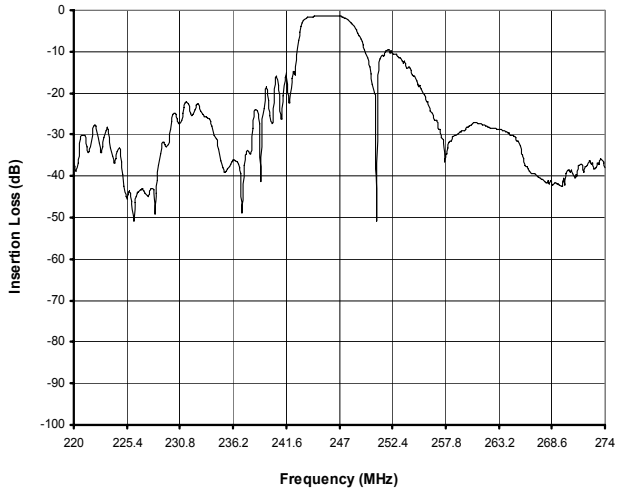

Figure 4. Simulated frequency response of the 2-IDT DMS filter on 42˚ YX $LiTaO_3$

The losses of the balanced transformers were eliminated from the measured insertion loss of the filter. At a center frequency of 246.7 MHz the filter has shown an insertion loss of about 1 dB, 3-dB fractional bandwidth of 5.9 MHz with a low ripple of 0.5 dB and stopband attenuation above 20 dB at ± 12 MHz offset from the center frequency. Fig. 4 and Fig. 5 show good agreement between the simulated and measured responses. A measured input impedance characteristic of the filter is shown in Fig. 6. As will be seen from Fig. 6 at the center frequency of 246.7 MHz the input impedance of the filter is close to real value of 50 Ω. The measured output impedance characteristic of the filter is shown in Fig. 7. As will be seen from Fig. 7 at the center frequency of 246.7 MHz the output impedance of the filter is close to real value of 200 Ω. Thus the impedance conversion from 50 Ω to 200 Ω was obtained experimentally in the 2-IDT DMS filter with a parallel connection of the input ITDs and a series connection of the output IDTs (Fig. 2). For the filter without an impedance conversion (with parallel connection of the input and output IDTs (Fig.1)) a very low insertion loss of less than 1dB was provided in a balanced 50-Ω system. It can be shown that the filters on 64° YX and 41° YX $LiNbO_3$ provide the similar frequency responses with 4% and 6% fractional bandwidth respectively and impedance conversion from 75 Ω to 300 Ω. The measured frequency response of the filter on 64° YX $LiNbO_3$ is shown in Fig. 8. At a center frequency of 367.14 MHz the filter has shown an insertion loss of about 1dB, 3-dB bandwidth of 14.3 MHz, stopband attenuation over 20 dB at ±35 MHz offset from the center frequency in a balanced 75-Ω – 300-Ω system. Fig. 9 shows the measured frequency response of the filter on 41° YX $LiNbO_3$. At a center frequency of 276 MHz the filter has shown an insertion loss of about 1 dB, 3-dB bandwidth of 16.7 MHz, stopband attenuation over 20 dB at ± 33 MHz offset from the center frequency in a balanced 75-Ω – 300-Ω system. To increase the stopband attenuation we can use the phase weighting and cascading two filters. The measured frequency response of the filter on 42° YX $LiTaO_3$ with phase weighting parallel-connected input ITDs is shown in Fig.10.

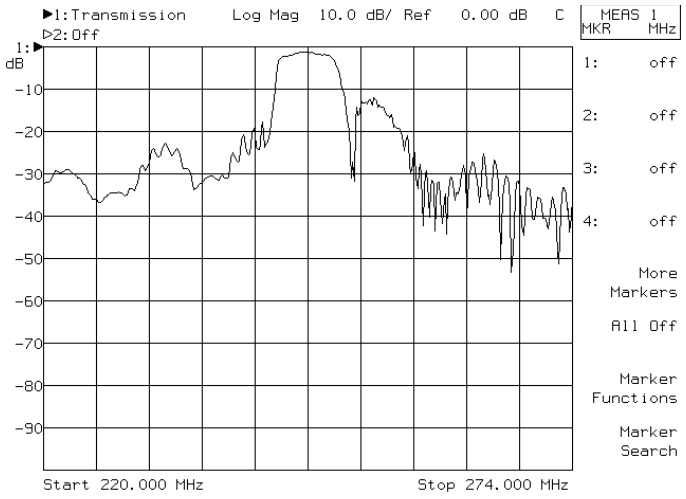

Figure 5. Measured frequency response of the 2-IDT DMS filter on 42˚ YX $LiTaO_3$

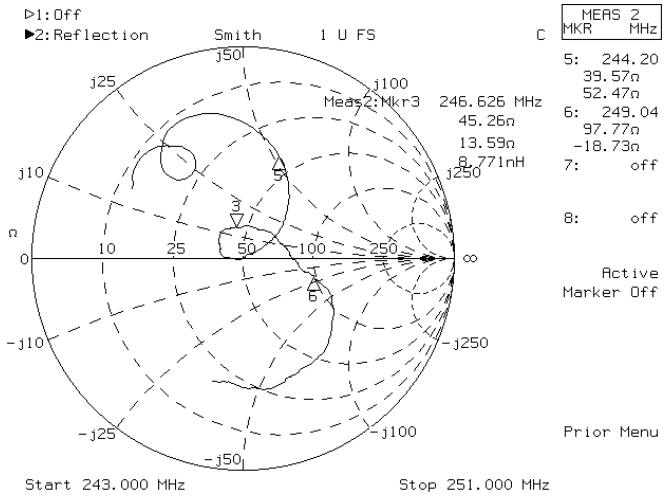

Figure 6. Measured input impedance characteristic of the 2-IDT DMS filter on 42˚ YX $LiTaO_3$

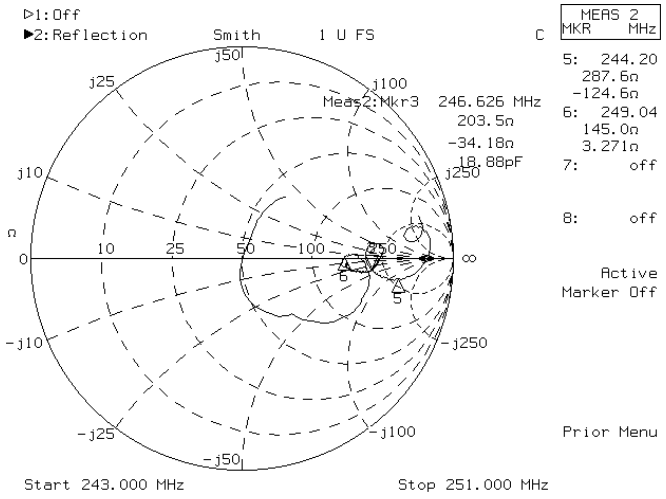

Figure 7. Measured output impedance characteristic of the 2-IDT DMS filter on 42˚ YX $LiTaO_3$

At a center frequency of 276 MHz the filter has shown an insertion loss of about 1 dB, 2-dB bandwidth of 3.3 MHz, stopband attenuation over 40 dB at ±11 MHz offset from the center frequency in a balanced 50-Ω – 200-Ω system. Fig.11. shows the frequency response of the cascade of two balanced filters on 42° YX $LiTaO_3$. The first filter is built without the impedance conversion (with parallel connection of the input and output IDTs). The second filter is built with the impedance conversion (with a series connection of the output IDTs). In a 50-Ω – 200-Ω balanced system the cascade filter has shown an insertion loss of less than 2 dB, 2-dB bandwidth of 4.3 MHz, stopband attenuation of about 50 dB at ±11 MHz offset from the center frequency.

III. CONCLUSION

Our new 2-IDT DMS filters have decreased insertion loss and wider functionalities than their much used prototypes [2-4] and they will be widely employed in the telecommunication equipment. For example these filters offer a single-chip solution for the front-end of the high frequency handheld transceivers for matching the low impedance antenna with modern high impedance double balanced mixer and for suppression of the local oscillator and image frequencies. The filters are housed in the 5x5x1.35 mm SMD packages.

***Abstract*— Langatate (LGT) is a member of the langasite family of crystals appropriate for high-temperature frequency control and sensing applications. This paper identifies multiple LGT SAW orientations for use at high temperature, specifically in the 400 to 900°C range. Orientations with low sensitivity to temperature are desired for frequency control devices and many sensors, conversely large temperature sensitivity is a benefit for temperature sensors. The LGT SAW temperature behavior has been calculated along orientation searches, sweeping the Euler angles (0°, Θ, Ψ), (90°, Θ, Ψ), and (Φ, 90°, Ψ). The temperature coefficient of delay (TCD) and total frequency change over the temperature range were analyzed from 400 to 900°C. Multiple SAW orientations were found with zero-TCD between 400 and 500°C, but no orientations were identified with turn-over temperatures above 500°C. Other orientations have a low variation, −0.8%, in frequency over the range from 400 to 800°C. Additionally, temperature-sensitive orientations were identified with TCD up to 75 ppm/°C at 900°C, for use as temperature sensors at high temperature. The predictions are shown to agree with measured behavior of LGT SAW delay lines fabricated along 6 orientations in the (90°, 23°, Ψ) plane.**

I. INTRODUCTION

There is growing need for high-temperature sensors and frequency control devices in oil and gas extraction, metal and ceramic manufacturing, aerospace, and energy generation industries [1]-[4]. Surface acoustic wave (SAW) devices can meet the demands for high-temperature survivability and wireless multi-sensor operation using substrates such as gallium orthophosphate ($GaPO_4$) and the langasite family of crystals, including langasite ($La_3Ga_5SiO_{14}$, LGS) and langatate ($La_3Ga_{5.5}Ta_{0.5}O_{14}$, LGT) [5]-[16]. Langatate, in particular, has a number of attractive properties for high-temperature operation: i) no phase change until the melting point at 1470°C [17], [18], ii) piezoelectric constants 2-4 times those of quartz [18], iii) higher resistivity than LGS [17], iv) demonstrated temperature-compensated SAW orientations both around room temperature and at elevated temperatures [18]-[22]. However, so far there has been very limited published on high-temperature orientation searches for LGT. In [9], [10] LGS SAW properties were calculated up to 1000°C, but the constants and temperature coefficients employed were taken from [23] and those were measured around at room temperature. Several modern high-temperature frequency control and sensing applications require operation beyond 400°C. For example, sensors are desired for high-temperature fuel cells, which operate in the 600-1000°C range [24], and for gas turbine engines in the compressor, combustor, and exhaust engine sections, which can typically reach temperatures around 450-750°C, 900-1500°C, and 650°C, respectively [24], [25].

In this work, LGT SAW propagation properties are investigated from 400 to 900°C utilizing constants and temperature coefficients extracted at high-temperature [21]. The SAW properties are calculated according to three different orientation sweeps. The search results are used to identify orientations with either low or high sensitivity to temperature. The orientations are investigated along the Euler angles (0°, Θ, Ψ), (90°, Θ, Ψ), and (Φ, 90°, Ψ), in which 2 Euler angles are swept. Multiple zero-TCD orientations are identified between 400 and 500°C. SAW orientations with a small total frequency shift, −0.8%, between 400 and 800°C were also identified, which are anticipated to find use in sensor and frequency-control devices. Orientations with large temperature sensitivity above 400°C are uncovered and those can be utilized as temperature sensors.

The LGT material constants used and the SAW property identification targets are described in Section II. The calculation results of the SAW orientation sweeps are presented in Section III and analyzed to identify high-temperature orientations with either low or high sensitivity to temperature along different temperature ranges. Section IV details high-temperature SAW measurements that provide experimental verification of predicted LGT SAW properties. Section V concludes the paper.

II. MATERIAL CONSTANTS AND SAW PROPERTIES CALCULATIONS

In this work the LGT stiffened elastic constants from [20], [21] and the density and thermal expansion from [26] are used for the high-temperature LGT SAW predictions. The SAW electromechanical coupling (K^2) predictions come from [27], [28], since the high-temperature stiffened elastic constants from [20], [21] do not separately consider the piezoelectric effects. Therefore in this paper all the reported values of K^2 refer to calculations at 25°C. In [21] the authors observed that

all the fabricated SAW devices at orientations where $K^2 > 0.2\%$ at room temperature operate up to at least 900°C.
