The SAW properties are calculated using the matrix method implemented with MATLAB (The MathWorks, Natick, MA, USA) [19] to sweep across three regions of Euler angles: Region A = (0°, Θ, Ψ), Region B = (90°, Θ, Ψ), and Region C = (Φ, 90°, Ψ). The LGT SAW velocity, frequency change, and TCD were calculated at 400, 500, 600, 700, 800, and 900°C over those three regions by varying two Euler angles, as indicated. These sweeps were selected because they represent cut planes with surface normals in the Y-Z, X-Z, and X-Y planes for easier wafer cutting and X-ray alignment. For the (Φ, 90°, Ψ) sweeps, Ψ was searched only from 0 to 40° because in this region $K^2 \geq 0.1\%$. Only orientations with $K^2 > 0.1\%$ at 25°C are discussed for TCD and frequency change in this work.

The LGT SAW propagation properties analysis at high temperature aimed at identifying potential orientations for three different conditions: (i) narrow temperature range of operation; (ii) large temperature range of operation (400 to 800°C); and (iii) operation of several orientations in a same plane (variation of third Euler angle, Ψ). First, SAW orientations for a narrow operation temperature range were searched for low and high TCD. Next, change in SAW frequency from 400 to 800°C is used to identify orientations for a wider range of operation temperatures. Finally, SAW cuts are investigated for multiple promising orientations in the same plane. Multiple devices on the same wafer with different orientations are useful for sensor applications [29]-[31].

III. Langatate SAW Properties at High Temperature

A. SAW TCD at High Temperature

The calculated LGT SAW TCD for Region A, the Euler angles (0°, Θ, Ψ), at 400°C, 600°C, and 900°C are displayed as contour plots in Fig. 1(a), 1(b), and 1(c), respectively, and are representative of the data calculated at the 6 temperatures (400, 500, 600, 700, 800, and 900°C) mentioned in Section II. The LGT SAW TCD calculated at 400°C for the Regions B, (90°, Θ, Ψ), and C (Φ, 90°, Ψ), are shown in Fig. 2 and Fig. 3, respectively.

For the three regions swept, A, B, and C, orientations with TCD=0 were only found at 400°C and none were found at 500°C or higher; however, multiple orientations have negative TCD at 400°C indicating the existence of turn-over temperatures between 400 and 500°C. In particular, LGT SAW orientations with Euler angles (90°, 40→70°, 60→75°) have $0.1 \leq K^2 \leq 0.2\%$ at room temperature, TCD ≈ −10 ppm/°C at 400°C and TCD ≈ 5 ppm/°C at 500°C. Therefore these orientations have TCD=0 between 400 and 500°C, the highest turnover temperatures for LGT identified in this work for orientations with $K^2 \geq 0.1\%$.

Multiple LGT SAW orientations were found that have close to zero or zero TCD at 400°C and $K^2 \geq 0.1\%$; their Euler angles are listed in Table I along with the respective TCD and K^2.

There are also regions with higher TCD that can be useful for temperature sensing. Specifically, (0°,135→150°, 20→25°) has TCD ≈ 25ppm/°C at 400°C and $K^2 \approx 0.7\%$. Orientations in the region (90°, 20→40°, 110→130°) have TCD between 15 and 35 ppm/°C at 400°C and $0.3\% \leq K^2 \leq 0.7\%$. At 900°C all the calculated orientations were found to have TCD between 40 and 75 ppm/°C.

B. SAW Frequency Change from 400 to 800°C

The LGT SAW behavior for a large temperature span was analyzed by calculating the total SAW frequency change from 400 to 800°C, $\Delta f/f_{400} = (f_{800°C} - f_{400°C})/ f_{400°C}$, shown in Fig. 4 for the Regions A, B, and C.

As can be seen from Fig. 4, the LGT SAW orientations in the range (90°, 55→75°, 55→80°) have the lowest temperature sensitivity from 400 to 800°C, $\Delta f/f_{400} = -0.6\%$, among the calculated orientations with $K^2 \geq 0.1\%$. The SAW orientations (0°, 40→90°, 40→50°) and (90°, 25→80°, 55→65°) have $\Delta f/f_{400} \approx -0.8\%$ with $0.1\% \leq K^2 \leq 0.3\%$. The moderate frequency change is partly due to the fact that these orientations have turnover temperatures between 400 and 500°C.

Conversely, other LGT orientations have larger temperature dependencies. Orientations in the ranges (0°, 10→30°, 65→90°), (0°, 110→160°, 15→45°) and (90°, 15→40°, 95→140°) have $\Delta f/f_{400}$ between −1.2% and −1.8% with $0.2\% \leq K^2 \leq 0.7\%$. These orientations have high TCD through out the temperature range: 15 to 40 ppm/°C at 400°C and 40 to 70 ppm/°C at 800°C.

C. SAW Plane Cuts for High-Temperature Sensor Suites

Multiple regions of LGT SAW planes have been identified as desirable for fabricating a suite of devices on the same wafer with $K^2 \geq 0.2\%$ and a variety of temperature sensitivities, useful for sensor applications. LGT planes in the range (0°, 120→140°, Ψ) contain SAW orientations with both low and high temperature-sensitivities, $\Delta f/f_{400}$ ranging from −0.8% to −1.4%, and K^2 ranging from 0.2% to 0.7%.

LGT planes in the range (90°, 20→40°, Ψ) have regions in which there are SAW orientations with small temperature sensitivity, $\Delta f/f_{400} = -0.8\%$, and others with large temperature sensitivity, $\Delta f/f_{400} = -1.8\%$, and K^2 varying between 0.2% and 0.7%. Additionally, there are a number of orientations in this range that have $\Delta f/f_{400} = -1.0\%$ and that are widely spaced over the plane, with potential for multiple measurand sensor applications.

IV. Experimental Verification and Discussion

The SAW high-temperature properties calculated in this work were compared to those of LGT SAW devices reported in [21] for experimental validation of the frequency and TCD predictions up to 900°C. Six SAW delay lines were fabricated along orientations (90°, 23°, Ψ) with Ψ = 0, 13, 48, 77, 119, and 123°. The interdigital transducers had periodicity given by wavelength λ = 32 μm and utilized 110-nm-thick Pt/Rh/ZrO_2 electrodes [13] to enable stable high-temperature operation above 900°C.

Figure 1. Contour plots of predicted LGT SAW TCD in ppm/°C for Region A, Euler angles (0°, Θ, Ψ): (a) at 400°C, (b) at 600°C, (c) at 900°C.

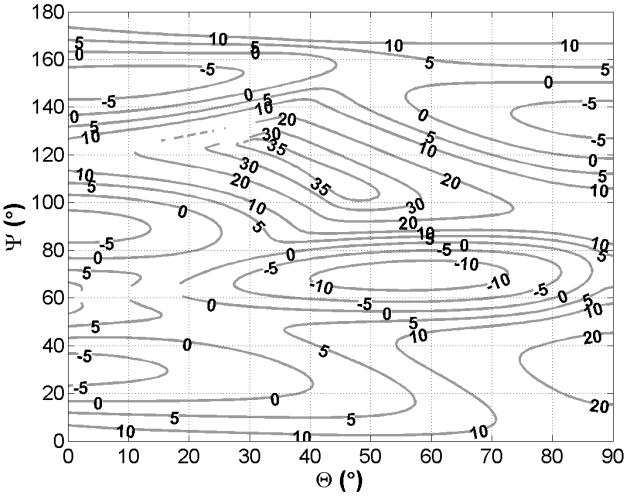

Figure 2. Contour plot of predicted LGT SAW TCD in ppm/°C for Region B, Euler angles (90°, Θ, Ψ), at 400°C.

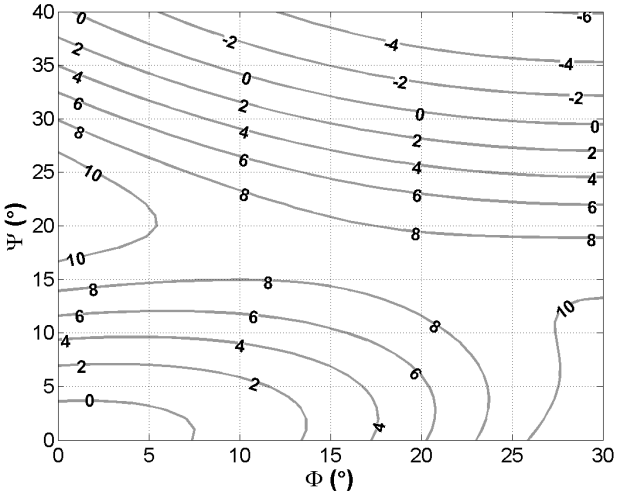

Figure 3. Contour plot of predicted LGT SAW TCD in ppm/°C for Region C, Euler angles (Φ, 90°, Ψ), at 400°C.

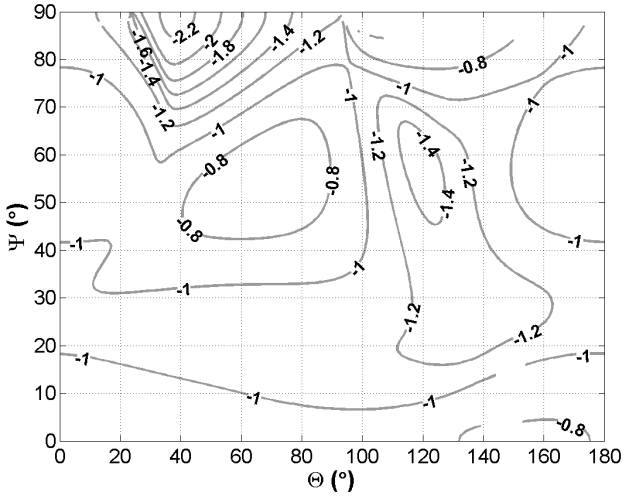
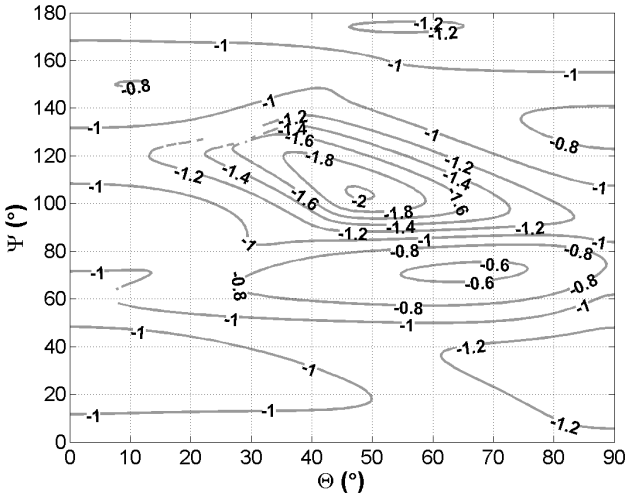
TABLE I. LGT SAW ORIENTATIONS WITH TCD ≈ 0 AT 400°C

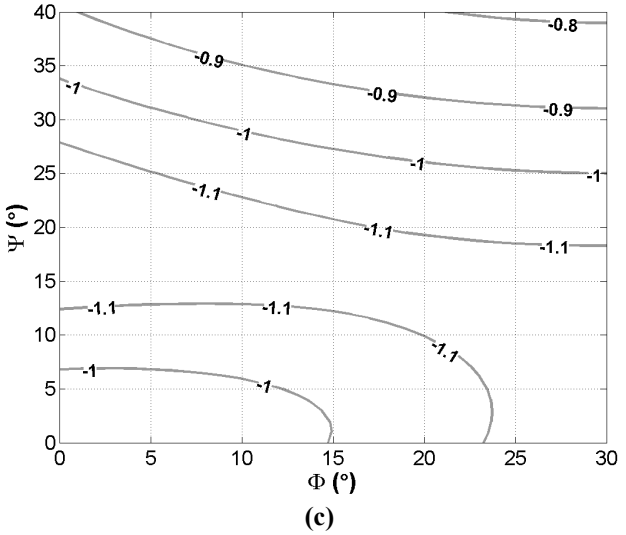
Euler Angle Sweep (°)	Orientation Euler Angles (°)	TCD at 400°C (ppm/°C)	K^2 at 25°C (%)
(0°, Θ, Ψ)	(0, 20→90, 30→50)	−5 to 5	0.1 to 0.4
Region A	(0, 30→130, 0→15)	−5 to 5	0.1 to 0.5
	(0, 110→180, 0→90)	−5 to 5	0.1 to 0.4
(90°, Θ, Ψ)	(90, 10→90, 40→80)	−10 to 5	0.1 to 0.4
Region B	(90, 0→20, 100→105)	≈0	0.1 to 0.2
	(90, 0→20, 35→140)	≈0	0.1 to 0.2
	(90, 0→40, 10→20)	≈0	0.1 to 0.2
	(90, 0→40, 155→170)	≈0	0.1 to 0.2
(Φ, 90°, Ψ)	(0→8, 90, 0→5)	≈0	0.5
Region C	(0→30, 90, 28→40)	≈0	0.1 to 0.2



(a)



(b)



(c)

Figure 4. Contour plots of predicted LGT SAW frequency change (percent) from 400 to 800°C, $\Delta f/f_{400} = (f_{800°C} - f_{400°C})/ f_{400°C}$, for orientation sweep (a) Region A, Euler angles (0°, Θ, Ψ), (b) Region B, Euler angles (90°, Θ, Ψ), and (c) Region C, Euler angles (Φ, 90°, Ψ).

The calculated and measured SAW frequencies responses are compared in Fig. 5(a) and 5(b) at 400 and 900°C, respectively, for the six orientations identified in the previous paragraph. Along the 6 fabricated orientations the measured and predicted operation frequencies agree within experimental and prediction uncertainties in the temperature range of 400 to 900°C. The calculated SAW frequencies are within 0.85% of the measured frequencies at 400°C and within 1.6% at 900°C.

The predicted and measured TCDs on the (90°, 23°, Ψ) plane are compared in Fig. 6 at 400°C. The predicted and measured TCD agree to within the experimental and prediction uncertainty for the 6 tested SAW orientations throughout the temperature range between 400 and 900°C. The discrepancy between the predicted and measured TCD is below 4.7 ppm/°C at 400°C and less than 24.4 ppm/°C at 900°C.

The agreement between the calculated and measured SAW frequency and TCD for the 6 orientations fabricated along the (90°, 23°, Ψ) plane validates the LGT high-temperature constants and coefficients for SAW predictions at high-temperature.

V. Conclusions

This work has investigated the high-temperature SAW phase velocity, frequency change, and TCD properties behavior of LGT up to 900°C for three regions in space, namely, (0°, Θ, Ψ), (90°, Θ, Ψ), and (Φ, 90°, Ψ). New LGT SAW orientations have been identified with zero TCD between 400 and 500°C and with low TCD up to 900°C with potential applications for frequency control, sensing, and signal processing. Alternatively, temperature-sensitive orientations have been found of interest to temperature sensing.

Orientations have been identified for high-temperature applications with: i) a narrow temperature range of operation; ii) large temperature range of operation (400 to 800°C); and iii) multiple orientations in a same plane for temperature measurement and separation of the thermal effect from other measurands, as appropriate in sensor applications.

The agreement between the calculated and measured SAW frequency and TCD responses reported in the work validates the LGT constants and temperature coefficients for SAW predictions up to 900°C.

Acknowledgment

The authors would like express their gratitude to the personnel of the Laboratory of Surface Science and Technology (LASST) and Department of Electrical and Computer Engineering at the University of Maine for valuable technical discussion and for assisting with the equipment used in this work and with the fabrication of the devices.

Temperature Coefficients of Elastic Constants of Trigonal and Tetragonal Crystals

B.P. Sorokin, A.V. Telichko
Technological Institute for Superhard and Novel Carbon Materials
Troitsk, Moscow region, Russia
E-mail: bpsorokin2@rambler.ru

***Abstract*—Temperature coefficients of elastic constants (TC_{ij}) for trigonal and tetragonal crystals have been obtained. The TC_{ij} of a number of trigonal and tetragonal crystals have been calculated and the comparison with known experimental data has been fulfilled. The nature of anomalous TC_{66} of quartz has been discussed.**

I. INTRODUCTION

Normal temperature behavior of elastic constants for most of the crystals is proportionally decreased with temperature increasing and a small dependence (or lack thereof) at low temperatures. Knowledge of these dependences is important for the solid state physics and applications of crystals.

One of most attractive properties of quartz is the temperature stability observed for some crystalline cuts and modes. Owing to combination of thermostability with piezoelectricity and small attenuation of acoustic waves quartz single crystal has great importance as a material for acoustoelectronic devices. There are only a few piezoelectric crystals possessing the same combination of properties. Nature of the temperature stability is closely connected with elastic anharmonicity of specified elastic modes in such crystals. In practice the search of cuts possessing thermostable orientation was commonly based on the data of temperature coefficients of elastic constants obtained from experiment. Unfortunately there is no exact theory which can be used for explanation of anharmonic behavior of crystals. Consequently a possibility to predict a trend of the search for the new thermostable materials and crystalline cuts is absent. On the basis of the theory explaining the small amplitude bulk acoustic waves (BAW) propagation in crystals under the influence of bias finite fields the temperature coefficients (TC_{IJ}) of elastic constants (C_{IJ}) of cubic crystals have been obtained earlier [1]. Satisfactory agreement between calculation and experimental results for a number of cubic crystals has been achieved. The similar method of calculations of frequency dependences on temperature in quartz piezoelectric resonators has been used by authors [2].

The main objective of this paper is to obtain the temperature coefficients for trigonal and tetragonal crystals.

II. EFFECT OF TEMPERATURE ON THE PROPAGATION OF BULK ACOUSTIC WAVES IN CRYSTALS

In the theory of BAW propagation in crystals under the action of the temperature as a bias field both two effects of geometrical and physical nonlinearity of elastic media should be taken into account. As a result of first effect the temperature action leads to anisotropic dilatation of low symmetry crystals, to the distortion of the sample's shape and therefore to the changing of the path of acoustic wave. Secondly the weakening of chemical bonds between atoms under the thermal expansion usually leads to the decreasing of the macroscopic elastic constants of a crystal. Modified Green-Christoffel's equation for elastic waves of small amplitude in a uniformly deformed elastic medium referred to initial (natural) state can be written as [3]:

$$\left[\Gamma_{BC}(\bar{\eta}) - \rho_0 v^2 \delta_{BC}\right]\tilde{U}_B = 0. \tag{1}$$

Here ρ_0 is the density of undisturbed crystal; v is the phase velocity and $\tilde{U}_B$ is the BAW displacement vector. For a mechanically free sample the static deformation arising due to thermal expansion can be described by the relation:

$$\bar{\eta}_{PQ} = \alpha_{PQ}\Delta T, \tag{2}$$

where α_{PQ} is the tensor of linear thermal expansion. Using the form of Green-Christoffel's tensor obtained earlier [3] and the static deformation (2), in this case we can write:

$$\begin{aligned}\Gamma_{BC}(\Delta T) &= \bar{C}_{FC} C^*_{ABFD} N_A N_D = \\ &= \bar{C}_{FC}\left(C^S_{ABFD} + C^S_{ABFDPQ}\alpha_{PQ}\Delta T\right)N_A N_D,\end{aligned} \tag{3}$$

where $\bar{C}_{FC}$ is Green's tensor of finite static deformation; C^*_{ABFD}, C^S_{ABKL} and C^S_{ABKLPQ} are the effective, 2nd and 3rd order elastic constants (SOEC and TOEC) respectively; N_A is

the unit vector of wave propagation direction. Under the thermal expansion of mechanically free crystal Green's tensor takes a form:

$$\overline{C}_{FC} = \delta_{FC} + 2\overline{\eta}_{FC} = \delta_{FC} + 2\alpha_{FC}\Delta T. \quad (4)$$

Substituting (4) into (3) and taking into account only the terms proportional to ΔT a linearized form of Green-Christoffel's tensor can be obtained:

$$\Gamma_{BC}(\Delta T) = [C^{S}_{ABCD} + (2C^{S}_{ABPD}\delta_{CQ} + C^{S}_{ABCDPQ})\alpha_{PQ}\Delta T]N_A N_D. \quad (5)$$

Solution of system (1) with tensor (5) for the chosen elastic modes in the certain directions of the crystals gives us the required temperature coefficients of elastic constants. So the main relations applying to the 32, 3m and $\overline{3}$m trigonal crystals have a form:

$$\begin{aligned}
\frac{dC_{11}}{dT} &= (2C_{11} + C_{111} + C_{112})\alpha_{11} + C_{113}\alpha_{33},\\
\frac{dC_{33}}{dT} &= 2C_{133}\alpha_{11} + (2C_{33} + C_{333})\alpha_{33},\\
\frac{dC_{44}}{dT} &= (2C_{44} + C_{144} + C_{155})\alpha_{11} + C_{344}\alpha_{33},\\
\frac{dC_{66}}{dT} &= \frac{1}{2}[(4C_{66} + C_{222} - C_{112})\alpha_{11} + (C_{113} - C_{123})\alpha_{33}],\\
\frac{dC_{13}}{dT} &= \frac{1}{2}[(C_{113} + C_{123})\alpha_{11} + (2C_{13} + C_{133})\alpha_{33}],\\
\frac{dC_{14}}{dT} &= (2C_{14} + C_{114} + C_{124})\alpha_{11} + C_{134}\alpha_{33}.
\end{aligned} \quad (6)$$

Similar relations for hexagonal (622, 6mm, $\overline{6}$2m, 6/mmm) crystals have a form:

$$\begin{aligned}
\frac{dC_{11}}{dT} &= (2C_{11} + C_{111} + C_{112})\alpha_{11} + C_{113}\alpha_{33},\\
\frac{dC_{33}}{dT} &= 2C_{133}\alpha_{11} + (2C_{33} + C_{333})\alpha_{33},\\
\frac{dC_{44}}{dT} &= (2C_{44} + C_{144} + C_{155})\alpha_{11} + C_{344}\alpha_{33},\\
\frac{dC_{66}}{dT} &= \frac{1}{2}[(4C_{66} + C_{222} - C_{112})\alpha_{11} + (C_{113} - C_{123})\alpha_{33}],\\
\frac{dC_{13}}{dT} &= \frac{1}{2}[(C_{113} + C_{123})\alpha_{11} + (2C_{13} + C_{133})]\alpha_{33}.
\end{aligned} \quad (7)$$

Note that for trigonal and hexagonal crystals there is the relation between elastic constants $C_{66} = \frac{1}{2}(C_{11}-C_{12})$. Temperature coefficients for the tetragonal (422, 4mm, $\overline{4}$2m, 4/mmm) crystals can be written as:

$$\begin{aligned}
\frac{dC_{11}}{dT} &= (2C_{11} + C_{111} + C_{112})\alpha_{11} + C_{113}\alpha_{33},\\
\frac{dC_{33}}{dT} &= 2C_{133}\alpha_{11} + (2C_{33} + C_{333})\alpha_{33},\\
\frac{dC_{44}}{dT} &= (2C_{44} + C_{144} + C_{155})\alpha_{11} + C_{344}\alpha_{33},\\
\frac{dC_{66}}{dT} &= 2(C_{66} + C_{133})\alpha_{11} + C_{366}\alpha_{33},\\
\frac{dC_{12}}{dT} &= (C_{12} + C_{112})\alpha_{11} + \frac{1}{2}C_{123}\alpha_{33},\\
\frac{dC_{13}}{dT} &= \frac{1}{2}[(C_{113} + C_{123})\alpha_{11} + (2C_{13} + C_{133})\alpha_{33}].
\end{aligned} \quad (8)$$

As a result of analysis of (6), (7) and (8) one can conclude that temperature coefficients of elastic constants substantially depend on the anharmonic 3rd order elastic constants and coefficients of linear thermal expansion. Terms formed as the productions of TOEC and coefficients of linear thermal expansion represent the physical nonlinearity; SOEC multiplying by coefficients of linear thermal expansion define the geometrical nonlinearity.

III. Results and Discussion

Using derived relations we have been calculated first order temperature coefficients of trigonal, hexagonal and tetragonal crystals with known SOEC and TOEC and linear thermal expansion. Calculated results have been compared with known experimental data (tabs. I-III). Material constants and experimental temperature coefficients were taken from [4-39].

In the most cases the agreement of signs between the experimental and calculated temperature coefficients has been obtained. A negative sign of TC_{IJ} is associated with normal temperature dependence. Anomalous positive sign of TC_{66} has been calculated for quartz in agreement with experiment. Especially good agreement between experimental and calculated data takes a place for diagonal constants. Note that some crystals (quartz, lithium niobate, magnesium) have shown the most adequate coincidence both in sign and magnitude of TC_{IJ}. On the contrary the most unsatisfactory coincidence is observed for Zn and Er data (tab. II).

The main origin of discrepancies could be connected with mistakes in measuring of SOEC and TOEC and linear thermal expansion coefficients. Commonly such investigations have been executed by different working groups using the samples of various origins. Especially the effect of real defect structure of various crystals should result in the discrepancy of 3rd order elastic constants. On the other side as one can see from the tables there are mistakes in experimentally obtained temperature coefficients.

Therefore the difference between the experimental and calculated temperature coefficients could be used for independent analysis of mistakes' origin.

dC_{12}/dT	-11,3	-16,9	-21,2	-13,0	-9,4	-
dC_{13}/dT	-2,9	-1,5	4,9	-4,2	-5,0	-

Let's analyze the nature of anomalous value of TC_{66} which can be observed in trigonal crystals. It is convenient to rewrite corresponding relation taken from (6) as:

$$\frac{dC_{66}}{dT} = \left[(2C_{66} + C_{166} + C_{266})\alpha_{11} + C_{366}\alpha_{33}\right]. \qquad (9)$$

Such form is obtained due to relations of coupling between dependent and independent components of TOEC tensor of trigonal crystals. Substituting the data on SOEC and TOEC as well as linear thermal expansion coefficients into (9) one can see that first term (geometrical nonlinearity) in the right side of (9) will always have a positive sign, but the other terms could be both positive and negative. Since linear thermal expansion coefficients have positive signs, the signs of the second and others terms are determined by the TOEC signs only. Usually in crystals the signs of the TOEC are negative, and as a rule the TOEC magnitudes exceed the SOEC ones. Analyzing the TOEC values of quartz among the known data one can see an unusual peculiarity: $|C_{112}| > |C_{111}|$. Calculation of the TOEC values useful for the analysis of (9) gives us $C_{166} = -3{,}775 \cdot 10^{10}$, $C_{266} = +3{,}525 \cdot 10^{10}$ and $C_{366} = +14{,}75 \cdot 10^{10}$ (in Pa). Consequently, the sum of first, third and fourth terms in (9) will exceed the negative contribution of the second one, and TC_{66} will be positive.

It is well known that the transformation of generalized Hook's law from linear to polynomial dependence between deformation and stress is defined by TOEC values [40]:

$$\tau_{AB} = C_{ABCD}\eta_{CD} + C_{ABCDPQ}\eta_{CD}\eta_{PQ}, \qquad (10)$$

where τ_{AB} is the tensor of thermodynamical stress. In the most cases when positive deformation increases and TOEC values are negative, the quadratic term in (10) produces a small decreasing of the stress in comparison with linear dependence in harmonic approximation. If TOEC values are positive, the trend will be opposite and non-equilibrium state of the crystal in respect of one or another elastic mode should arise. Returning to quartz one can conclude that the positive signs of C_{266} and C_{366} nonlinear elastic modules indicate an unusual behavior under the shear deformation in the XY plane.

***Abstract*— A resonator using shear waves of lithium niobate is used in this paper to achieve large fractional bandwidth BAW filter. Electromechanical couplings in the 20 – 50 % range are obtained for the shear waves of a thin layer of Lithium Niobate suspended on a silicon substrate. By this way a filter with fractional bandwidth over 20% has been designed for space applications.**

I. INTRODUCTION

Acoustic waves, using surface or bulk propagation, are used in numerous applications in frequency generation, control or filtering in modern wireless communication systems [1] [2]. With the growing demand for multimedia and mobile applications, new generations of telecommunication satellites require higher performances, higher functionalities and still stronger cost and size constraints [3] [4]. In that context, Bulk Acoustic Waves (BAW) devices can offer many potentialities for smart RF components or systems. For instance this technology is now used as alternative to Surface Acoustic Waves (SAW) filters in handset duplexers for UMTS and DCS standards around 2 GHz with Aluminum Nitride piezoelectric layers [5]. However, Aluminum Nitride is not suitable for large band applications, due to its electromechanical coupling coefficient. This material is mainly processed for local oscillators or narrowband filtering operations (<5%) [6] [7] [8].

Single crystal-based acoustic resonators for filtering have received a strong interest for many years. Various developments have been particularly achieved using Quartz with either SAW delay lines or resonators. However, most approaches have been developed exploiting quartz machining along standard etching, rarely compatible with batch processes as used for Micro-ElectroMechanical Systems (MEMS) [9][10][11].

That is why Lithium Niobate ($LiNbO_3$) layers bonded on silicon substrates are studied to reach large band pass specifications. It is essential to maximize the values of the electromechanical coupling coefficient in Lithium Niobate, and to use wisely crystallographic cuts to achieve very efficient filters. Thanks to Lithium Niobate shear wave propagation behavior, it is possible to synthesis and to achieve band-pass filters with fractional bandwidth over 10 or 20 %. The resonant frequency of the resonator and the filter proposed in this paper is not given because the industrial partner of this project keeps this value confidential.

II. ELECTROMECHANICAL COUPLING COEFFICIENT

By solving the generalized Christoffel equation in piezoelectric materials, we can use tensorial expressions that give phase velocity and polarization [12]. For "z" propagation (fig1.), three plane waves are created, which have orthogonal polarization with different velocities.

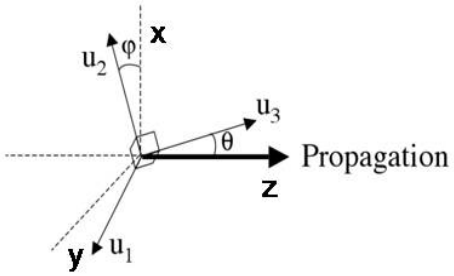

Fig.1: Propagation in anisotropic crystal

It results a thickness wave polarized along the "Z" axis, and two shear waves, polarized in the "XY" waves plane. These velocities permit to define very important parameters for BAW resonators: thickness, electromechanical coupling coefficient kt^2 and shear electromechanical coefficient ks^2.

The higher these coefficients are, the best electromechanical coupling the piezoelectric layer gives. The following expression describes the dependence of kt^2 (or k_s^2) according to resonance and anti-resonance.

$$k_t^{\,2} = \frac{\pi^2}{4}\left(\frac{f_p - f_s}{f_p}\right)$$

It is not possible for Aluminum Nitride to have a coupling coefficient kt^2 higher than 7%. We propose to use two different cuts of Lithium Niobate: the (YXl)/ 36° and the (YXl)/163° cuts. The first one allows for the excitation of high velocity (7000 $m.s^{-1}$) longitudinal modes whereas shear waves are used in the second one, allowing for electromechanical coupling. For these orientations we obtain k_s^2 around 30% for the (YXl)/36° cut and around 45% for the (YXl)/163° cut.

III. 1D Simulation

The first step is to size the thicknesses of the several layers of the structure to reach the targeted frequencies. In the case of figure 2, we used the cut Y+36°; we obtain a coupling coefficient kt^2 equal to 33%. This resonator with very large electromechanical coupling will enable to reach easily fractional bandwidth filter over 10%.

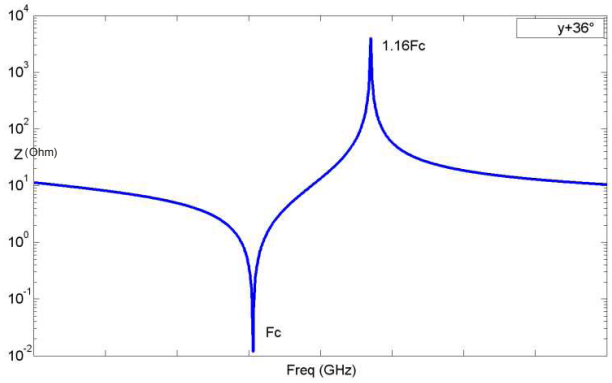

Fig.2: simulation response of a lithium niobate resonator (cut Y+36).

IV. Fabrication and Measurements

In this work, we propose a filter fabricated on $LiNbO_3$/Silicon substrates obtained by Au/Au bonding at room temperature and a lapping/polishing on the upper face of the lithium niobate substrate. This approach allows for a collective and accurate production of filters, the filter frequency being controlled by the membrane thickness of the lithium niobate layer.

We based our device fabrication on gold bonding with a lapping/polishing process to prepare wafer compound to different devices. It allows us to manufacture a BAW resonator on $LiNbO_3$ membrane as shown in fig. 3. A gold thin layer (200nm) is deposited first by sputtering on both $LiNbO_3$ (bottom face) and silicon (top face) wafers. Both wafers are then bonded together via gold layer compression into an EVG bonding machine. During this process, we apply a pressure of 65 $N.cm^{-2}$ to the whole contact surface, yielding a high quality bond. $LiNbO_3$ is subsequently thinned by lapping and polishing steps to an overall thickness of several microns. The resonator is finally suspended by etching the back side of the silicon substrate by DRIE. Aluminum electrodes are deposited on the $LiNbO_3$ upon the cavity to achieve working BAW resonators. A cross section of the resonator is presented figure 3.

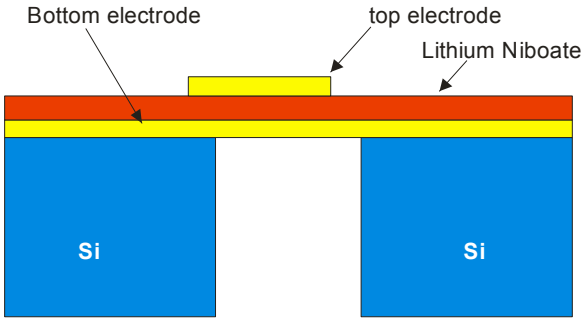

Fig.3: cross section of the structure

Photography of the fabricated resonator is presented figure 4, in a top view. We can see CPW accesses for measurement and apodized shape of the electrodes to prevent from parasitic modes.

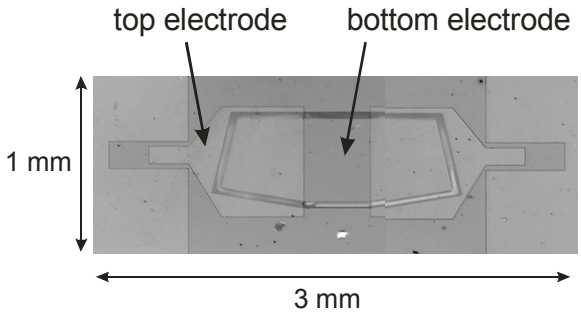

Fig.4: fabricated resonator (top view).

S_{21}-parameter measurements for the structure shown in Fig. 4 were performed using a HP 8510 A network analyzer system. The measured response is presented figure5.

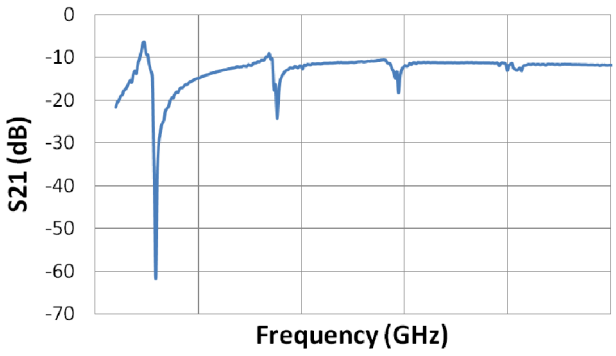

Fig.5: measured resonator.

It exhibits an electromechanical coupling of 31 %, wich is very close to the predicted one (33%). This resonator can then been used to synthesis large fractional bandwidth filter. Figure 6 presents a lithium niobate based BAW 3 pole filter with a 3 dB fractional bandwidth of 22 % in a ladder configuration.

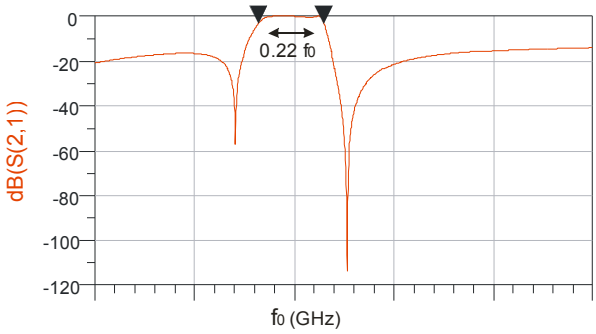

Fig.6: computed ladder 3 pole filter with large fractional bandwidth for space application.

V. Conclusion

In this paper an efficient method to compute BAW filter using shear waves has been presented using a scalar approach. By this way, very important electromechanical coupling coefficients have been obtained with lithium niobate. Large band pass filter become then very easy to achieve for space applications.

Abstract — Intrinsic stress and electromechanical coupling coefficient are the most important parameters of piezoelectric thin films used in membrane as well as cantilever type MEMS such as energy harvesters, transducers and others.

In this paper, practical aspects controlling stress and crystallinity in aluminum nitride (AlN) film used in manufacturing of Bulk Acoustic Wave (BAW)/ Film Bulk Acoustic Resonator (FBAR) filters [1], [2], [4] have been presented. Controlling stress by modifying deposition parameters was compared to controlling stress by surface modification. Stress was found to be an important indicator in predicting crystallinity of AlN films. Impact of the substrate material and electrode deposition on stress and crystal orientation of piezoelectric AlN was studied. In process applications where control of the surface layer thickness is critical and surface topography is variable, use of ion mill to reduce surface roughness is preferable to CMP. It was generally found that for most amorphous materials such as silicon dioxide or silicon nitride that are placed under the electrode or piezoelectric AlN, it is critical to get the best possible surface smoothness. On the other hand for the electrode material such as molybdenum, it is more important to get material with the best crystal orientation. Polishing of the well oriented electrode material did not provide further improvement. It was also observed that if AlN is deposited on a smooth or well oriented layer, orientation of the AlN is improved when the stress in the film is more tensile. On the other hand if the tensile stress is caused by residuals on the surface or surface roughness, tensile stress usually leads to poorly oriented films.

I. INTRODUCION

Early in the development of AlN films, it was observed that stress could vary for variety of reasons. Sometimes most compressive stress in the AlN film produced best crystallinity, other time tensile stress produced best results. Controlling stress was particularly important for FBAR applications where membranes are susceptible to cracking or delaminating due to high stress. Even in BAW technology, high stress can simply cause yield loss in photo-lithography due to high warpage of the wafers. Three major factors must be addressed to control stress in the AlN films:

- Substrate or pre-electrode processing
- Electrode or pre-AlN processing
- Deposition of AlN

We propose some practical guidelines to successful stress control with high electromechanical constant.

II. EQUIPMENT

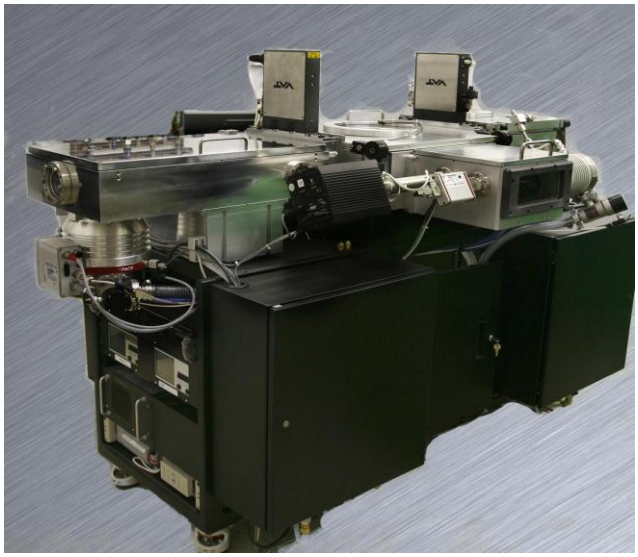
In this investigation we used Advanced Modular Systems cluster tool with three modules: AlN deposition chamber, electrode deposition chamber and ion beam trimming module (shown in Figure 1).

AlN deposition uses a dual magnetron with AC power applied between targets. It is a reactive deposition using aluminum target and, argon and nitrogen process gasses. Electrode deposition chamber is a dual magnetron with DC power supply, electrode target (Mo, W, Pt, etc…) and argon process gas. The trimming module uses DC focused ion source with argon process gas to improve thickness/uniformity of either electrode or AlN films. Use of the trimming module opens up a much wider process window

978-1-61284-110-6/11/$26.00 ©2011 IEEE

for stress control because we don't need to spend too much effort on controlling thickness uniformity during deposition.

Figure 1: AMSystems cluster tool



III. SUBSTRATE OR PRE-ELECTRODE PROCESSING

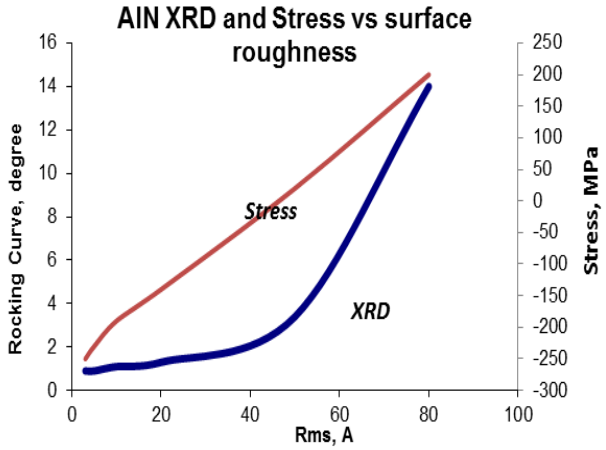
A. *Surface Cleaning*

The surface on which the electrode is deposited can irreparably damage quality of the piezoelectric aluminum nitride. It is very critical to have a smooth and uncontaminated surface before depositing the electrode material. If substrate was exposed to the photoresist, it is critical to have the surface adequately cleaned. Depending on the materials used, either wet chemical or dry strips can be effective. If wafers are not adequately cleaned, it can lead to high tensile stress in the future deposited films with very poor crystal orientation and, in worse cases, delamination.

B. *Surface smoothness*

After adequate cleaning it is important to make sure that the surface is smooth. Typically, 0.6nm surface roughness is acceptable. There are two common methods for the surface smoothing: Chemical Mechanical Polishing (CMP) and ion beam milling. CMP can be performed on most materials and with appropriate selection of polishing slurry it is capable of both planarizing and smoothing the surfaces. One limitation is that it is hard to control the amount of material removed, especially if there is diverse topography of features on a wafer. Ion milling can be precise in the amount of material removed, but is only effective on hard dielectric materials such as SiN, AlN or SiO2. It requires too much material removal on metals to be useful. Figure 2 shows impact of surface roughness on the crystallinity and stress of AlN deposited on the PECVD oxide that is polished to different level of smoothness. Ion beam trimming tool was used to improve the surface roughness.

Figure 2: AlN Rocking curves and Stress as a function of oxide surface roughness

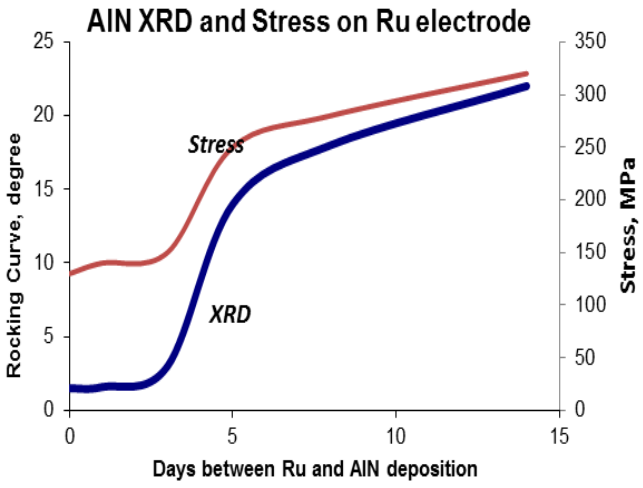


IV. ELECTRODE OR PRE-ALN PROCESSING

Before piezoelectric AlN is deposited, the electrode material is typically deposited and in most cases patterned. It is important to keep track of the stress in the electrode films because it is a good indicator of the problems with the substrate preparation. Erratic stress in the electrode usually results in problems with AlN deposition.

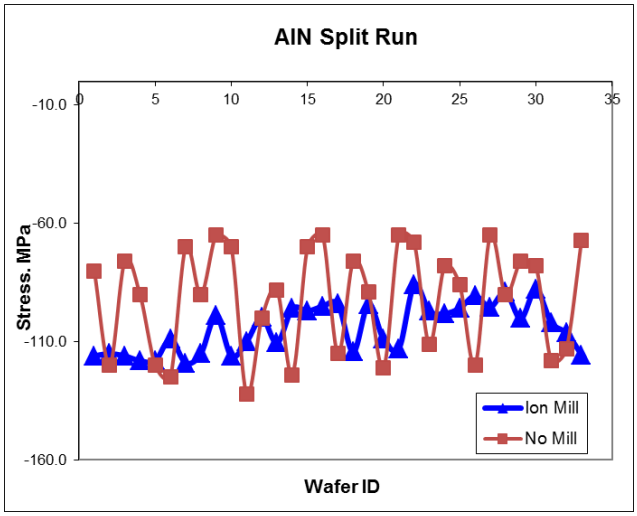
Some electrode materials such as Ru oxidize in the air if AlN is not deposited within relatively short period of time. Significant variations in both stress and rocking curves have been observed if Ru electrode is left in the ambient atmosphere for a long time. Figure 3 shows the impact on AlN parameter as Ru is left exposed for significant amount of time.

Figure 3: AlN properties on differently exposed Ru electrodes



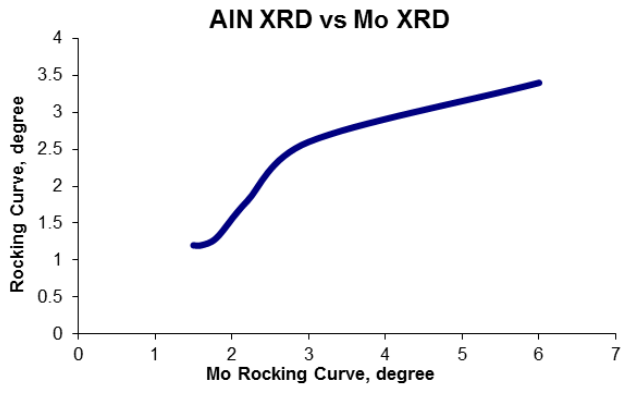
Even though electrodes such as W and Mo are not easily oxidized, it was found that removal of 10nm to 20nm of the electrode material by CMP has beneficial impact on repeatability of stress as can be seen in Figure 4. Polishing the surface of the W also produces improvement in rocking curve, but no improvement was observed for Mo.

Figure 4: Repeatability of AlN stress on polished vs. unpolished electrodes



Measuring rocking curve on Mo deposition has been useful in predicting better crystal orientation in the following AlN deposition, see Figure 5. Rocking curve measurements had no correlation to the rocking curves on AlN or stress repeatability for either W or Ru.

Figure 5: AlN rocking curve depends on Mo electrode property



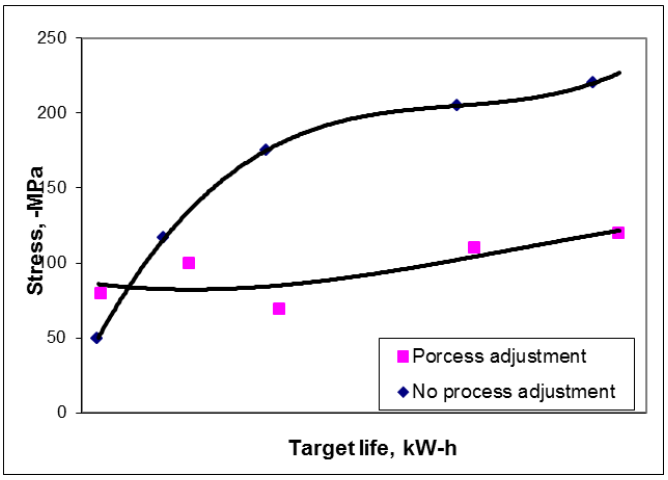
V. DEPOSITION OF AlN

Stress control in the AlN deposition is typically accomplished be controlling either deposition pressure or substrate bias. Higher deposition pressure produces more tensile stress and higher substrate bias more compressive stress [3]. It is important to establish baseline stress repeatability in the deposition module. High resistivity Si is best suitable for such application. Wafers with resistivity of >15ohm-cm are acceptable. Lower resistivity can lead to substrate interaction with the chamber components and variable stress results.

Another common cause of stress variation is a plasma-substrate coupling due to variation of plasma potential and contact through the electrode structure to the wafer holding/clamping mechanism. We have observed as much as 700MPa difference in stress due to the conductive contact to the wafer surface vs. insulated contact.

As the target material gets eroded and a thick insulating layer builds up on the shields, it is not uncommon to see stress changing from the beginning of the target life to the end of the target life. Usually such changes are repeatable from target to target and can be built into automated software adjustment on the deposition system, see Figure 6.

Figure 6: AlN film stress vs. target life



VI. CONCLUSION

In many cases it is more important to prepare the substrate and the electrode for the AlN deposition than trying to control deposition itself. Making sure that both electrode and substrate have been treated correctly will go a long way towards producing excellent AlN films.

***Abstract*—This paper reports the simultaneous fabrication of Receive and Transmit Bulk Acoustic Wave filters for the WCDMA standard on the same die. Both filters are based on Solidly Mounted Resonators using a common Bragg mirror, but with each having a specific piezoelectric film thickness. Electrical measurements reveal that the process steps required to provide the two different piezoelectric film thicknesses on the same die does not impact the electrical performances of resonators and filters and that this approach could thus be generalised to more than two filters.**

I. Introduction

Acoustic filters are an enabling technology for radiofrequency front-ends, where they are used for RF band pass filtering. Among them, Bulk Acoustic Wave (BAW) filters are commercially available for almost 10 years now, and find their use for stringent filtering applications, where low losses, steep skirts and sharp roll-off are required [1]. They consist in a piezoelectric thin film sandwiched between two electrodes, and operating on a thickness-extensional vibration mode. Therefore, their operation frequency is fully defined by the set of layers from which they are obtained and especially by thicknesses. Unlike other technologies, like Surface Acoustic Wave (SAW), Lamb Wave Resonators, or other Micro Electro Mechanical (MEMS) resonators, their characteristics depend only weakly on their geometric design. This means that a unique set of resonators, operating at a given frequency, can be fabricated at a time. Local addition of mass by depositing an added layer over some resonators enables to shift their frequency through the mass loading effect, and thus enables to obtain the two sets of resonators required to obtain a conventional ladder or lattice type filter. However, it is hardly possible to synthesize two filters for different standards. Instead, only one bulk acoustic wave filter is usually fabricated at a time and current RF front-ends thus require as many filter dies as they include filters. This will surely become a critical problem in mobile phone applications with newer standards making use of even more frequency bands, what will cause an increase in the number of filters necessary in a radiofrequency front-end. Therefore, the integration of these components in systems will become critical.

Previous studies have focused on co-integrating two RF filters on the same die, at least to provide both Receive (Rx) and Transmit (Tx) filters of the same standard on the same die, thus enabling to assemble only a single filter die on a duplexer module. This means being able to provide four sets of resonators having each a different set of resonance frequencies. The most intuitive way is to exploit the mass-loading effect in a way similar as to the one in which two sets of frequencies are defined in a conventional filter [2]. It has been recently applied for example to the fabrication of a Film Bulk Acoustic Resonator (FBAR) based duplexer for the WCDMA standard [3]. By using both a so-called band tuning layer to define resonators at Rx frequencies, and then a second loading layer to define the parallel resonators of both filters, a set of four frequencies was obtained. The same principle could be similarly applied with Solidly Mounted Resonators (SMR). The advantage of this solution is that it requires only an additional layer and an additional mask level used to pattern the band tuning layer compared to a conventional BAW process. However, this additional band-tuning layer normally causes a reduction of the effective electromechanical coupling factor of resonators, making the synthesis of wide bandwidth filters more difficult. This reduction increases as the frequency shifts between the two filter bands becomes large. This means in practice that this approach can only be used where a reduction in effective electromechanical coupling factor for one of the two filters is acceptable. This also means that this solution is only applicable to two close frequency bands.

In order to fabricate simultaneously filters with arbitrary bandwidths and frequency spacing, without sacrificing effective electromechanical coupling factor, i.e., ultimately, insertion losses and ripple, several piezoelectric layer thicknesses need to be provided on the same substrate [4]. A first approach proposed to implement such a device was first to deposit the thinner piezoelectric film, then to protect it where the highest frequency filter will be located, and finally to deposit an additional thickness of the piezoelectric layer where the lowest frequency filter will be located [5]. However, authors have shown that in practice, with Aluminum Nitride (AlN), piezoelectric properties of the thicker film are decreased compared to the initially deposited one. Investigations have proven that the cause of this decreased piezoelectric properties is attributed to either a bad crystallinity of the re-grown layer, or by a regrowth of AlN with a reverse polarity, causing a partial cancellation of the effective piezoelectricity of the piezoelectric film. The origin of this phenomenon is the surface

978-1-61284-110-6/11/$26.00 ©2011 IEEE

degradation of the initial AlN film, caused by reaction to chemical agents during photolithography steps, but it was also noticed, although less significantly, in samples having only been exposed to air for some time. The conclusion of this first approach was that oxidation or reaction with humidity may trigger surface deterioration and cause re-growth with the wrong polarity.

Another approach would be to start with the deposition of the thickest piezoelectric layer first, and then to partially etch this film to provide a thinner layer where the highest frequency filter will be located. The advantage is that it ensures that the structural quality of AlN remains unaffected. However, there are two critical issues: first AlN is still exposed to chemicals during photoresist development or stripping, which are known to damage it, in partially etching it and increasing its surface roughness. Conjugated effects of roughness increase and surface contamination of the piezoelectric film are expected to prove detrimental towards quality or effective electromechanical coupling factors of resonators. Secondly, although the deposition processes of AlN in an industrial environment is very well controlled and reaches unmatched thickness homogeneity in order to reduce frequency dispersions, while offering growth rates compatible with mass production in an industrial line, etching processes are much less optimized. Processes with reasonable etch rates suffer from much lower uniformity and thickness control, especially when it comes to partially etch a layer without proper etch-stop. On the other hand, some equipments, for example dedicated to frequency trimming of resonators, offer an excellent control over etching depth and uniformity, but at the expense of very slow etch rates, making these approaches difficult to implement for mass production. So using direct partial etching of AlN does also not seem to be an interesting alternative.

To avoid the drawbacks of the above-mentioned methods for fabricating several BAW filters simultaneously, we propose in this paper a new approach based on multiple depositions and patterning of the piezoelectric layer [6]. In section II, we discuss the design of two filters compatible with the proposed approach. Then, in section III, we describe the fabrication of both Reception and Transmission filters for the WCDMA standard. Section IV provides the electrical characteristics of the fabricated filters and a comparison with conventional filters with the same design.

II. WCDMA DUPLEXER FILTERS DESIGN

The two filters were designed to match the WCDMA standard, using the procedure described in [7], [8]. Based on a first estimation of achievable resonator electromechanical coupling and quality factors, Butterworth-Van Dyke (BVD) lumped element models of resonators were built and used for filter synthesis. An equivalent filter model, based on an initial filter architecture, is first proposed. The transmission filter is based on a 50 Ω single stage ladder topology, with only three resonators, since most of the rejection will be provided by the duplexer itself. The reception filter is implemented as a double lattice topology, as it requires higher rejection and

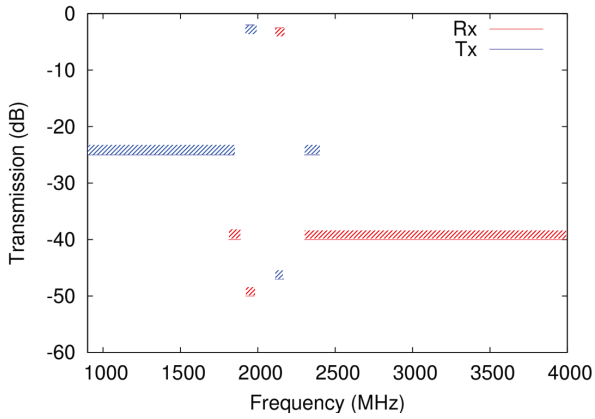

Fig. 1. Filter masks for the WCDMA duplexer : antenna to Rx path (red) and Tx to antenna path (blue).

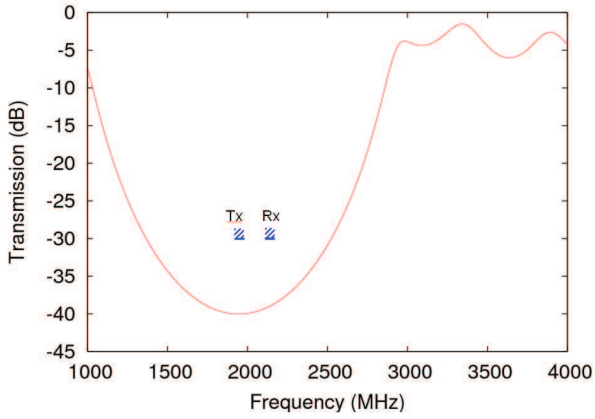

Fig. 2. Transmission coefficient of the designed SiN/SiOC Bragg mirror.

differential input and output. This model is then optimized to meet specifications for the whole duplexer module, which are summarized by the masks shown in Figure 1. The output of this optimization basically provides required resonator static capacitances and, more importantly for this study, resonance and antiresonance frequencies.

From this basis, a more precise Mason model of resonators is used. First, a Bragg mirror is designed to cover the two filter bands. This mirror is made of SiN and SiOC, which exhibit an acoustic impedance ratio larger than 6 and thus can provide a mirror offering a transmission lower than -30 dB over a bandwidth of more than 1 GHz with 3 pairs of layers, as seen in Figure 2. Such a wide bandwidth is more than sufficient to cover the two filter bands. It also ensures a rather small change in reflection coefficient between the filters: this is mandatory to ensure that both devices will benefit from a quasi-similar acoustic isolation and from small changes in phase of the reflection coefficient, what is necessary for the maximum achievable effective electromechanical coupling factor of resonators to remain similar for the two filters.

Two Molybdenum/AlN/Molybdenum piezoelectric stacks have been designed so that resonators simultaneously reach

the specified resonance and antiresonance frequencies in the series paths of the two filters. This design also takes into account an additional SiN passivation layer whose thickness is otherwise defined for reliability reasons [9]. However, we added the additional constraint to try to have as many common layers as possible, to ease subsequent processing. For the set of frequencies defined during the optimization of the filter topology, it proved impossible to achieve sufficient electromechanical coupling factor with the same piezoelectric layer thicknesses or with the same bottom or top electrodes. However, the required amount of mass loading necessary to induce frequency shifts of 69 and 56 MHz between series and parallel resonators, respectively for the Rx and Tx filter, is obtained by almost adding the same thickness for the two material stacks. This means that the same mass-loading can be applied at least to the two filters.

III. Filter fabrication

From these acoustic design considerations, one can see that the fabrication of the two filters differs only at the level of the two electrodes and at the level of the piezoelectric film. Therefore, for most of the fabrication process, we use a conventional BAW fabrication process. We start with the deposition onto a high resistivity wafer of the 7 layers forming the common Bragg mirror, alternatively SiOC (335 nm) and SiN (1200 nm). These layers are deposited by chemical vapor deposition (CVD). The whole deposition process has been optimized to minimize stress wile providing a flat and smooth surface on which to grow the piezoelectric stacks.

A Molybdenum film is deposited on top of these Bragg mirrors by sputtering the thickest of the two bottom electrodes, i.e. 400 nm of Molybdenum corresponding to the thickness required for the Tx filter. This metal film is then locally partially etched over 50 nm to reach the thickness required by the Rx filter. To ensure a precise control of this thickness difference, we use very slow etching process in an ion beam tool. Then, the bottom electrodes for the two filters are simultaneously patterned using standard photolithography and a fluorine-based dry etching step.

A first piezoelectric AlN film close to 1300 nm is deposited by reactive pulsed DC sputtering, followed by the deposition of the first top molybdenum electrode (140 nm) in the same cluster tool (a Sigma Fxp sputtering system from Aviza Technologies) to avoid any vacuum break. These layers form the piezoelectric stack for the Tx filter. Large patterns are then defined on the top metallization to define areas where Tx filters will reside, using standard photolithography and dry etching. The molybdenum film then serves as a metal mask for the chemical wet etching of AlN. We checked that this chemical etching leaves a flat surface without any AlN residues which could locally degrade the growth of the second piezoelectric stack.

This second piezoelectric stack is deposited the same way as the previous one on top of the existing materials. It consists in an AlN film of 1150 nm and a Mo film of 120 nm. The top Mo film is patterned to define a second metal mask,

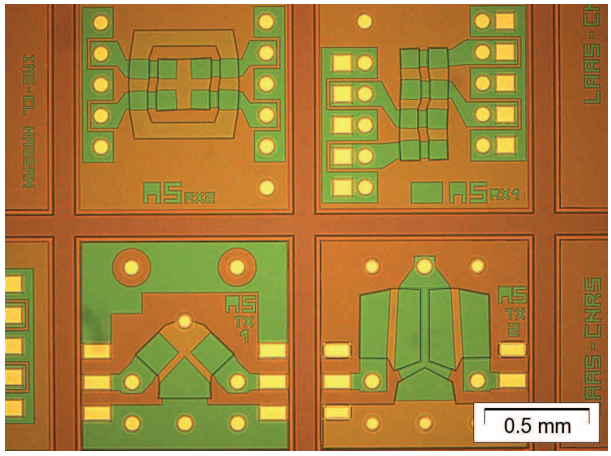

Fig. 3. Optical photograph of Rx and Tx filters after fabrication.

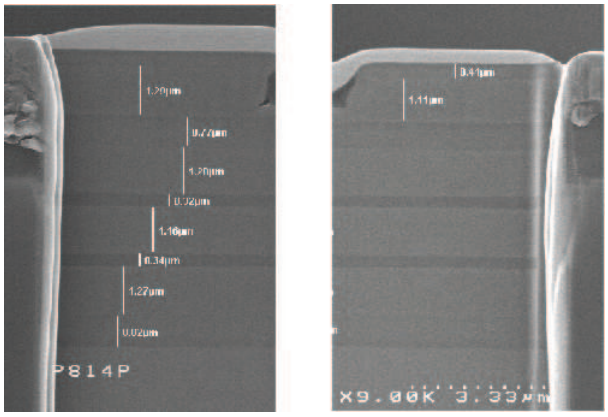

Fig. 4. SEM cross sections of Tx (left) and Rx (right) islands.

complementary of the previous one, which defines the areas where the Rx filters will reside, and the second AlN layer is etched again. At this stage, the first Mo metal mask protects the first AlN film, acting as an etch stop for the second AlN, so that two kinds of islands with varying piezoelectric stacks are defined. Microscope inspection revealed that no remains of the second AlN film were noticed over the top electrode of Tx islands after this etching step, so that the fabrication process could be continued safely. We also assessed the crystalline quality of AlN films by rocking curve measurements. No noticeable change in AlN texture was noticed between Rx and Tx islands and between reference wafers which have only seen the deposition of one piezoelectric stack.

Frequency separation between series and parallel resonators for the two filters is obtained by partially etching the two top molybdenum layers over the locations where series resonators will reside. As for the bottom electrode, we partially etch these layers using slow ion beam etching for a precise thickness control and a high on-wafer uniformity. The top electrodes are then patterned and vias are etched in the AlN islands using photolithography and another wet etching to reach the bottom electrodes. Devices are then passivated using an SiN film covering the whole surface, except where contacts towards

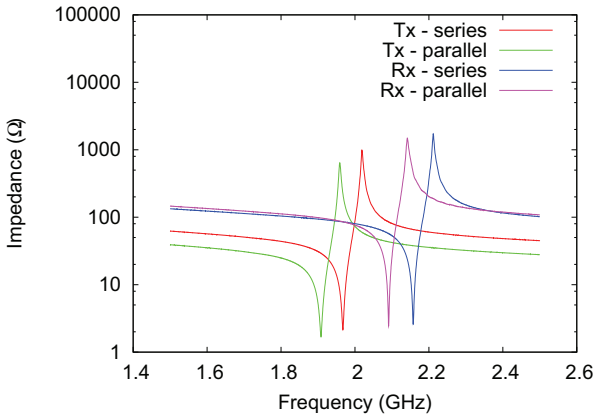

Fig. 5. Electrical response of Tx and Rx resonators measured on the same wafer die.

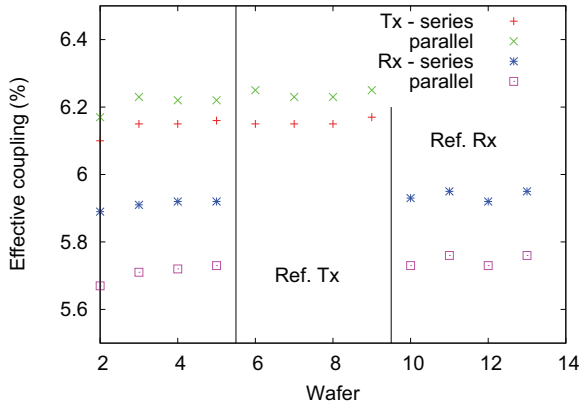

Fig. 6. Comparison of average electromechanical coupling factors measured between wafers having seen the fabrication of the two filters and reference filters.

top and bottom electrodes are opened by fluorine based dry-etching. Finally, a thick aluminum layer is deposited and patterned to cover vias and to form contact pads for RF probing.

Figure 3 is an optical photograph showing filters after fabrication. Each filter resides on an 1×1 mm^2 die having its own piezoelectric stack. Vertical and horizontal lines separate islands corresponding to the Rx or the Tx material stack. Due to the relatively small change in AlN thickness between the two types of filter, no noticeable colour change can be observed. Figure 4 shows cross sections of Tx and Rx islands obtained on the same wafer at a small distance from each other.

IV. Electrical Characterizations

After fabrication, a set of 167 test resonators regularly distributed accross each wafer were tested using RF probes connected to a vector network analyzer and calibrated using the conventional SOLT method. For each of them, we extracted resonance and antiresonance frequencies, as well as quality and electromechanical coupling factors. Figure 5 shows sample impedance responses of resonators for the Rx and Tx filters measured on the same wafer die. Figure 6 gives the values of electromechanical coupling factor averaged over each wafer (i.e. over 167 samples) compared to reference wafers having only seen the fabrication of one filter. As can be seen, changes in resonator properties remain within measurement uncertainties, showing that the multiple frequency process has not significantly impacted resonator performances. Measurements of two filters located in the same 2 mm^2 die are shown in Figure 7: these two filters exhibit excellent performances: respectively 1 and 2.3 dB insertion losses for the Transmit and Receive filters. It is to be noted that the somehow reduced rejection of the Transmit filter will be greately improved when mounted inside the duplexer chip.

V. Conclusion

We have simultaneously fabricated Rx and Tx filters for the WCDMA standard based on SMR. The fabrication process

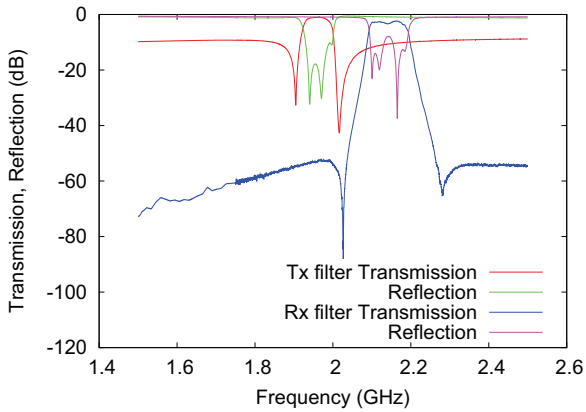

Fig. 7. Transmission and reflection measurement for adjacent Tx and Rx filters.

employed makes use of the deposition and patterning of two piezoelectric films which are then patterned thanks to the very large etching selectivity between AlN and the Molybdenum electrodes used. Electrical measurements reveal that no change in performances is induced in individual resonators or in filters compared to a standard single-frequency BAW process, proving the interest of this method, and moreover does not put strict constraints in terms of acoustic design of resonators. Moreover, this approach can be easily generalized to alternative technologies using other electrode materials or other piezoelectric films. It could also be generalized to a larger number of filters, being only limited by the ability to design a common Bragg mirror suitable for all filters.

***Abstract*—A superfine resonant structure with a voltage spacing of about 19 nV (corresponding frequency 9 MHz) and an extremely low differential resistance has been observed in the Josephson Flux Flow Oscillator (FFO) IVCs. We have analyzed coherent phonon radiation and detection due to the interaction of Josephson's electromagnetic oscillations with mechanical displacement field caused by piezoelectric effect or electrostriction effect. In contrast to the other works we consider sound generation in the Josephson tunneling structure, deposited on the rather thick substrate. This layered structure plays the role of high overtone composite resonator for bulk acoustic waves propagating normally to the layers.**

I. INTRODUCTION

The spectrum of acoustic phonons covers frequencies up to several terahertz. So the excitation of coherent acoustic waves (AW) with subterahertz frequencies is a problem of great importance. As attenuation of AW is reduced at liquid helium temperatures, in 1970s and later the superconducting tunnel junctions have been used to generate and also to detect both incoherent and coherent AW above 100 GHz [1-4]. The possibility of AW generation in high T_c Josephson junctions has been considered in [5, 6]. Recently, phonon radiation in the Josephson junctions as a reason for decoherence of superconducting quantum bits is also discussed [7]. Most of the papers mentioned above deal with interaction of AW with electromagnetic fields in the junction via piezoelectric coupling.

In the present paper the possibility of AW generation due to electromagnetic wave, accompanying Josephson vortex motion, is considered. The Josephson flux flow oscillator (FFO) based on unidirectional flow of vortices in a long tunnel junction is shown in Fig.1. Usually in these structures with low dumping the step-like current-voltage characteristics, so called Fiske steps (FS), are occurred. The position of the steps depends upon Josephson junction resonant frequencies defined by junction length. We'll consider AW generation in the tunneling structure, deposited on the relatively thick flat substrate with double side polished parallel surfaces. This layered structure plays the role of high overtone composite resonator for bulk AW propagating normally to the layers. The resonant generation and detection of AW are displayed on I-V curve (IVC) as a series of additional steps on the top of the ordinary FS series. The experiments carried out on Nb-AlO_x-Nb junction on Si substrate revealed the fine structure of IVC with steps separation and low differential resistance, which is pointing out AW generation [8].

II. THEORY

A. Dynamics of long Josephson junction

Consider two superconductors biased at the constant voltage and spaced by dielectric layer of thickness *d*. External magnetic field lies in the interface along the x axis (Fig. 1). This structure is deposited on a substrate of thickness *D*. The current flowing in the dielectric interlayer will be in the form $j_y = j_{s,y} + j_{n,y} = j_1 \sin\varphi(z,t) + \sigma_T e_y^0$. Here $j_{s,y}$ and $j_{n,y}$ are, respectively, Josephson tunneling current of Cooper pairs with amplitude j_1 and normal electrons current with tunnel conductivity σ_T, $\varphi(z,t)$ is the difference of SC wave functions.

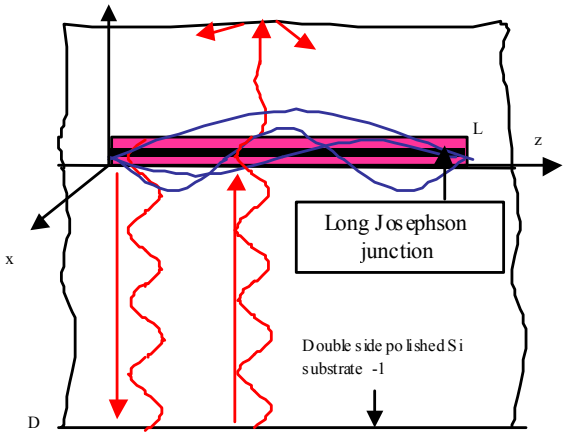

Figure 1. Schematics of the structure: 1- the Si substrate, 2 -long Josephson junction Nb-AlO_x-Nb, the black area – the AlO_x insulator film.

In linear approximation upon field amplitudes one can write down the expression for phase difference $\varphi = \varphi_0 + \varphi_1$, where $\varphi_0 = \omega t - qz$. Hereafter upper subscript (0) denotes the values integrated on dielectric layer thickness. The Josephson relations $\omega = \partial\varphi_0 / \partial t = 2eV_0 / \hbar$, $q = \partial\varphi_0 / \partial z = 2e\bar{d}H_0 / \hbar c$ connect the frequency ω and the wave vector q with constant voltage V_0 and magnetic field H_0. Here $\bar{d} = d + 2\lambda_L$ is an effective size of magnetic field localization, λ_L is a London penetration depth. The phase addition φ_1 is connected with ac voltage on the junction $v_1 = e_y^0 d$ as $\partial\varphi_1 / \partial t = (2e/\hbar)v_1$ [9].

The interaction of Josephson's electromagnetic oscillations in the junction with mechanical displacement field $\vec{u}$ caused by piezoelectric effect or electrostriction effect produces a polarization density $\vec{p}$ and contributes to an electrical displacement $d_y^0(z) = \varepsilon_d e_y^0(z) + 4\pi p_{(U)y}^0(z)$. By standard integration of Maxwell equations the generalized Josephson relationship between phase gradient and polarization can be deduced in the form

$$\frac{\partial^2\varphi_1}{\partial z^2} - \frac{1}{\tilde{c}^2}\left(\frac{\partial^2\varphi_1}{\partial t^2} + \Gamma\frac{\partial\varphi_1}{\partial t} + \frac{8\pi e d}{\hbar\varepsilon_d}\frac{\partial p_{(U)y}}{\partial t}\right) = \frac{1}{\lambda_J^2}\sin\varphi_0, \quad (1)$$

with a Swihart electromagnetic wave velocity $\tilde{c} = c\sqrt{d/(\varepsilon_d \bar{d})}$, a Josephson penetration depth $\lambda_J^2 = \hbar c^2 / (8\pi e \bar{d} j_1)$, a Maxwell relaxation frequency Γ. For typical Nb- AlO_x-Nb junction with $2\lambda_L \sim 170$ nm, d ~ 1-2 nm, $\varepsilon_d \sim 10$ the estimation gives a wave slowing-down $\tilde{c}/c \approx 0.03$. In spite of this, electromagnetic wave velocity in the Josephson junction is much greater than AW velocity.

B. Equations for elastic displacements

Effective piezoelectric constants $\tilde{\beta}_{i,kl} = \beta_{i,kl} + a_{imkl}E_m / 4\pi$ describe both normal piezzoeffect and the induced one by the electrostriction. In linear approximation the electric field in dielectric layer is uniform $E_m = V_0 / d$. Piezoelectric interaction contributions to stress tensor and electric polarization are $\Delta T_{ij} = \tilde{\beta}_{l,ij} e_l$ and $p_i = -4\pi\tilde{\beta}_{ikl}u_{kl}$ respectively. While the piezoelectric effect is absent in bulk dielectrics with inversion symmetry, it is not possible to eliminate this coupling at the superconductor-insulator boundary where this symmetry is always broken. Assuming that electromechanical coupling tensor has 4mm symmetry with axis lying in the interface, one can obtain the desired polarization as $p_2^0 = -4\pi\beta_{24}(\partial u_2^0 / \partial z)$.

After integration of the equation of motion for elastic medium along dielectric thickness we get

$$\rho\frac{\partial^2 u_2^0}{\partial t^2} = \frac{T_2(d) - T_2(0)}{d} + C_{44}\frac{\partial^2 u_2^0}{\partial z^2} + \beta_{24}\frac{\partial e_2^0}{\partial z} \quad (2)$$

The boundary conditions for elastic displacements and stresses at the dielectric layer surfaces are $T_2(0) = T_2^{(1)}(0)$, $T_2(d) = T_2^{(2)}(d)$, $u_2(0) = u_2^{(1)}(0)$, $u_2(d) = u_2^{(2)}(d)$, where the quantities with superscripts 0, (1), (2) refer to dielectric layer and surrounding media. If we assume that elastic displacements slightly vary along the thickness of dielectric, then we can easily obtain the following relationships

$$u_2(0) = u_2^0 + \frac{d}{2C_{11}}Z_1\frac{\partial u_2^{(1)}(0)}{\partial t}, \qquad u_2(d) = u_2^0 - \frac{d}{2C_{11}}Z_2\frac{\partial u_2^{(1)}(d)}{\partial t}.$$

Here $Z_{1,2}$ are acoustic impedances of the surfaces $y = 0, d$ respectively. For perfectly reflecting lower surface of the substrate ($y = -D$) $Z_1 \approx iZ_0 \tan kD$, where $k = \omega / v_l$, v_l - longitudinal AW velocity in the substrate, $Z_0 = v_l\rho_s$ - acoustic impedance of the substrate. If the upper surface of the structure (Fig. 1) is not perfectly reflecting, the impedance Z_2 contributes to acoustic losses.

C. Dispersion equation and current-voltage characteristics

For harmonic dependence of all variables on time and coordinates $\exp i(k_y y + qz - \omega t)$ one can get the dispersion relation $\omega^2 = q^2\tilde{c}^2(\varepsilon/\varepsilon^*)$ for coupled electroacoustic oscillations in the form

$$\omega^2 = q^2\tilde{c}^2\left(1 + \frac{4\pi\tilde{\beta}_{24}^{\,2}}{\varepsilon\rho\tilde{c}^2}\frac{1}{1 + i(Z_2' - Z_1')/(\omega d\rho) - q^2(v_\perp/\tilde{c})^2}\right) \quad (3)$$

with $Z_{1,2}' = Z_{1,2}/(1 \pm id\omega Z_{1,2}/C_{11})$, $v_\perp = \sqrt{C_{44}/\rho}$. The last term in the denominator of (3) may be ignored owing to inequality $v_\perp << \tilde{c}$.

According to standard procedure [9] one can find the uniform component of Josephson current. For the case of long junction the following expression can be obtained

$$j_0(V_0, H_0) = -\tilde{j}_0\Omega_n^2\,\mathrm{Im}[\omega^2 + i\bar{\Gamma}\omega - q^2\tilde{c}^2(\varepsilon/\varepsilon^*)]^{-1} \quad (4)$$

where $\tilde{j}_0 = j_1\tilde{c}^2/(2\lambda_J^2\Omega_n^2)$, $\Omega_n = \pi n v_l / D$ - the frequency of n-th mode of high overtone resonator. The value $\bar{\Gamma} = \Gamma_E + \Gamma_{AW}$ describes electromagnetic losses and nonresonance AW radiation. For the frequencies from 100 to 700 GHz mode numbers of excited AW fall in the range of (10^3 – 10^4). As shown in Fig. 2, there are several bumps of current at AW resonance frequencies $\omega = \Omega_{n+m}$ against a background of usual Lorentz form of one of the FS, corresponding to the voltages $V_{n+m} = \Omega_{n+m}\hbar/(2e)$.

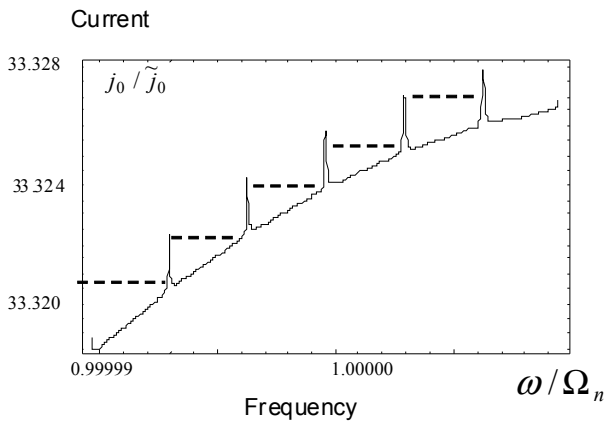

Figure 2. Calculated dependence of relative current $j_0 / \tilde{j}_0$ versus relative frequency ω / Ω_n or relative voltage $\hbar\omega/(2e\Omega_n)$ at the electromechanical coupling constant $\delta = 4\pi\tilde{\beta}_{24}^{\ 2}/(\varepsilon\rho\tilde{c}^{\,2})$=2.510^{-7}, $\overline{\Gamma} = 3\cdot 10^{-2}\Omega_n$, $\mathrm{Im}\,k / \mathrm{Re}\,k = 10^{-6}$.

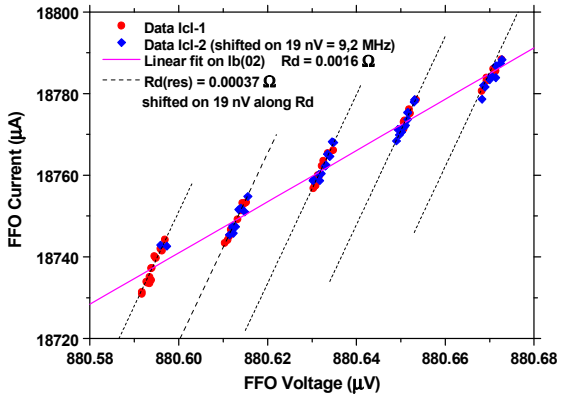

Figure 3. Reconstructed IVC of the FFO. Data marked "$I_{CL-1,-2}$" are measured at a slightly different currents I_{CL} that flow under the FFO and induce magnetic field.

III. SUPERFINE RESONANT STRUCTURE

Flux flow oscillator on the base of Nb-AlO_x-Nb superconducting tunnel junction was fabricated on double side polished Si substrate (350 μm). The thicknesses of the junction layers were correspondingly 1-2 nm for AlO_x, 200 nm and 500 nm for base and top Nb electrodes. By measuring the frequency of the FFO radiation emission [10], its IV-curve can be reconstructed with accuracy better than 1 nV [8]. From Fig. 3 one can see that the FFO IVC consists of a set of separate steps rather than being a continuous curve. The differential resistance on these steps is extremely low, R_d^B(res) = 0.00037 Ω. It is important to note that this value is considerably lower than the average value on the FS (R_d^B = 0.0016 Ω).

The voltage spacing of 19 nV, corresponding to a separation of 9 MHz, coincides with difference between the acoustic modes frequencies of the resonator structure consisting of substrate plate and the covering FFO layers

$$v_l /(2D) = (\Omega_{n+1} - \Omega_n)/(2\pi).$$

The value of voltage (frequency) spacing and separate steps with low differential resistance show a good agreement with theoretical treatment.

IV. CONCLUSION

The superfine resonant structure of the FFO IVC with step separation that coincide with acoustic modes frequency spacing may be attributed to acoustic wave generation by the FFO and propagation in thick Si substrate as in acoustic resonator. So the generation and detection of coherent acoustic waves with frequencies up to 700 GHz due to piezoelectric effect in dielectric interface in superconductor junction may be achieved.

***Abstract*— For the first time, in this work, we report on the transfer of single crystal quartz layers onto silicon wafer through wafer bonding and grinding. A Film Bulk Acoustic Resonator (FBAR) made of a free standing quartz membrane vibrating on the thickness-shear mode has been achieved using this approach. Electrical measurements have been achieved for various temperature conditions. The obtained resonators exhibit fundamental resonance frequencies close to 200 MHz for the fundamental mode. The electromechanical coupling factor is about 0.4 % and the temperature coefficient of frequency is near +26 ppm/°C. These first electrical results highlight the quality piezoelectric response of the reported layer conforms to the bulk material properties.**

I. INTRODUCTION

Quartz has been among the first piezoelectric materials exploited in electronic devices such as resonators and filters [1]. Although it suffers from relatively low piezoelectric properties, yielding radiofrequency (RF) filter manufacturers to use other piezoelectric substrates such as Lithium Niobate or Lithium Tantalate for Surface Acoustic Wave (SAW) devices or Aluminum Nitride (AlN) for Bulk Acoustic Wave (BAW) devices, its very low viscoelastic losses and the existence of crystalline orientations offering thermal compensation effects made it a key element in time references. In current industry, BAW or SAW quartz resonators are fabricated from single crystal wafers and thus suffer from two major drawbacks: first, their operation frequency is limited by the ability to thin these wafers or to locally etch them to reduce their thickness; secondly, and most importantly, they are reputed to be incompatible with CMOS circuits and require lying on a specific die.

In this paper, we propose a first step to overcome these limitations by transferring a single crystal quartz film onto a silicon wafer and to use it for the fabrication of a Film Bulk Acoustic Resonator (FBAR) made of a free standing quartz membrane vibrating on its fundamental thickness-shear mode. In section II, we describe the fabrication of such resonators, using a direct bonding and thinning processes. In section III, we then describe the electrical characterization of these devices and discuss their actual properties.

II. EXPERIMENTAL PROCESS

The manufacturing of Quartz-on-Silicon stacks highlights some physical property differences. The main problem is linked to the Temperature Coefficient of Expansion (TCE) difference between quartz (13.2 ppm/°C) and silicon (2.3 ppm/°C). This induces very high mechanical constraints during thermal steps of the process.

The fabrication process used is summarized in Figure 1. In principle, it is similar to an approach previously employed to transfer thin films of lithium niobate onto silicon substrates [2]. We start with an AT-cut quartz wafer and a silicon wafer which are cleaned to remove any particle without degrading the initial surface quality so as to leave these substrates compatible with the direct bonding technology employed.

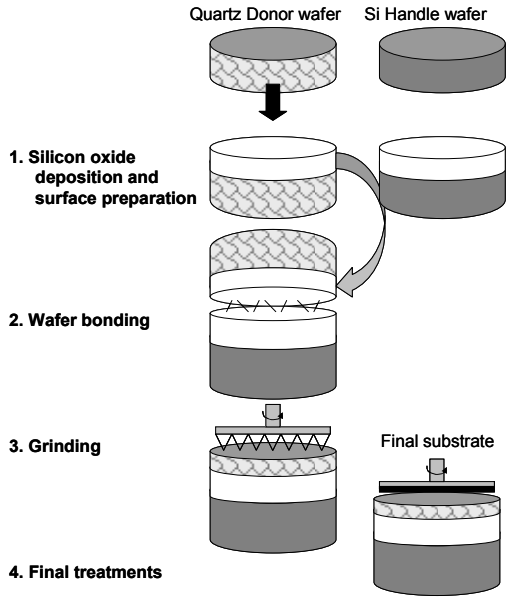

Figure 1. Thin single crystal Quartz transferred layer technique.

A PECVD silicon oxide layer is then deposited onto both wafers. The top surfaces are then prepared by combination of Chemical Mechanical Polishing (CMP) and cleaning, and bonded at room temperature thanks to hydrophilic direct

bonding. The silicon oxide / silicon oxide bonding interface has been observed by Transmission Electron Microscopy (TEM) which reveals a sharp and uniform interface (Figure 2).

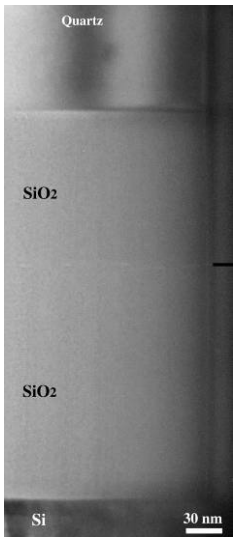

Figure 2. Silicon oxide interface TEM cross section of the quartz/silicon substrate.

Finally the quartz layer bonded onto the silicon substrate is thinned down to a thickness between 10 µm and 15 µm. The backside of the bonded quartz wafer is then grinded and finally polished, with a careful control of process parameters. Due to the non-uniformity of the CMP process, the quartz wafer cannot be thinned below 5 µm using this fabrication process.

The crystal quality of the thinned quartz film has been characterized to provide some insight into the influence of the grinding process onto the transferred film. For this, we measured both thinned and bulk quartz substrates using Rutherford Backscattering Spectrometry Channelling (RBS-c). Results shown in Figure 3 reveal that the used thinning process caused the increase of quartz crystal disorder.

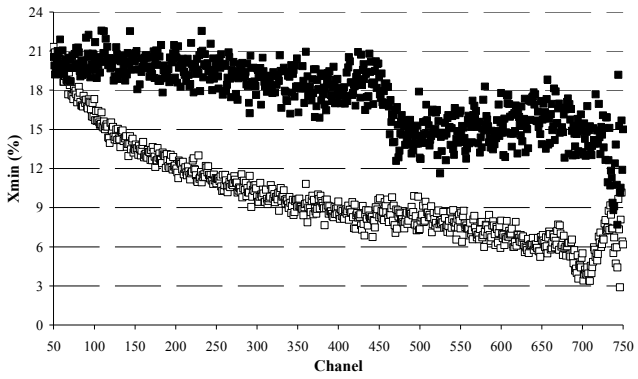

Figure 3. Crystal order variations obtained by RBS-c for bulk substrate (empty symbol) and thinned quartz layer (filled symbol).

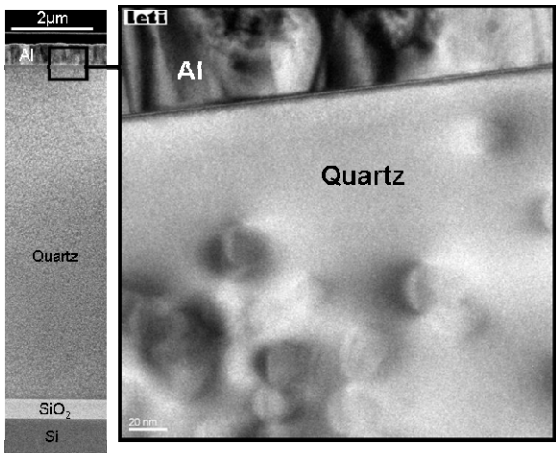

Figure 4. TEM cross section: punctual defects can be observed in the transferred quartz layer after the thinning process.

TEM observations revealed defects in the whole transferred layer, and not only at the surface of the film, as shown in Figure 4. Such defects, linked to dislocation formations, have been already observed in specific process conditions of pressure and temperature [3]. However pole figures measurements by X-ray diffraction (Figure 5) reveal same crystal orientation between initial bulk quartz wafer and quartz transferred layer.

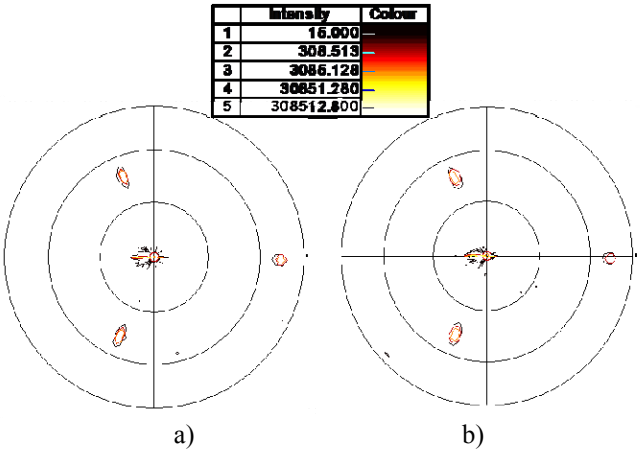

Figure 5. (101) pole figures measurements by –X-ray diffraction on bulk (a) and transferred (b) AT-cut quartz.

After the transfer of the quartz film onto silicon, we deposited top aluminum electrodes by evaporation and patterned them using standard photolithography and wet etching. The quartz film was released by a backside Deep Reactive Ion Etching (DRIE) of the Si substrate using a conventional Bosch process with the silicon oxide bonding layer acting as an etch stop. The backside of the wafer was then metalized by evaporation to allow metal to fill the bottom of the membranes and thus to provide a bottom electrode, as shown in Figure 6(a).

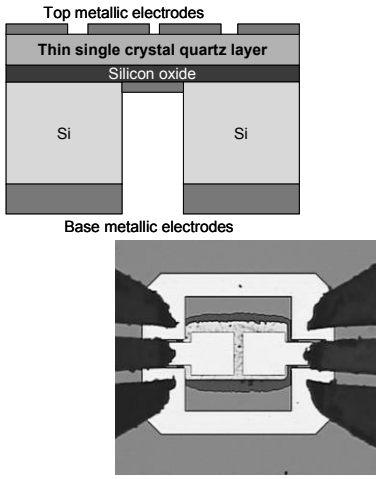

Figure 6. (a) Schematic cross section view of the final thin film quartz resonator. (b) Electrical tip on top metallic electrode of the measured device.

III. RESONATOR CHARACTERIZATION

The fabricated resonators are shown on the photograph in Figure 6(b). They consist in two resonators connected in series through the metallization of the backside of the quartz membrane. A ground ring is also located along with the two top electrodes.

These resonators were measured using two coplanar GSG probes. First, a resonator without the two square pads located on the top electrode seen in Figure 6(b) was measured, to determine the parasitic capacitance brought by the contact pads and the ground ring. This measurement was then subtracted from the measurement of the full device to suppress these parasitic influences. Although we measured this resonator as a two port device, we numerically shorted one of the two ports to retrieve the electrical behavior of a single resonator.

The resonance frequencies of the fundamental and of the third order resonance were found respectively at 156 and 464 MHz (Figure 7). Their respective electromechanical coupling factors, derived from the relative frequency spacing between resonance and antiresonance, were estimated at 0.4 and 0.03 % respectively. Quality factors are respectively of 2000 and 2500.

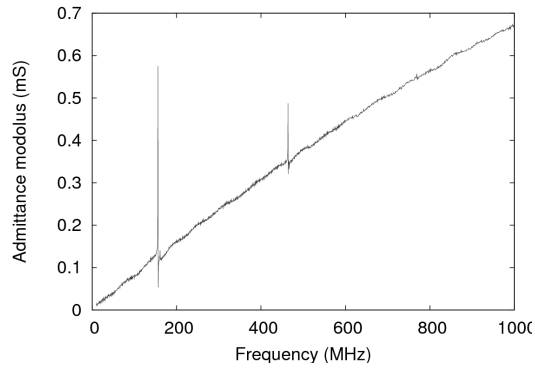

Figure 7. Electrical response of a thin film quartz resonator.

Figure 8 shows the comparison between measurements and simulations of the electrical response of a resonator based on the material stack performed using the scattering matrix method [4]. As it can be seen, an excellent agreement is obtained for the two frequencies. However, the theoretically expected electromechanical coupling factor is close to 0.75 %, being larger than what was measured. Also, the quality factor is slightly overestimated, which is attributed to lack of homogeneity of the bottom electrode layer deposited inside the membrane.

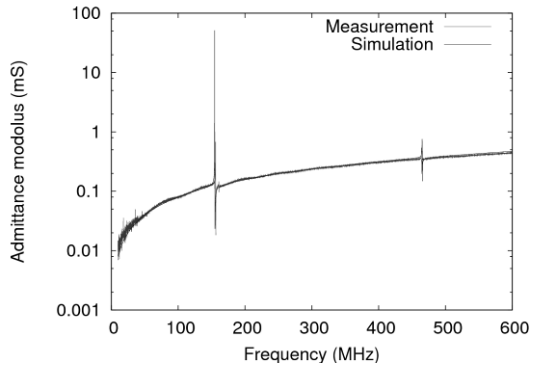

Figure 8. Comparison between the theoretical (light grey) and measured (dark grey) electrical response of a resonator.

For further investigations, we measured resonators for temperatures ranging from -25 to +125°C, by steps of 50°C. These measurements were carried out in an oven, with a narrow frequency span around the fundamental and third overtone so as to allow precise frequency steps of respectively 200 and 400 Hz. Figure 9 shows the relative frequency drifts as a function of the oven temperature: the two measured resonances exhibit almost similar linear temperature dependence (as expected). An average TCF of +26 ppm/°C was obtained. This result yields two main observations: first, its magnitude is rather large, being far from what was expected from the nearly temperature-compensated AT-cut of quartz, even if in our case metallizations are relatively thick with respect to the acoustic wavelength. Secondly, frequency shifts with temperature are positive, and can therefore not be attributed to the electrode materials or to any possible silicon remains, which would all ensure negative variations. Indeed, the theoretical temperature coefficient of frequency lies in the –3 ppm/°C, due to the silicon oxide bonding layer partially compensating metallizations. Only the silica layer may be responsible for such TCF result, but its thickness (200 nm) tends to eliminate this explanation.

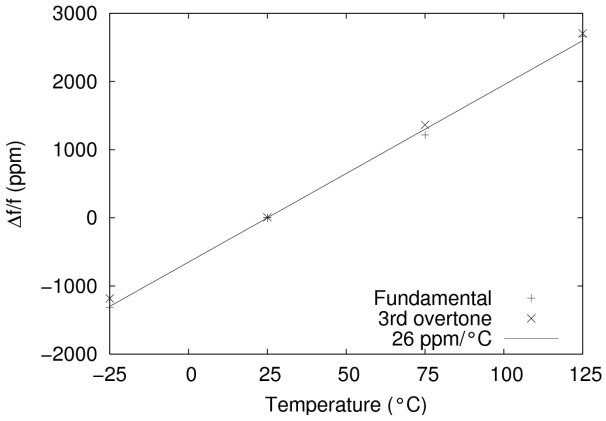

Figure 9. Relative frequency drifts vs temperature for the fundamental resonance and the third overtone.

A possible explanation for both large positive TCF and the decrease in effective electromechanical coupling factor could be the quartz amorphization during grinding. To assess the impact of the generation of an amorphous quartz layer, we modeled the resonators with an added silicon oxide layer which partially replaces the quartz film. Its impact on coupling factor and TCF is shown in Figure 10. This reveals that an equivalent layer of 4 µm of silicon dioxide could reasonably explain at the same time an effective coupling factor of 0.4 % and a TCF of +26 ppm/°C. Another explanation, implying less radical changes, could be the formation of twinned crystals in the material during grinding [5], leading to changes in the crystalline orientation of part of the material, which would manifest as changes in acoustic properties such as electromechanical coupling factor and temperature dependence, and could therefore lead to similar effects. Such a phenomenon would however have been revealed by X-Ray pole figures (Figure 5). Instead, pole figures performed on samples after bonding revealed only the existence of the crystalline orientation corresponding to the AT-cut without any other noticeable parasitic orientation.

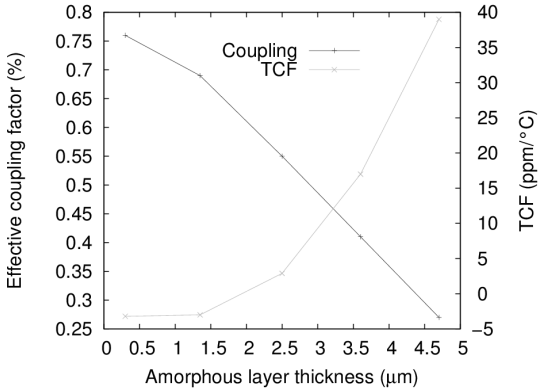

Figure 10. Impact of an amorphous (silica) layer on the performances of a quartz thin film resonator.

IV. CONCLUSION

This work reports on the transfer of a thin quartz film on a silicon substrate through wafer bonding and grinding. This was used to fabricate quartz crystal-based FBAR resonators, which were measured and characterized under various temperature conditions. The electromechanical coupling factor of 0.4 % and the temperature dependence of frequency of +26 ppm/°C, respectively lower and larger than theoretical predictions, suggest that the grinding step had somehow an impact on the piezoelectric material: possibly leading to the formation of an amorphous layer below its top surface. Future work will investigate these effects more into details and will focus on suppressing them to leave a fully defect-free quartz film.

Abstract— **This work describes the assessment of the acoustic properties of sputtered tantalum oxide films intended as high impedance films for the acoustic isolation of bulk acoustic wave devices operating in the GHz frequency range. The films are grown by sputtering a metallic tantalum target under different oxygen and argon gas mixtures, total pressures, pulsed DC powers and substrate bias. The structural properties of the films are assessed through infrared absorption spectroscopy and X-ray diffraction measurements. Their acoustic impedance is obtained after estimating the mass density by X-ray reflectometry measurements and the longitudinal acoustic velocity by analyzing the longitudinal λ/2 resonance induced in a tantalum oxide film inserted between an acoustic reflector and an AlN-based resonator. A second measurement of the sound velocity is achieved through picosecond acoustic spectroscopy.**

I. INTRODUCTION

Bulk acoustic wave resonator technology is a recent solution for low cost, high performance bandpass filters for digital wireless communications, such as wireless networking, cellular phones, or global positioning systems. These filters are composed of several resonators electrically connected to obtain the desired filter characteristics. To obtain well-performing devices, a good acoustic isolation of the resonators is required to avoid energy losses through the substrate that reduce their quality factor. There are two typical methods to achieve a good acoustic isolation. The first one consists in creating an air gap between the resonator and the substrate; as the acoustic radiation to the air is minimal, energy losses can only take place through the supports. These structures, called film bulk acoustic resonators (FBAR), have some drawbacks, as a complex fabrication technology or a too high thermal isolation that limits the power handling. The alternative method is the use of acoustic reflectors between the resonators and the substrate; the resulting structures are called solidly mounted resonators (SMR) [1]. Bragg mirrors are typical acoustic reflectors formed by alternating a quarter wavelength-thick layers (λ/4-layers) of low and high acoustic impedance [2]. The acoustic isolation achieved (reflection coefficient) increases with the number of layers and the mismatch between the acoustic impedances of two consecutive layers. Considering that the acoustic impedance of a given material is the product of the longitudinal sound velocity and the mass density, these two material properties have to be perfectly known in order to set the thickness of the films to λ/4 to get the targeted resonant frequency and to fix the number of layers required for a specified mirror reflectance. Table I summarizes the experimental values of such material properties for the most commonly used acoustic mirrors constituents.

TABLE I. ACOUSTIC IMPEDANCE OF METALLIC AND INSULATING MATERIALS

Material	Mass density ($kg \cdot m^{-3}$)	Sound speed ($m \cdot s^{-1}$)	Acoustic impedance ($kg \cdot m^{-2} \cdot s^{-1}) \times 10^{-3}$
SiOC	1500	2400	360
Al	2700	5100	1122
SiO_2	2200	6000	1320
Si_3N_4	2200	9900	2178
AlN	3300	11000	3630
Ta_2O_5	7000 – 8200	4000-5000	2800-4100
Mo	10300	6190	6376
W	19290	5180	9992
Ir	22500	5300	11920

Silicon dioxide (SiO_2) layers are commonly used as low acoustic impedance material, owing to their easy processing and full compatibility with standard silicon technologies [3]. Other low impedance materials are aluminum (Al) [4] and silicon oxicarbide (SiOC) [5], although they are less frequently used due to the metallic character of Al and the elevated acoustic losses of SiOC. On the other hand, materials with high acoustic impedance are typically high density metals exhibiting, additionally, a moderate sound velocity, such as iridium (Ir) [6], molybdenum (Mo) [7], or tungsten (W) [8]. If these high impedance layers are substituted by insulating films, the fabrication process of BAW filters can be

978-1-61284-110-6/11/$26.00 ©2011 IEEE

significantly simplified, as there is no need to define the continuous metallic layers that short circuit the different resonators built on top of the same acoustic mirrors. Achieving insulating Bragg mirrors requires, thus, high acoustic impedance insulating layers, which are unfortunately not easily available. So far, insulating acoustic mirrors have been obtained by combining SiO_2 or SiOC layers with aluminum nitride (AlN) [9], silicon nitride (Si_3N_4) [5] or tantalum oxide (Ta_2O_5) [10, 11], although the acoustic properties of this last have not been extensively characterized. However, none of these three materials exhibits really high acoustic impedances, in comparison with that offered by high density metallic layers. The considerably large acoustic velocity of AlN combined with a low mass density (see table I) provides a moderate acoustic impedance. On the other hand, TaO_x films offer similar acoustic impedance than AlN by virtue of its high mass density, although the sound velocity appears to be considerably smaller.

In this work we have characterized the acoustic properties of TaO_x films in order to investigate whether these layers, in combination with SiO_2 films, may provide better acoustic isolation than SiO_2/AlN-based Bragg mirrors. The structure, mass density and sound velocity of sputtered TaO_x films have been assessed by different techniques, which include the fabrication and characterization of specific devices for the evaluation of the sound velocity.

II. EXPERIMENTAL

A. *Sputtering Process*

TaO_x films were deposited in a Leybold Z-550 system by pulsed-DC magnetron sputtering of a 150 mm-wide Ta target in Ar/O_2 admixtures. A pulsed-DC power of 50 kHz and duty cycle 75% was applied to the target. More than 150 films were deposited under different conditions by varying the total pulsed-DC power between 500 W and 1200 W, the total pressure in the chamber between 1.5 mTorr and 3.3 mTorr and the percentage of O_2 in the gas between 30% and 100%. An RF source was used to polarize the substrate between -50 V (with no RF power applied to it) and -150 V. The substrates were not intentionally heated during deposition.

The sputter process of a Ta metallic target in Ar/O_2 atmospheres shows a transitory behavior owing to the oxidation of the target. When bombarding a clean metallic surface at constant power with a gas containing a certain amount of oxygen, the time to stabilize the plasma impedance can reach several hours. In order to guarantee that the target had reached a stationary state before starting deposition, the target was first preconditioned at the deposition power in pure oxygen atmosphere; the voltage of the cathode attained a constant value after around 15 min, when the plasma impedance reached the steady state. The selected gas mixture was then fed into the chamber at the chosen pressure and the voltage of the cathode controlled until the new steady state was attained (15 to 30 min). At this moment the shutter was opened for film deposition during the desired time. Subsequent depositions under identical conditions required only a few minutes for stabilization. Every time the deposition conditions were modified, the complete conditioning process was restarted. The TaO_x films were deposited on (100) silicon wafers for IR transmission measurements and on acoustic reflectors (described below) built on top of silicon substrates for the assessment of the sound velocity through the frequency response of test solidly mounted resonators (SMR).

B. *Film characterization*

The structure and morphology of the TaO_x were assessed by infrared transmission measurements carried out with a Fourier transform infrared (FTIR) Nicolet 5-PC spectrophotometer, which provided the chemical bonding configuration of the films. We used non-polarized light at normal incidence over the 400 cm^{-1} to 4000 cm^{-1} range with a spectral resolution of 4 cm^{-1}. The absorption bands corresponding to the Si substrate were eliminated by subtracting the absorbance spectrum measured in bare Si. X-ray diffraction patterns were measured in conventional Bragg-Brentano geometry in a Supratech XPert MRD diffractometer between $2\theta = 10º$ and $2\theta = 80º$.

The assessment of the acoustic properties of TaO_x films requires very precise measurements of their mass density, acoustic velocity and thickness. The thickness of the TaO_x films and that of the other films involved in test devices were measured with a Veeco Dektak 150 profilometer. The density of the TaO_x layers was assessed by X-ray reflectometry (XRR) measurements using the same diffractometer operated at grazing incidence between 0.05º and 2.5º. Finally, the longitudinal sound velocity was assessed using two different techniques. First, the sound speed was measured in different test structures by the picosecond ultrasonic technique [12]. A second assessment was deduced from the frequency response of the electrical impedance of specific SMR test devices containing the TaO_x layers under study, measured with an Agilent PNA N5230A network analyzer. The TaO_x films, with thickness ranging between 150 nm and 1000 nm, were inserted between a well characterized acoustic reflector composed of four alternated porous-SiO_2 and Mo films and a Mo/AlN/Mo resonator, as shown in Fig. 1. The excitation of the resonator induced a $\lambda/2$ resonance in the TaO_x film. The fitting of the experimental data with Mason's model allowed deriving the longitudinal acoustic velocity, provided that the material properties and the thickness of all the layers involved in the device were known.

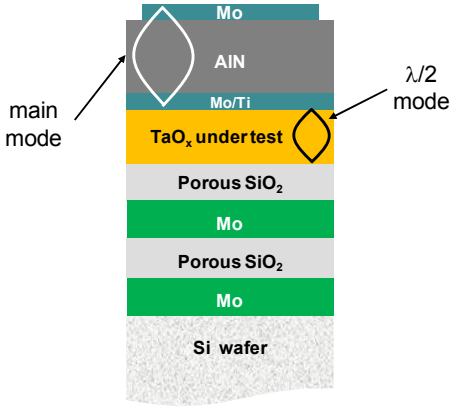

Figure 1. Sketch of the test devices used for assessing the sound velocity in sputtered TaO_x films. The main resonant mode in the piezoelectric stack is represented in white, and the $\lambda/2$ mode in the TaO_x film in black.

III. RESULTS AND DISCUSSION

A. *Structure and Composition of Sputtered Tantalum Oxides*

Fig. 2 shows the IR transmission spectra of three TaO_x of different thickness. The bands at 950 cm^{-1} and 650 cm^{-1} have been associated to the Ta-O-Ta stretching mode and the O≡Ta bond, respectively, of amorphous TaO_x films [13]. The main absorption band at 650 cm^{-1} has been reported to shift to lower wavenumbers (down to 510 cm^{-1}) in polycrystalline films. In our spectra this band appears as a shoulder in the 530 cm^{-1} region. The spectra suggest that our TaO_x films are mainly amorphous, but contain a certain amount of microcrystals. Considering the amplitude ratio of the bands at 530 cm^{-1} and 650 cm^{-1} as a qualitative estimation of the amount of microcrystals embedded in the amorphous matrix, a slight increase is observed with the thickness of the films. However, in films of similar thickness, we have not observed any clear dependence between the amount of microcrystals and the deposition conditions.

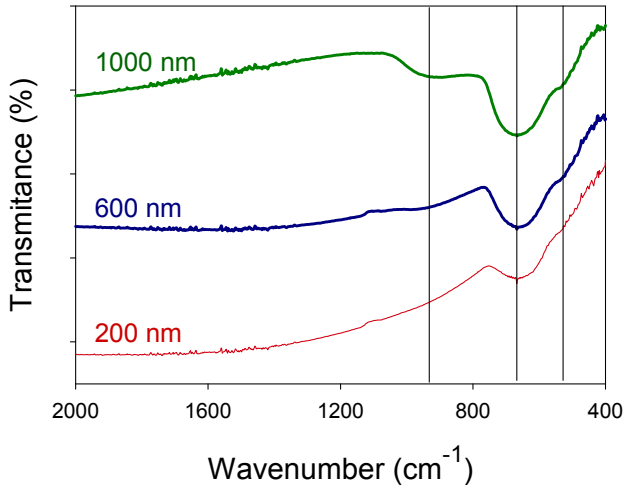

Figure 2. Infrared transmision spectra between 2000 cm^{-1} and 400 cm^{-1} of three TaO_x films of different thickness.

X-ray diffraction measurements confirm this behavior. Fig. 3 shows the XRD patterns of the three TaO_x films of different thickness analyzed by FTIR. It is important to note that, among all the films deposited, only a few exhibited clear XRD peaks corresponding to the orthorhombic β-phase of Ta_2O_5, whereas most of the films deposited in similar conditions were clearly amorphous. Peaks at 2θ=26º, 52º, 48º, 56º and 62º corresponding to the (210), (200), (3121), (200), and (201) directions of the Ta_2O_5 orthorhombic β-phase appear in the patterns corresponding to the thicker films, whereas no traces of these peaks are visible in the thinner one, which indicates its amorphous character. Additional peaks corresponding to AlN and Mo are also observed, as the films are characterized after depositing the piezoelectric stack for electric characterization. The data suggest again that thicker films tend to contain some nanocrystals whose grain size, derived from the width of the TaO_x peaks, is around 10 nm. However, we have not found any clear trend between the microcrystalline character of the samples (or any other film property) and the deposition conditions.

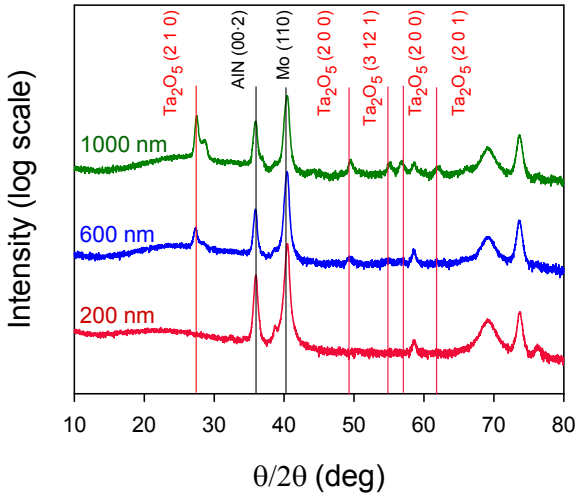

Figure 3. XRD patterns of TaO_x films of different thickness.

B. *Density assessment*

The mass density ρ of the TaO_x films was measured by XRR, which provides a direct assessment of ρ independently of the thickness. X-rays impinging on smooth TaO_x surfaces at grazing incidence below a critical angle θ_c are totally reflected. When the incident angle exceeds θ_c, the X-rays penetrate into the film and the intensity of the reflected beam drops sharply. According to [14], the ρ can be obtained through the measured θ_c. The XRR patterns of the densest and less dense TaO_x films are shown in Fig. 4; the patterns of all the remaining films lie between these two traces. The experimental data were fitted using the commercial software RCREFSimW from IHP [15] which provided an accurate value of ρ. The values obtained were 8100 kg/m^3 and 7300 kg/m^3, respectively, revealing that even the denser films do not reach the nominal mass density of Ta_2O_5 (8200 kg/m^3). These low values of ρ could be associated either to a lack of stoichiometry (films containing oxygen in excess) or more likely to a non-packed structure associated to the amorphous structure of most of the films. The high value of the refractive index (2.26) measured at a wavelength of 400 nm confirms this hypothesis.

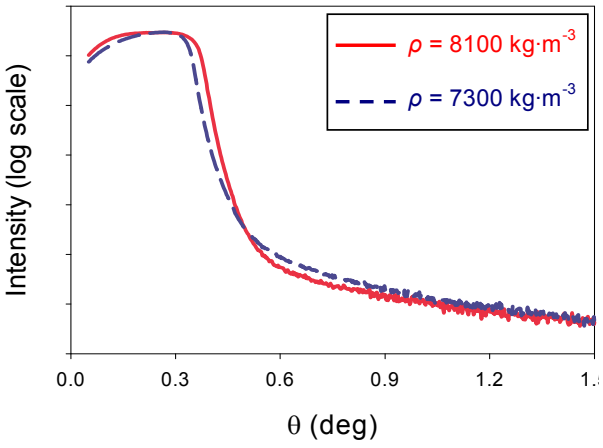

Figure 4. X-ray reflection curves of two 200 nm-thick TaOx films grown on acoustic reflectors. The red solid line corresponds to the film of highest mass density and the blue dashed line to the film of lowest mass density.

C. Sound Velocity Assessment

1) Assessment through test SMRs: The first way to assess the longitudinal sound velocity in the TaO_x films consisted in the measurement of the λ/2 resonant mode induced in these layers when they were placed in intimate contact with a piezoelectric resonator, as shown in Fig. 1. Taking into account that the wavelength of the stationary wave of this mode is ideally twice the thickness of the layer, the sound velocity v_s can be estimated, in a first approach, from the resonant frequency f_0 of the $\lambda/2_{TaOx}$ and the thickness t of the layer through:

$$v_S = f_0 \times 2 \cdot t \qquad (1)$$

However, as the resonant frequency also depends on the weight of the different layers involved in the test SMR, reliable values of the longitudinal sound velocity were only achieved if the whole experimental frequency response of the test resonator was fitted with Mason's physical model [16].

The variation with frequency of the modulus of the electrical impedance of two test SMR containing TaO_x layers of different thickness is shown in Fig. 5. Two resonances appear in each spectrum at different frequencies. The low frequency modes correspond to the main resonance in the AlN layer whereas the high frequency modes are associated with the λ/2 mode in the TaO_x film. Fig. 5 shows that upon decreasing the thickness of the TaO_x film, the two main resonances shift to higher frequencies, because the weight of this layer decreases and influences the travel of the wave in the whole structure.

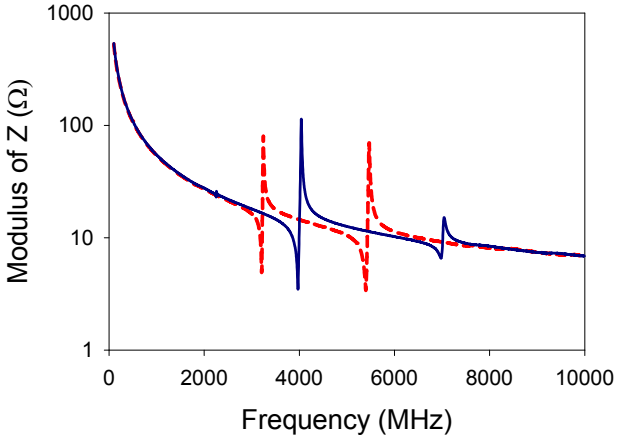

Figure 5. Modulus of the impedance versus frequency of two identical test SMRs containing 180 nm-thick (blue solid line) and 400 nm-thick (red dashed line) TaO_x films.

Fitting the experimental data to Mason's model requires precise values of the material properties of all layers involved in the test structures and of all the dimensions of the devices (thickness of layers and areas of the resonators). The area of the top electrode, which defined the areas of the SMRs, was measured carefully with an optical microscope to avoid errors due to the undercutting during the electrode definition. The properties of the different materials used for fitting the experimental data are listed in Table II. Data of Mo and AlN were taken from the literature and those of porous SiO_2 had been carefully characterized in a previous work [17]. Besides, all these layers have been routinely tested in other devices that do not contain TaO_x films.

TABLE II. MATERIAL CONSTANTS FOR SMR MATERIALS

Material	v_S (m/s)	ρ (kg/m^{-3})
Mo	5500	10500
SiO_2	5350	1900
AlN	11000	3300

The fitting of the experimental data of Fig. 5 allowed deducing the value of the longitudinal sound velocity of the different TaO_x layers, which are presented in Fig. 6. The dispersion observed is very likely due to the structural variations of the TaO_x films revealed by XRD and FTIR.

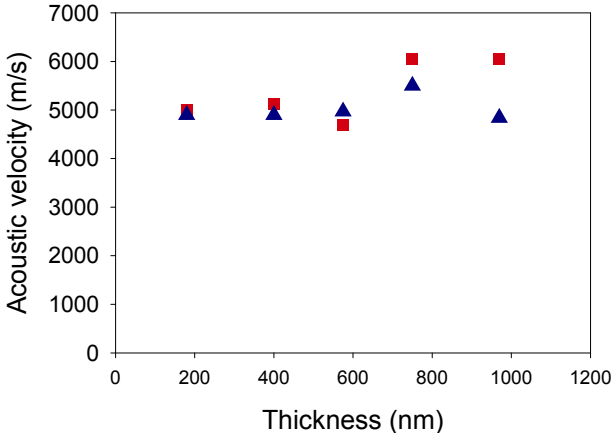

Figure 6. Sound velocity of a set of TaO_x of different thicknesses grown under identical conditions. BAW devices measurements (▲) and picosecond ultrasonics measurements (■).

2) Assessment through picosecond measurements: An alternative way of assessing the sound velocity is by the picosecond ultrasonic technique [18]. In this technique, a pump laser pulse heats the surface of the metallic layer producing a local dilatation. This generates a very high frequency longitudinal strain wave that propagates through the film to the surface at the longitudinal sound velocity. Two different methods were used to detect acoustic waves.

In the first method we detect the arrival of the acoustic pulse in the substrate. Assuming the thickness of the layer is known, the longitudinal acoustic velocity is obtained by dividing the thickness d by the time of transit τ of the echo:

$$v_s = \frac{d}{\tau} \qquad (2)$$

In the second method and as the strain wave propagates through the transparent film, it causes local variations of the refractive index. These changes can be detected by a second light beam, called the beam probe. The beam probe reflected at the surface of the films interferes with the beam reflected at the front of the traveling strain wave, causing the intensity of

the signal in the detector to oscillate with time. The period T of the so-called Brillouin oscillations is directly related to the longitudinal sound velocity through the equation,

$$v_s = \frac{\lambda}{2nT\cos\theta} \quad (3)$$

where λ is the probe wavelength, n the refractive index of the dielectric layer at λ and θ the incident angle [19,20].

The measurements were carried out on test structures composed of TaO_x layers of different thicknesses deposited on top of bare silicon substrates. A thin Al layer was deposited on the TaO_x film to allow the pumping pulse to be absorbed. The picosecond acoustic response of a representative sample is presented in Fig. 7, showing the first echo of the acoustic pulse at 133 ps and the period of the Brillouin oscillations of 20.3 ps. The value of the refractive index (2.26) at the laser probe wavelength (400 nm) was measured by ellipsometry. The acoustic velocity of this particular sample calculated by the two methods is 4500 m/s.

The sound velocities obtained by this technique are depicted in Fig. 6 together with those obtained by the BAW resonator fitting method. The results suggest that the sound velocity tends to increase with the thickness of the films, which would be in agreement with the nanocrystallites observed in the thicker films by XRD. They also reveal some discrepancies between the values achieved with the two techniques, especially for the thicker films. This can be due to the fact that the two techniques use different layered structures; whereas the TaO_x films assessed through the BAW test devices are grown on SiO_2 layers, those assessed by the picosecond measurements are grown on crystalline Si substrates. The structural differences of the underlying substrates may have affected the crystalline properties of the TaO_x films, and hence their sound velocities. Other picosecond measurements performed in TaO_x films deposited on molybdenum films yield sound velocities slightly greater than those achieved on Si substrates, which confirms the influence of the substrate on the TaO_x deposition.

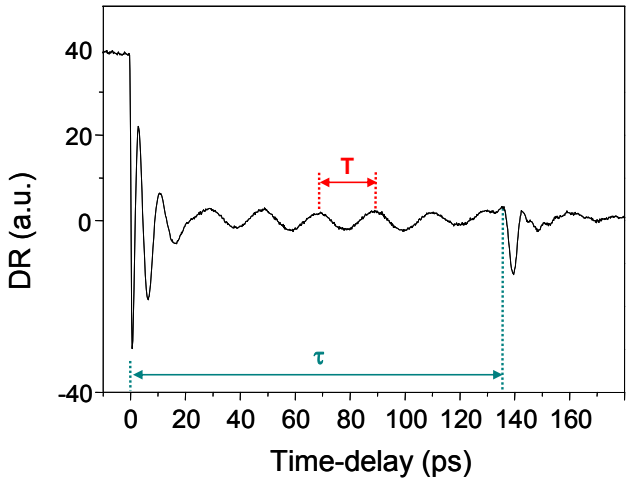

Figure 7. Picosecond acoustic response of a Al/TaO_x/Si structure showing the Brillouin oscillations of period T and the time of transit of the echo τ.

In order to investigate whether these TaO_x films may contribute to optimize the performance of insulating acoustic reflectors, we have simulated the acoustic transmittance of mirrors composed of nine alternated layers of porous SiO_2 and TaO_x films and compared it with that of conventional AlN-based mirrors. The simulations, shown in Fig. 7, suggest that even for the lowest values of the mass density and acoustic velocity, TaO_x-based mirrors exhibit lower transmission coefficients in a wider frequency band that AlN-based reflectors. Additionally, the dispersion of the values of the mass density and acoustic velocity does not affect significantly the performance of the reflectors in the middle of the band.

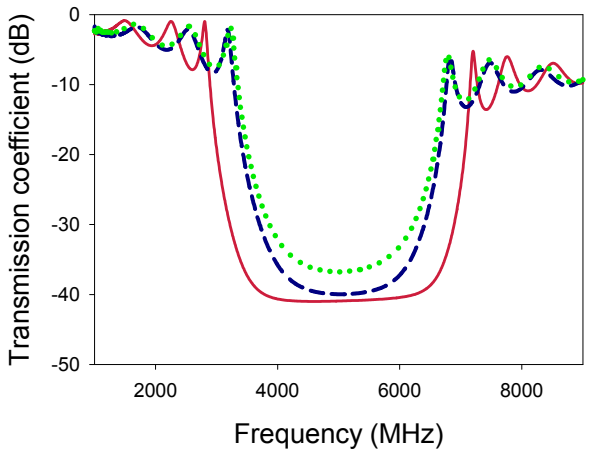

Figure 8. Simulated transmision coefficient of acoustic reflectors composed of nine porous SiO_2/TaO_x layers using a) the greatest values of ρ and v_s (red solid line) and b) the smallest values of ρ and v_S (blue dashed line) compared to that of conventional SiO_2/AlN reflectors (green dotted line).

Preliminary results on the performance of AlN-based SMRs using insulating TaO_x/SiO_2 acoustic reflectors yield quality factors up to 500 at 8 GHz.

IV. Conclusions

In this paper we assessed the acoustic properties of TaO_x films deposited at room temperature by reactive pulsed-DC sputtering. The sound velocity derived from picosecond measurements and the frequency response of BAW test devices slightly depends on the thickness of the films, which has been associated to their different structure. Thinner films appear to be amorphous whereas films 600 nm-thick and above tend to exhibit some nanocrystallites. The typical sound speed in films with thickness below 400 nm is around 5000 m/s. The mass density of the TaO_x films was assessed by X-ray reflectometry; the average value is 7600 kg/m^3, around 93% of the nominal density of Ta_2O_5 films. The typical acoustic impedance of the films is 38×10^6 kg·m^{-2}·s^{-1}, which is greater than that of AlN. Combined with a low acoustic impedance material, such as porous SiO_2, TaO_x films allow to fabricate all dielectric acoustic reflectors with good performances for GHz filtering applications.

Introducing porous silicon as a getter using the self aligned maskless process to enhance the quality factor of packaged MEMS resonators

***Abstract*—Vacuum encapsulated MEMS resonators are used in frequency references and gyroscopes. We present the use of porous silicon as a getter material for MEMS devices. Two types of devices were fabricated using the electrochemical etching and compared for quality factor. One type was with a cavity in the substrate of an SOI die, which helps in reducing the parasitic capacitance and the air damping. The other was with cavity and porous silicon (getter) in the substrate. The measured resonant profiles show that the device with the getter material has 2x higher quality factor than the one without the getter.**

I. INTRODUCTION

Encapsulation of MEMS devices protects structures from external environment and maintains low package pressures. As the typical mass of the resonating structure is in the order of 10^{-13} to 10^{-9} kg, any micro/nano dust particle could significantly increase the mass and cause a major drift in the frequency [1]. Several encapsulation techniques have been discussed in [2], such as anodic [3], fusion, eutectic, solder, adhesive and glass frit. Commercially available Bosch airbag and yaw rate sensors are one example of mass produced wafer bonded devices [4]. Hermetic encapsulation is needed in different devices such as accelerometers [5], RF switches for controlled air damping, sensitive gears and gyroscopes for moisture control of drag and friction, IR MEMS for vacuum insulation [6]. The main challenge in MEMS encapsulation is achieving the low pressure.

Getters are widely used to lower the effect of out gassing and maintain the required vacuum. The beneficial effects of getter material for MEMS resonators are well documented [6, 7]. Marco *et al* [6] presented a method to pattern the getter film named as High Porosity Thick Film (HPTF). The conventional method of using the getter films in ceramic and metallic packages uses the mixture of Ti and Zr getter alloy deposited on the metallic substrates. The getter has high porosity that absorbs H_2O, O_2, CO, CO_2, H_2 and N_2. The drawbacks of this approach are that *1.* An external layer needs to be introduced *2.* The process needs a mask alignment for pattering.

*Currently at VTI Technologies, Pasadena, CA.

We have presented a self aligned, mask-less electro-chemical etching process to etch cavities in the substrate of commercially available SOI wafers [8]. It was shown that with the introduction of cavity in the substrate of SOI, the quality factor increases by two times as compared to the quality factor of a device with no cavity. Using the same technology we present here the introduction of porous silicon (PS) in the substrate of SOI wafers, after the cavity is introduced, so that the porous silicon can be used as a getter material.

II. POROUS SILICON AS GETTER MATERIAL

Porous silicon has large internal surface area (in our case 200 m^2/cm^3). This surface is highly reactive silicon that can absorb gases. For example, the porous silicon layer is easily oxidized to capture oxygen gas as shown in Figure 1. The advantages of porous silicon getter along with cavity are: *1.* The cavity and porous layer reduces the parasitic capacitance and air damping that helps resonators perform better *2.* The porous layer needs no mask and is self aligned *3.* The porous getter material needs no external heat to be activated.

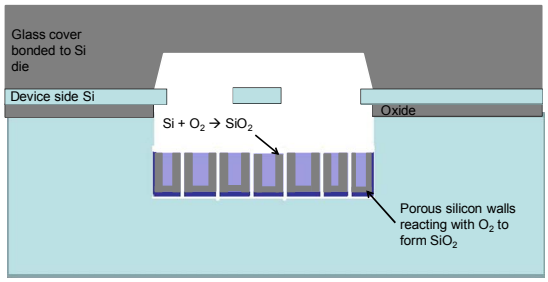

Figure 1. Schematic of the bonded SOI die that shows the reaction of silicon with oxygen resulting in silicon dioxide

III. EXPERIMENTAL SETUP AND RESULTS

Two types of encapsulated devices were fabricated for the comparison of non-getter and getter devices. First is with only a cavity in the substrate, and the second has a thick layer of porous silicon (PS) introduced in the substrate that acts as a getter. Our self-aligned process is shown in Figure 2. The cavity is formed by electrochemical etching of the substrate through the openings in the structural wafer. First, the buried oxide layer is removed with the concentrated HF solution. Next, a 10-µm thick PS layer is formed by electrochemical etching in diluted HF solution (10% HF, current density of 3.0 mA/cm^2 for 20minutes). This electrochemical etching works on the areas where the oxide has been removed. The sacrificial porous silicon layer is removed by a KOH etch. A 40 second KOH etch at room temperature is sufficient for removing the porous silicon layer but crystalline silicon is etched by less than 5 nm. Figure 2C shows the schematic of the die with only cavity in the substrate. Figure 3 shows the SEM image of the die with only cavity. To introduce the porous silicon in the substrate, after the KOH etch step, another cycle of electrochemical etching with the same process parameters mentioned above is performed. Figure 2 shows the schematic of the device with cavity and porous silicon getter in it. Figure 4 shows the SEM of the die with cavity and porous silicon. The dies were anodic bonded with glass for comparison of packaging pressure. Figure 5 shows the SEM of a bonded die that shows the glass and silicon bonded sample. A cavity of 100-150µm is introduced in the capping die. The cavity in the glass cap increases the volume in the encapsulated MEMS die and hence decreases the air damping on the resonator. Figure 6 shows the tuning fork resonator used to test the use of porous silicon as a getter.

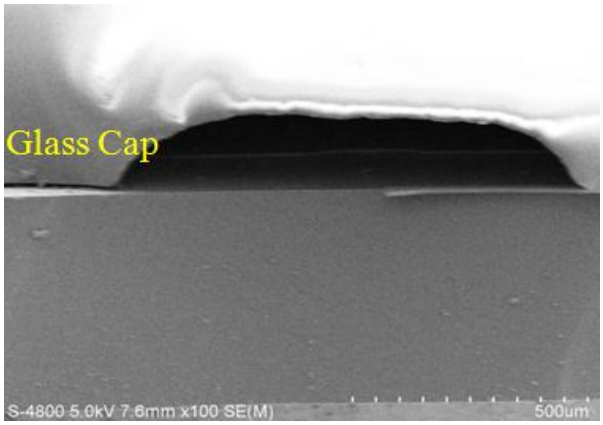

Figure 5. Anodic bonded SOI and glass die with cavity in the glass for extra volume in sample.

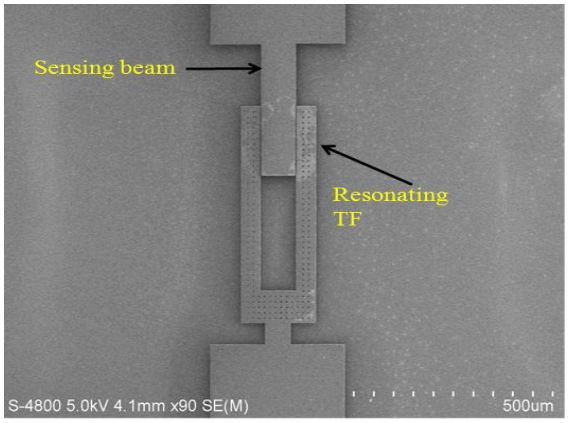

Figure 6. The tuning fork resonator used to test the use of porous silicon.

IV. RESULTS OBTAINED

The encapsulated devices were then tested for the resonant profiles with a network analyzer. Figure 7 shows the transmission response of resonators with the resonance frequency of f_o =243.54Khz. The device with only cavity had a quality factor of 8,000 and device with cavity and getter had a quality factor of 14,000. Hence the device with cavity and getter had a quality factor approximately two times higher than the device with only the cavity. Multiple samples were fabricated to confirm the performance of the porous silicon getter.

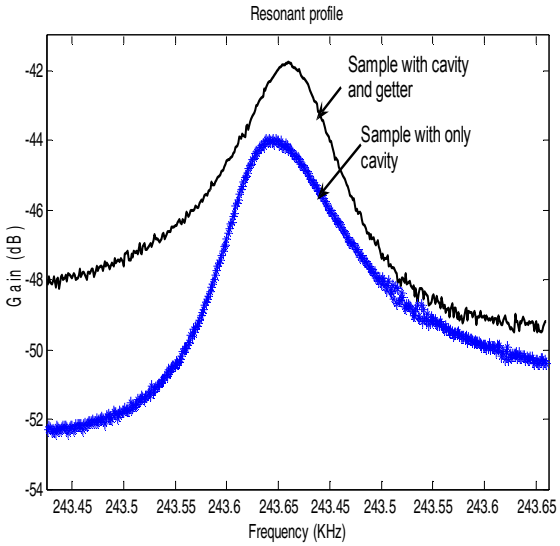

Figure 7. Resonant profiles of the devices with cavity and porous silicon getter, and with only cavity in the substrate.

Table I summarizes the quality factors obtained from these samples. It could be seen that the quality factor of the devices with getter was always better than the devices without getter.

TABLE I. SUMMARY OF QUALITY FACTORS OBTAINED FROM DIFFERENT DEVICES

	Q of devices with only cavity	**Q of devices with cavity and porous silicon**
Batch 1	7000	13520
Batch 2	5873	16083
Batch 3	2410	6701

V. PRESSURE IN THE BONDED SAMPLES

To estimate the pressure inside the bonded MEMS device, an uncapped die was tested in vacuum at different pressures. The pressure in the cavity was back calculated to be 5 Torr for the sample with only cavity and 1 Torr for the sample with cavity and getter. As the process parameters remained same in bonding both type of devices, the low pressure in the sample with the cavity and the getter is due to the getter in the device.

VI. THE NUMBER OF GAS MOLECULES ABSORBED BY PS

The SOI die size is 8mm×8mm and the area where porous silicon can be formed is 3.3 $\times 10^{-7}$ m^2. The volume of the porous silicon (V_{PoSi}) in the die is 3.3×10^{-11} m^3. The BET (Brunauer, Emmett and Teller) [9] surface area (A_{BET}) for the electrochemical etching parameters used is 200 m^2/cm^3 [10]. The surface area of the porous silicon (A_{PoSi}) is

$$A_{PoSi} = A_{BET} \times V_{PoSi} = 6.6\ m^2. \quad (1)$$

The number of active sites (N_{AS}) present on the surface of porous silicon that can react to the gases present are

$$N_{AS} = A_{PoSi} / CA_{Si} = 22\times10^{18}. \quad (2)$$

In Equation (2), the CA_{Si} represent the area of the crystalline Si. The number of moles of gas molecules (n)

present in the bonded devices can be calculated using the ideal gas law equation

$$n = \frac{PV}{RT}. \quad (3)$$

Table II summarizes the values of pressure (P), volume (V), gas constant (R), and temperature (T) used to calculate the number of moles of gas present in the sample with only cavity and in a sample with cavity and getter.

TABLE II. VALUES USED FOR COMPUTING THE NUMBER OF MOLES OF GAS MOLECULES

	Only cavity	**Cavity and getter**
P	5 Torr = 666 Pa	1 Torr = 133 Pa
V	33×10^{-12} m^3	33×10^{-12} m^3
R	8.314JK^{-1} mol^{-1}	8.314JK^{-1} mol^{-1}
T	300 K	300 K
n	8.8×10^{-11}	1.8×10^{-11}

The difference between the number of moles of gas present in the sample with only cavity ($n1$) and the number of moles of gas present in the sample with cavity and getter ($n2$) gives us the number of moles of gas molecules absorbed by the porous silicon getter which is

$$\Delta n = n1 - n2 = 7.0\times10^{-11} \text{ mol.} \quad (4)$$

Hence the number of molecules of gas molecules absorbed is estimated to be 4.3×10^{-13}.

VII. DISCUSSION

The benefits of cavity in the substrate of the MEMS devices are:

1. The parasitic capacitance to the substrate is reduced. The parasitic capacitance C_P is related to the device-substrate gap d by

$$C_P = \frac{\varepsilon_o A_{el}}{d}, \quad (5)$$

Where A_{el} is the area and ε_0 is the permittivity of free space. Hence, with the increase in the depth of the cavity, the parasitic capacitance C_P shown in Figure 7 is decreased. According to Eq. (2), the increase in distance of movable structure to the substrate from 2 to 10 μm reduces the parasitic capacitance by a factor of five.

2. The air damping is reduced. The main damping mechanisms are the squeeze film damping between the moving resonator and the fixed electrode caused by the air flowing from the gap to empty space above the device and the shear damping between the device and the substrate. By providing additional space under the device, the travel length for the air in between the electrodes is effectively reduced by half with air escaping to above and below the structure. In theory, this reduces the air damping by a factor of six. If shear damping (Couette damping) dominates, the quality factor is related to the distance between the movable structure and substrate [11, 12] by

$$Q = \frac{d\sqrt{mk}}{\mu A}, \quad (6)$$

where d is the distance between the devise and the substrate, m is the resonator mass, k is the spring constant, μ is the viscosity, A is the device area. According to (6), we expect 5x improvements in the quality factor.

3. The cavity under the resonator essentially eliminates the stiction problem where the device gets stuck to the substrate. We find that with the 10-μm cavity, even a millimeter long and slender structures never get stuck to the substrate.

The benefit from porous silicon getter:

The highly reactive porous silicon can readily react to the oxygen gas and form the oxide layer that can trap other gas molecules and hence maintain low pressure in the cavity. This benefit is realized without additional materials or masks in the process.

***Abstract*— a dedicated micro-resonator in a length-extension mode (LEM) has been developing for fundamental physics experiments, aiming to detect the quantum ground state of a resonator. The experiment is based on a high frequency, high quality factor and low mass micro-resonator, implemented in a high finesse Fabry-Perot cavity at cryogenic temperature. Very interesting preliminary measurements have been obtained on a 3.9 MHz, 25 µg resonator, given a 1.95 million quality factor, at room temperature and under a 5 10^{-2} mbar vacuum. By its planar configuration compatible with collective etching process, this resonator should also find interesting applications in the field of ultra stable oscillator (USO) and future quartz-MEMS USO.**

I. INTRODUCTION

Highlight the quantum ground state (QGS) of a micro-resonator is a quest involving many fundamental physics laboratories [1-6]. Such quantum fluctuations correspond to ridiculously small position fluctuations for usual macroscopic objects and two very stringent conditions must be fulfilled in order to reach and detect the mechanical QGS.

Firstly, the thermal energy ½ $k_B T$ at the cooled temperature T (T= temperature in Kelvin and k_B = Boltzmann constant) has to be small compared to the fundamental quantum energy ½ $\hbar\Omega_m$ of the harmonic oscillator (Ω_m = its mechanical resonance angular frequency of the resonateur, $\hbar$ = reduced Planck constant). Typical temperatures range of 50 mK for a 1-GHz resonator must be met which is a readily accessible temperature by standard dilution cryogenic techniques. However, temperature down to 50 µK is required for a resonator oscillating at 1 MHz. In that case, other cooling technique has to be implanted like the recently-demonstrated laser cooling based on the optomechanical coupling between the resonator and a laser beam in a detuned Fabry-Perot cavity [7-9].

Secondly, very small position fluctuation $\Delta x_0 = (\hbar/2M\Omega_m)^{1/2}$ of the QGS has to be detected, depending on the mass resonator M, its quality factor Q and its frequency Ω_m: For a 3-MHz oscillator with a 25-µg mass and a 3.10^6 quality factor (corresponding to a 1-Hz mechanical resonance bandwidth), this condition requires measurement sensitivity better than 10^{-34} m^2/Hz.

To fulfill these both conditions, the experiment is based on a high finesse Fabry-Perot cavity (figure 1) at cryogenic temperature, able to detect extremely small position fluctuation, better than 10^{-36} m^2/Hz, thanks to a high cavity finesse of 10 000, a power source of 1 mW and a laser wavelength λ of 1064 nm.

.

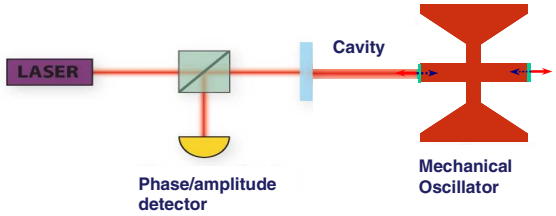

Figure 1. Experiment to detect the quantum ground state of a resonator : The resonator takes place of a moving mirror of a high finesse Fabry-Perot cavity at cryogenic temperature.

In this experiment, the resonator takes place of the moving mirror of the cavity and we have choosen a length-extension mode (LEM) in order to maximize the optomechanical coupling (the position fluctuations are indeed directly coupled with the cavtiy length).

An other important advantage of a length-extension resonator concerns the mirror-carrying surface at the top of the resonator. This area corresponds to a quasi null strain zone, lowering the coating losses of the highly reflective mirror deposited on it [10]. The intrinsic quality factor of the resonator is thus preserved .

978-1-61284-110-6/11/$26.00 ©2011 IEEE

A few MHz resonator with a few 10 µg mass and a quality factor in the order of 10^6 at room temperature is to be achieved in order to be able to highligth the QGS. A high initial quality factor is needed because of the laser cooling technique used in this experiment which reduces the quality factor of the resonator in same factor than the temperature: lowering the dilution cryogenic temperature of 50 mK to 50 µK reduces the quality factor by a factor 1000 and requires more acurate detection.

Quartz crystal has been chosen for the realisation of the resonator, because of its well known high intrinsic quality even at cryogenic temperature [11]. Quality factor above 300 million has also been recently reported [12] for a quartz macro-resonator in a length-extension mode at 15 MHz.

This paper describes the design, the optimization, the manufacturing and the first evalution of these dedicated length extension resonator. First reflexions of its possible application in time and frequency domains is also discussed.

II. RESONATOR CONCEPT

The design of a high Q resonator is not so easy and care must be taken in order to confine the vibrating energy into the resonator. The quality factor Q of a resonator is indeed defined as the ratio between the stored vibrating energy (W) and the total dissipated energy (ΔW) per cycle of vibration (times 2π). Just consider a 10^{-6} energy loss of the resonator energy, for example in its clamping, and further consider that all of this energy loss is dissipated, you finally obtain a resulting Q factor limited to a maximum of 10^6.

The initial concept of length-extension resonator was based on pillar, clamped at its center by a thin membrane. In that case, reducing the energy loss out of the resonator is a real challenge because of the well-know Poisson effect (figure 2.), relating the fact that a pillar submitted to an extension strain induces a transverse strain in the ratio of the Poisson coefficient ν (generally of 0.1 to 0.5, ν = 0.5 corresponding to incompressible material).

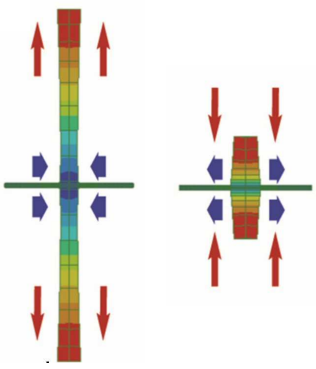

Figure 2. Resonator in length-extension mode: the Poisson effect induces a strong lateral displacement

An original concept has been proposed [13] in order to solve this problem. It is based on a complementary ring around the pillar and an external membrane for the clamping of the resontor (figure 3.).

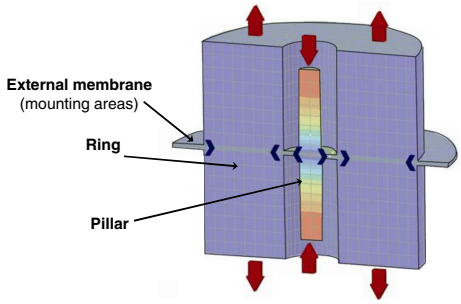

Figure 3. Proposed concept: a ring around the pillar with an out of phase length-extension vibration compared to the pillar.

Thanks to particular tuning conditions of the pillar and the ring frequencies, it is possible to avoid the lateral displacement of the external membrane, allowing a mounting of the resonator without energy loss. This effect is illustrated on figure 4. showing the resonator vibration displacement in free-free boundary conditions (the external membrane is not clamped).

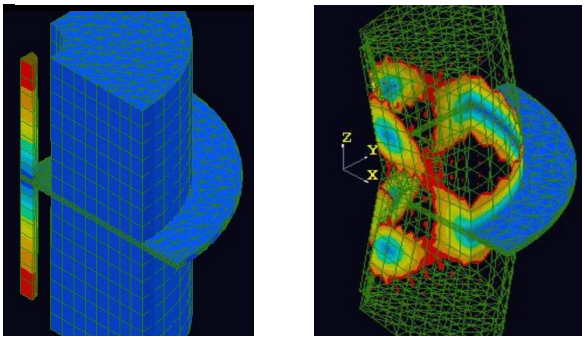

Figure 4. Resonator in free-free boundary conditions
-Left: pillar vibration
-Right: observation scale magnified by 400. No displacement of the external membrane.

On the left, the length-extension pillar vibration is shown (only one quarter of the structure is represented) and the right picture gives the same picture with an observation scale magnified by a factor 400. No vibration displacement is induced to the external membrane, thanks to a compensation of the pillar Poisson effect by an out of phase length-extension of the ring (coupled with a ring bending).

III. QUARTZ RESONATOR OPTIMIZATION

A dedicated optimization has been undertaken, taken into account the specificity of quartz crystal and the chosen

micromachining by wet chemical etching for the manufacturing of the quartz resonator. A crystallographic orientation of the pillar along the Z axis has been chosen, as well as a pillar equilateral cross-section with respect to the quartz trigonal symmetry: a nominally symmetric structure with regard to its median plane is thus possible, which is a sine qua non condition to obtain a good balancing of the length extension mode (manufacturing by wet chemical etching).

Figure 5. gives the planar shape of the quartz resonator (left picture) and its 3D Finite Element Model (FEM), including the etching facets created by the chemical etching.

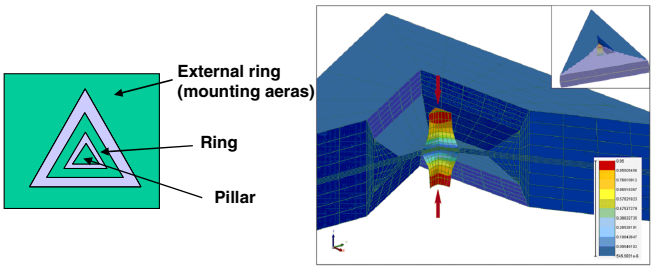

Figure 5. Quartz resonator configuration :
-Left: triangular shapes taken into account the trigonal symetry of quartz (Z cut quartz wafer).
- Right: finite element model taking into account the etching patterns obtained by chemical etching of quartz.

The typical dimensions of the pillar are a triangular cross-section side of 200 µm and a total length of 1 mm. The external and internal are 50 µm thick, given a theoretical resonance frequency and an effective mass around 3.5 MHz and 25 µg respectively.

Finite Element simulations (SAMCEF code) have been done in order to optimize the resonator dimensions and study the impact of some dissymmetry effects as a lateral misalignment (figure 6.) or a dissymmetry with respect to the median plan (figure 7.). The optimization has been focused on the dynamic behaviour of the resonator to avoid any interference with other vibration modes and to reduce the energy loss out of the resonator.

By defining the $Q_{support}$ as the ratio of the total stored energy in the resonator by total energy out of the resonator (the clamping for example), the last optimization of the quartz structure gives a $Q_{support} > 10^6$, including a lateral misalignment and a height dissymmetry of 2 µm, corresponding to our actual technology limitation. This $Q_{support}$ is thus compatible with an intrinsic quality factor in the range 1 – 10 million, depending of the effective support energy dissipation.

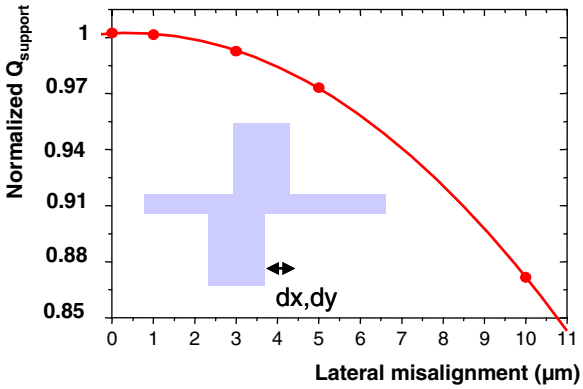

Figure 6. Effect of a lateral misalignment on the $Q_{support}$ for the optimiezd quartz strcuture.

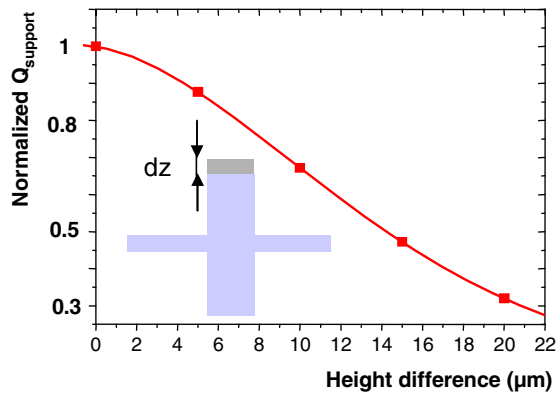

Figure 7. Effect of a dissymmety with respect to the median plan on the $Q_{support}$ for the optimizd quartz structure.

IV. QUARTZ RESONATOR MANUFACTURING & CARACTERIZATION

Only one step of chemical etching is needed to obtain the quartz LEM resonator (figure 8.). This very simple process is very similar to those developed for other advanced quartz MEMS devices [14-15].

A dedicated NH_4F/HF mixture is used for the chemical etching of quartz, allowing a low roughness of the etched surface defining the internal and external thin membranes.

Critical steps concern photoresist deposition on the 3D structure obtained after chemical etching, the photolithographic process defining the front and back mirrors, and most of all the removing of the photoresist after the coating of the multilayer high reflective SiO_2/Ta_2O_5 mirrors (because of the high temperature reached by the photoresist during the ion beam sputtering). The photoresist will be soon replaced by a metallic mask at this process step.

Figure 9. shows a 1.5" square quartz wafer including 9 LEM resonators obtained by collective chemical etching.

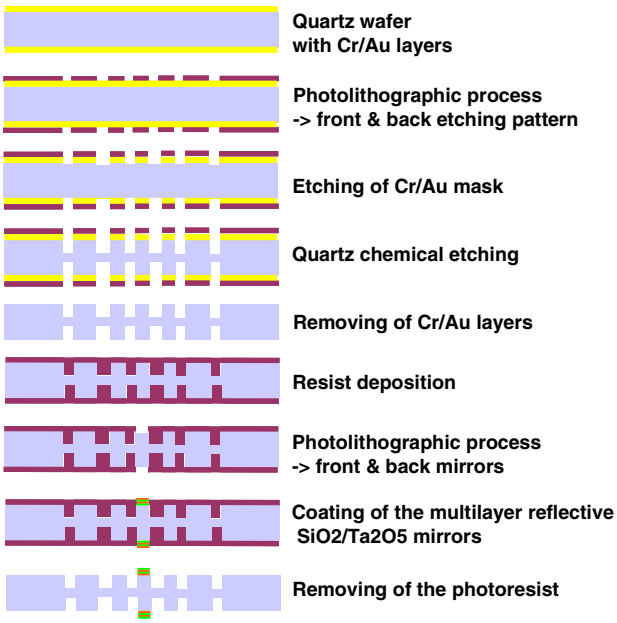

Figure 8. manufacturig process of the planar-planar LEM resonator: only one step of chemical etching is needed to obtain the quartz structure.

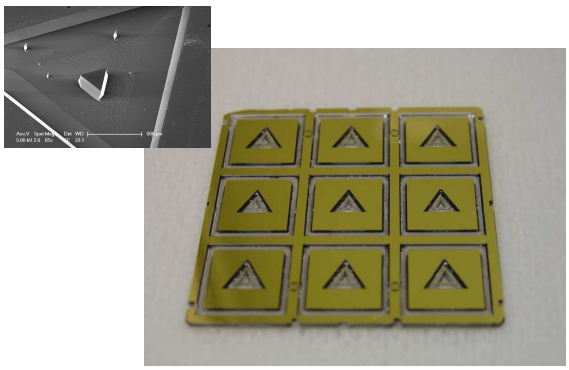

Figure 9. 1,5" square quartz wafer including 9 LEM resonators obtainend collectivelly by wet quartz chemical etching. Top & left, detail of the micro-pillar.

Charaterization of the second generation of LEM resonators (at this time, still without the hight refelctive mirrors), have been made thanks to a dedicted test-bench based on a Michelson-interferometer configuration, able to work under vacuum [16]. Particularly intersting results have been obtained since a quality factor of 1.95 million has been measured at room temperature (by a ring-down method), for a LEM resonateur frequency of 3.87 MHz and a vacuum of 0.2 mbar vacuum (figure 10.). These results are in improvement by a factor 5 in comparaison with previous results [16], mainly due to the new optimization of the structure and the improvement of the manufacturing quality.

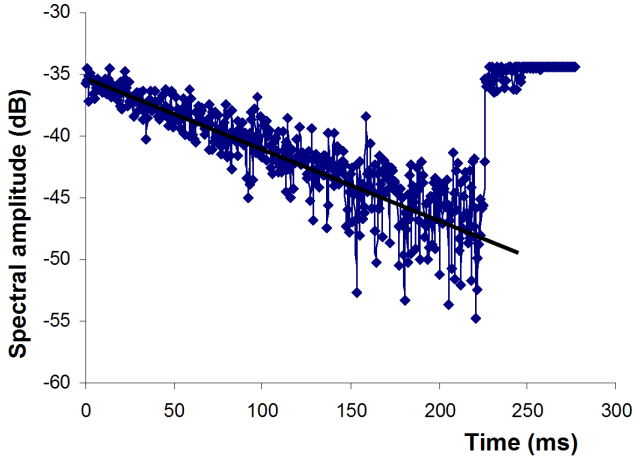

Figure 10. Measurement of the last generation of quartz LEM resonator:s a quality factor of 1.95 million at a frequency of 3.87 MHz has been obtained at room temperature and under a vacuum of 0,2 mbar.

V. CONCLUSION & PERSPECTIVES

A new concept of a length-extension mode (LEM) quartz resonator has been proposed and developed for the observation of its quantum ground state. Very interesting results have been obtained on the last generation of resonators, given a quality factor near 2 million at a frequency around 4 MHz and a very small effective mass of 25 µg: the measured Q x F product of 8.10^{12} is near the state of the art of ultrastable oscillator [17] where the best shear mode macro quartz resonators show a 3. 10^{13} Q x F at room temperature.

Next steps will be the coating of a highly reflective mirror on the top of the resonator, and its implementation in a dedicated Fabry-Perot cavity. Thanks to the high mechanical quality factor of the resonator and thus to the efficient cooling mechanisms that can be used, low temperature operation of such an optomechanical device would open the way to the observation of the quantum ground state of a micro-mechanical resonator.

By its planar configuration compatible with collective etching process, this resonator should also find interesting opportunities in the time and frequency domain, in particular for a new generation of miniature ultrastable oscillator (USO) compatible with collective manufacturing (Quartz MEMS USO). Work has been undertaking in this way to first identify a temperature compensated cut suited to our resonator design and its actuation/detection by piezoelectric effect, as it has been found for other length-extension design resonators [18]. Collective micromachining of quartz wafer based on recent quartz Deep Reactive Ion Etching techniques will be also developed, as well as a quartz wafer level packaging compatible with the vacuum requirement.

***Abstract*—The characteristics of aluminum nitride (AlN) Lamb wave resonators utilizing the lowest symmetric (S_0) mode with grounded, floating, and open bottom surface configurations are theoretically and experimentally investigated. The Lamb wave resonator without the bottom electrode exhibits a quality factor (Q) as high as 2,573 but a low effective coupling of 0.18% at 949.7 MHz. On the contrary, the Lamb wave resonator with a floating bottom electrode shows an effective coupling of 1.05% but a low Q of 850 at 850.3 MHz because the imperfect interface between the AlN plate and bottom electrode usually degrades the Q. Limited by the larger static capacitance, in contrast to the floating bottom electrode, the Lamb wave resonator with a grounded bottom electrode shows a smaller effective coupling of 0.78% and a low Q of 800 at 850.5 MHz. These results suggest that the resonator with a floating bottom surface is suitable for filter applications, whereas that with an open bottom surface is preferred for sensor and oscillator applications.**

I. INTRODUCTION

Recently, there are a large number of long-term evolution (LTE) frequency bands that are being designated as the possibilities for the third generation (3G) and the fourth generation (4G) wireless mobile systems. For the frequency division duplex (FDD) and time division duplex (TDD) technologies, most of the LTE frequency bands are allocated within the ultra-high-frequency (UHF) region. Several LTE frequency bands have designated with the narrow bandwidths between 0.75% and 2% [1]. In recent years, a new class of aluminum nitride (AlN) Lamb wave resonators utilizing the lowest symmetric (S_0) mode is being widely explored [2]–[7]. The AlN Lamb wave resonator usually exhibits a high phase velocity around 10,000 m/s and a moderate electromechanical coupling, very suitable for the high-frequency and narrowband wireless transmission systems.

During the past six years, two distinct designs of S_0 mode Lamb wave resonators are simultaneously developing. One is based on the Lamb wave excitations from the interdigital transducer (IDT) and the reflections from the periodic gratings on the AlN membrane (the grating-type reflector) [2], [3]; instead, the other one is based on the Lamb wave excitations from the IDT and the reflections from the suspended free edges of the AlN membrane (the edge-type reflector) [4]–[7]. Furthermore, the robust temperature compensation for the two types of S_0 mode Lamb wave resonators has been theoretically analyzed and experimentally demonstrated [8]–[10]. These aforementioned results reveal the potential of Lamb wave resonators for the future narrowband wireless transmission systems because this technology can reliably provide a wide frequency range from hundreds MHz to several GHz on the single silicon chip and simultaneously offer the high quality factor (Q) as well as the low motional resistance (R_m) in air.

In this work, the S_0 mode Lamb wave resonators utilizing the edge-type reflector with the various bottom surface configurations are studied. As shown in Fig. 1, the electric field distributions in the AlN membrane would dominate the performances of the resonators with grounded, floating, and open bottom surface configurations. Based on the same IDT

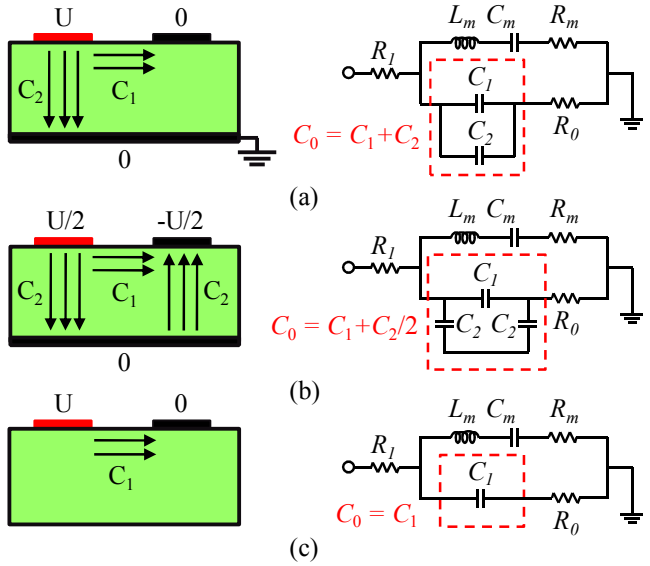

Figure 3. A simple physical model for the capacitive feedthrough to ground in the one-port Lamb wave resonator and the equivalent C_0 in the modified Butterworth-Van dyke (MBVD) models for the electrically (a) grounded, (b) floating, and (c) open bottom surfaces.

design, the AlN Lamb wave resonator with a floating bottom electrode provides a larger effective coupling (k^2_{eff}) of 1.05%, presenting a 1.35× increase in k^2_{eff} over that with a grounded bottom electrode because the floating bottom electrode makes a smaller static capacitance in the membrane. However, the electrode-to-resonator interface stress causes the degradation in Q. In contrast to the metallized bottom surface, the Lamb wave resonator with the non-metallized bottom surface (i.e. the open bottom surface) provides a Q as high as 2,573 but a small k^2_{eff} of 0.18% due to the weak electric field in the 1.5-μm-thick AlN membrane.

II. Fininte Element Analysis of One-Port Lamb Wave Resonators With Various Bottom Surfaces

By using Adler's approach [11] or finite element analysis (FEA) method [12], the dispersive electromechanical coupling in the piezoelectric plate can be theoretically calculated. In the simulation, the S_0 mode Lamb waves propagate in the plane normal to the c-axis of the AlN membrane and the bottom electrode is assumed to be infinitely thin. As illustrated in Fig. 2, the dashed and solid lines represent the electromechanical coupling dispersion of the S_0 mode Lamb waves in the AlN membrane with the non-metallized and metallized bottom surfaces, respectively. In general, the metallized bottom surface enhances the electromechanical coupling coefficient because the electric field strength through the AlN thin plate is higher than that between the IDT electrodes. However, the electromechanical coupling calculated using Adler's approach is identical for the both grounded and floating bottom surfaces because the short-circuited boundary condition is considered in the two configurations. This is not true for the real Lamb wave resonator since the parallel frequency and the effective coupling are significantly influenced by the static and parasitic capacitances in the resonator. Therefore, the actual effective couplings for the grounded and floating bottom electrodes are different because of the distinct static capacitances in the two configurations.

As shown in Fig. 3, a simple physical model can be used to illustrate the effect of capacitive feedthrough to ground in the one-port Lamb wave resonator and the static capacitance (C_0) in the modified Butterworth-Van dyke (MBVD) models for the electrically grounded, floating, and open bottom surfaces. For the grounded bottom surface in Fig. 3(a), the lateral and vertical electric fields induce the in-line capacitance (C_1) and cross-field capacitance (C_2) so the C_0 is simply assumed to be the summation of C_1 and C_2. As for the floating bottom surface in Fig. 3(b), the electric potential in the bottom electrode is presumed to be zero and the electric potentials in the electrodes are equivalent to be U/2 and –U/2 because of the symmetric electric filed. As a result, the C_0 is simply assumed to be the summation of C_1 and $C_2/2$ for the floating bottom surface. As illustrated in Fig. 3(c), C_0 is simply equal to the in-line capacitance, C_1, in the open bottom surface. The excitation efficiency of the IDTs with grounded and floating bottom surfaces would be the same and larger than that with an open bottom surface because the backside metallization strongly enhances the vertical electric field in the AlN plate. In addition, C_0 in the open bottom surface is the smallest among the three configurations; C_0 in the floating bottom surface is smaller than C_0 in the grounded bottom surface, resulting in a larger k^2_{eff} for the resonator with a floating bottom electrode.

In order to verify the above physical model, as shown in Fig. 4, the two-dimensional (2D) model in COMSOL FEA software is used to simulate the frequency spectra of one-port AlN Lamb wave resonators with the grounded, floating, and open bottom surfaces. With the same 11 electrode design but different electric conditions in the bottom surfaces, the 2D COMSOL FEA model predicts that the floating bottom electrode provides a 1.8 times larger k^2_{eff} than the grounded bottom electrode on a 1.5-μm-thick AlN plate. The simulation results also confirm that the transduction efficiency of the IDTs with grounded and floating bottom electrodes would be

TABLE I. GEOMETRIC DIMENSIONS OF LAMB WAVE RESONATORS

	Design 1	Design 2	Design 3
IDT electrodes	11	11	11
Aperture	100 μm	100 μm	100 μm
Electrode width	2.77 μm	2.77 μm	2.77 μm
Pt IDT electrode thickness	100 nm	100 nm	100 nm
Pt bottom electrode thkickness	100 nm	100 nm	-
AlN membrane thkickness	1.5 μm	1.5 μm	1.5 μm
Bottom electric condition	Grounded	Floating	Open

identical when the same even electrode pairs and acoustic loss conditions are considered in the simulation.

III. EXPERIMENTAL RESULT AND DISCUSSION

In order to study the effect of the bottom electric condition on the resonator performance, the AlN Lamb wave resonators with electrically grounded, floating, and open bottom surfaces are designed as summarized in Table I. The micro-fabrication process has been presented in [6] so it is not further considered in this work. To diminish the experimental error resulted from the fabrication process, the resonators were fabricated on the same wafer and placed in the vicinity. Lamb wave resonators were all tested in air and S_{11} parameters were extracted using an Agilent E5071B network analyzer. The measured Q was extracted from the admittance plot by dividing the resonance frequency by the 3 dB bandwidth. The k^2_{eff} of the measured devices is defined as

$$k_{eff}^2 \approx \frac{\pi^2}{4}\left(\frac{f_p - f_s}{f_p}\right) \quad (1)$$

where f_s and f_p are the series frequency and parallel frequency, respectively.

Fig. 5 presents the measured frequency spectra of one-port AlN Lamb wave resonators with the grounded, floating, and open bottom surfaces. With the same 11 IDT electrodes but different bottom electric conditions as listed in Table I, the Lamb wave resonator with the open bottom surface exhibits the smallest k^2_{eff} of 0.18% and transduction efficiency as expected. However, it exhibits a loaded Q as high as 2,573 among the three resonator designs. The transduction efficiency and effective coupling of the resonator with an open bottom surface can be enhanced by increasing the IDT electrodes or thickening the AlN membrane [13].

On the other hand, the Lamb wave resonator with a floating bottom electrode shows the highest k^2_{eff} of 1.05%, presenting a 1.35× enhancement in k^2_{eff} over that with a grounded bottom electrode, whereas the presence of additional bottom electrode decreases the Q to 850 because of the high stress levels in the interface. In addition, the extracted C_0 in the AlN plate with the floating and grounded bottom electrode are 195 fF and 355 fF, respectively. The result confirms that the floating bottom electrode efficiently reduces C_0 and boosts k^2_{eff} in the one-port AlN Lamb wave resonator. Moreover, the employment of the floating bottom electrode also makes the micro-fabrication process easier because the electrical contact via is no longer needed.

In the 2D COMSOL FEA model, the simulated C_0 ratio of the grounded bottom electrode to the floating bottom electrode is approximately equal to 2 for the same design parameters listed in Table I. However, the measured C_0 ratio is equal to 1.82 because some additional significant parasitic capacitances occur and influence the experimental C_0 ratio. In fact, these additional parasitic capacitances are dead and do not take the responsibility for the Lamb wave excitation, but only decrease the parallel frequency and consequently reduce the k^2_{eff} for a given AlN plate thickness.

In addition to k^2_{eff} and C_0, the experimental transduction efficiency of the Lamb wave resonators with grounded and floating bottom electrodes is of interest. For this purpose, the coupling-of-modes (COM) transduction coefficient, $\alpha(\omega_0)$, which is responsible for the excitation efficiency of the IDT,

TABLE II. PERFORMANCE OF LAMB WAVE RESONATORS

	Grounded	Floating	Open
f_s [MHz]	850.5	850.3	949.7
Q	800	850	2573
Motional resistance, R_m [Ω]	78	90	685
Motional capacitance, C_m [fF]	2.22	1.66	0.14
Static capacitance, C_0 [fF]	355	195	96
k^2_{eff} [%]	0.78	1.05	0.18
Figure of merit, $k^2_{eff}Q$	6.2	8.9	4.6
TCF [ppm/°C]	–27.0	–26.6	–25.9

can be introduced to compare the excitation efficiency of the IDTs with grounded and floating bottom electrodes. The COM transduction coefficient $\alpha(\omega_0)$ is derived as [14]

$$\alpha(\omega_0) = \frac{Q_F(\beta)}{\Lambda_T}\sqrt{\frac{\omega_0 W \Gamma_s}{2}}, \quad (2)$$

where Λ_T is the wavelength of transduction, $Q_F(\beta)$ is the elemental charge density function, $\beta=2\pi/\Lambda_T$ is the acoustic wave number, ω_0 is the resonance angular frequency, W is the IDT aperture, and Γ_s is expressed as [14], [15]

$$\Gamma_s = \frac{k^2}{2\varepsilon_s(\infty, \beta h_{AlN})}, \quad (3)$$

where $k^2=2(v_{oc}-v_{sc})/v_{oc}$ is the intrinsic electromechanical coupling coefficient in Fig. 2, v_{oc} and v_{sc} are the S_0 mode Lamb wave velocities at the open-circuited and short-circuited surfaces, respectively, $\varepsilon_s(\infty, \beta h_{AlN})$ is the effective permittivity for infinite slowness (the effective static permittivity), and h_{AlN} is the AlN thickness. Moreover, the acoustic conductance at the resonance frequency ω_0 of a reflector-less IDT having an aperture W and N_P pairs of electrodes is defined as [15], [16]

$$G_a(\omega_0) = \omega_0 W \Gamma_s \left|Q_F(\beta)\right|^2 N_p^2. \quad (4)$$

The latter can be presented as a function of the COM transduction coefficient as:

$$G_a(\omega_0) = 2\left[\Lambda_T \alpha(\omega_0) N_p\right]^2, \quad (5)$$

revealing further the physical meaning of the COM transduction coefficient. The latter is directly related to the IDT conductance which in turn is proportional to the radiated acoustic power.

When comparing the performance of the Lamb wave resonators, one should bear in mind that (5) becomes more general. The conductance at resonance depends not only on the COM transduction and the IDT length but also on the acoustic losses since the latter determines the Q. Accordingly, only comparing the resonators with the same topology could reveal the information about the transduction efficiency. Here we compare the Lamb wave resonators of the same topology with the electrically grounded and floating bottom surfaces, respectively. As shown in Fig. 6, both the AlN Lamb wave resonators show quite similar conductance characteristics. The conductance ratio between the resonators with floating and grounded bottom electrodes is equal to 0.88, resulting in a transduction efficiency ratio of 0.94, which is very close to the simulated ratio, 0.91, obtained from the 2D COMSOL FEA model. The different IDT transduction efficiency for grounded and floating bottom electrodes is caused by the unsymmetrical electric filed in the 11 IDT electrodes, while the experimental transduction efficiency ratio is 1.01 for 12 IDT electrodes. As discussed above, when simulating the transduction efficiency ratio, all remaining contributions to the conductance should be kept the same except for the bottom electric condition. The results further confirm our preliminary observation that the excitation efficiency is the same for the IDTs with electrically grounded and floating bottom surfaces, whereas the larger static capacitance in the AlN Lamb wave resonator with a grounded bottom electrode results in the smaller k^2_{eff}.

Fig. 7 shows the plot of measured fractional frequency variation for the Lamb wave resonators listed in Table I from

room temperature to 100°C. As expected, the AlN Lamb wave resonator without the bottom electrode exhibits a smaller first-order temperature coefficient of frequency (TCF) of –25.9 ppm/°C because the platinum (Pt) bottom electrode has a large negative TCF and decreases the overall TCF accordingly. The resonators with the electrically grounded and floating bottom electrodes show the first-order TCF of –27.0 ppm/°C and –26.6 ppm/°C, respectively. Table II compares the measured performance of the AlN Lamb wave resonators with grounded, floating, and open bottom surfaces. All in all, the experimental results are in qualitative agreement with the simulated conclusions from the 2D COMSOL FEA model. It is noted that the Q and k^2_{eff} reported in this work are not optimal by far. The better resonator design, micro-fabrication process, and thin film stress control can improve the figure of merit (FOM) to a large extent.

IV. Conclusion

Based on a 1.5-μm-thick AlN plate and the same IDT design, the characteristics of one-port Lamb wave resonators with the electrically grounded, floating, and open bottom surfaces are theoretically analyzed using the FEA method and experimentally investigated. The employment of the floating bottom electrode simultaneously provides a larger effective coupling, an easier micro-fabrication process, and a higher FOM than the grounded bottom electrode without sacrificing the IDT transduction efficiency much. In particular, the Lamb wave resonator with the floating bottom electrode shows the highest FOM which is most suitable for the filter applications. The high phase velocity, moderate electromechanical coupling, weak dispersion, and ability to tune the effective coupling (i.e. the bandwidth) by changing the bottom electric condition also shows the potential of AlN Lamb wave resonators for the future high-frequency and narrowband wireless transmission systems. On the contrary, the resonator with the open bottom surface configuration usually provides a higher Q which is most suitable for the oscillator and sensor applications.

Abstract—**A novel multi-band active inductor (AI) voltage controlled oscillator (VCO) is discussed and implemented using SiGe heterojunction bipolar transistors (HBTs). A design strategy centered on improving the locking range and broadband tunability of the transistorized tuned-inductor is being discussed and validated through an example of triple-band (0.9-1.8 GHz, 1.8-3.6 GHz, and 3.6-6.9 GHz) VCOs. Detailed analysis has been performed to minimize the phase noise by incorporating dynamic self-injection mechanism, and study the method of suppression of undesired modes in active inductor VCOs for current and later generation communication systems**.

I. Introduction

Recent trend pushes towards multi-standard terminals where tunable oscillator is a key element to cover different wireless standards and applications such as cellular phones, bluetooth, and wireless local area network. The important requirements of multi-band oscillator are low cost, low phase noise, low power consumption, and should be amenable for integration in small chip area [1]-[3]. Varactor-tuned multi-band VCOs solution using switched inductors, switched capacitors, and switched resonators can cover different wireless standards operated at different frequency bands but not preferable due to die-size, cost, tuning-range, switching noise, and speed [4].

Tunable active inductor (TAI) technology offers advantages of wide tuning-range in small chip area and enabling as a cost-effective alternative but at the cost of lower dynamic range and poor phase noise performances [5]. The broadband tuning at high frequencies become very difficult with varactor-tuned VCOs topologies due to package parasitic associated with the tuning diodes, therefore, even with the degraded dynamic range and poor phase noise still it is a win-win situation to use active inductor topology for monolithic integrated multi-band VCOs solution at high frequencies [6].

An in-depth research of different active inductor circuit topologies are needed in order to lower the phase noise, power consumption, and improve the dynamic range prior to a large scale deployment of inductor-tuned oscillators where varactor-tuned oscillators are dominating currently. In this paper, detailed analysis has been performed to minimize the phase noise by incorporating dynamic self-injection mechanism using group-delay and phase-shifter network for controlling the large-signal drive-level and also study the method of suppression of undesired modes in active inductor-tuned VCOs.

A design strategy centered on improving the locking range and broadband tunability of the active inductor VCO is being discussed and validated through an example of triple-band (0.9-1.8 GHz, 1.8-3.6 GHz, and 3.6-6.9 GHz) VCOs for current and later generation communication systems.

II. Oscillator Inductive Dynamics

One of the key inductive dynamics in communication systems is the tunable LC oscillators using passive spiral inductors. With monolithic microwave integrated circuit (MMIC) technology, inductances are traditionally realized using spiral or stacked spiral inductors [1].

Figs. 1 and 2 show the simplified representation and characteristics of the spiral inductor. As shown in Fig.2a, the values of the inductance is proportional to the number of the turns/layers resulting silicon area required for routing is large [5]. Moreover, with the increase in the number of turns/layers, self-resonant frequency (SRF) decreases, and limits the applications at high frequencies (Fig. 2b). In this paper, we explore the possibility to replace the spiral inductor in multi-band oscillator with a tunable active inductor which is amenable for integrated circuit realization requiring only a fraction of the die-area and with improved noise dynamics at microwave frequencies.

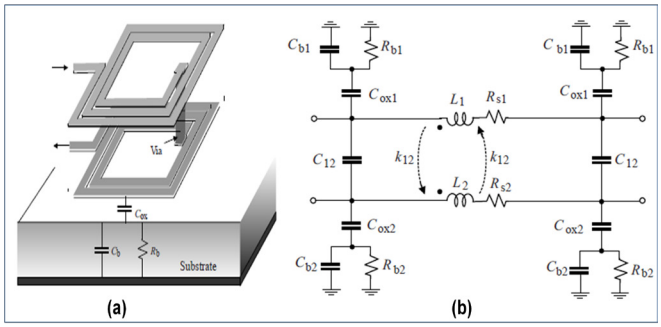

Fig. 1: (a) a typical sketch of spiral inductor, and (b) lumped model

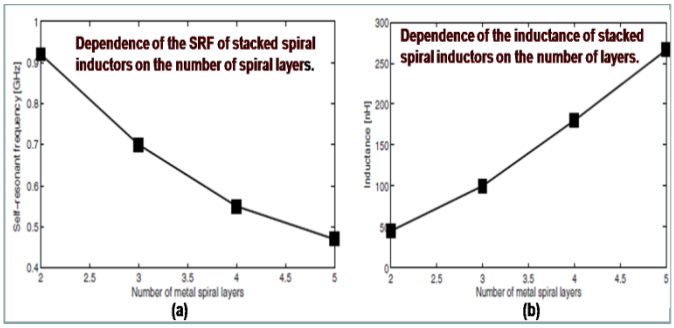

Fig. 2 Plot shows the dependence of the (a) Inductance, and (b) SRF.

Tunable multi-band oscillators can be realized using different technologies depending on the cost, performance, and applications [6]-[12]. Table 1 describes the different approach for the multi-band VCOs with pros. and cons. features for a given figure-of-merit (FOM). The performance comparison criterion (Q-factor, Die-area, Power-consumption, Linearity, Noise, Electro-Magnetic Interference, and Floor-planning) establishes important design guide lines for a selection of active inductor topologies for a given application and FOM. Table 2 summarizes the performance criteria and comparative analysis of the passive and active inductor for multi-band integrable tunable oscillator applications.

Table 1 Different approaches: Realization of Multi-Band VCOs

Topology	Features: Pros. (+) and Cons.(-)	Topology
Switched capacitor LC resonator	+Reduced K_{VCO} Limited C_{Max}/C_{Min} -Trade-off in switch size	Switched inductor LC resonator	+Reduced K_{VCO} -Large area -Trade-off in switch size	Switched coupled inductor LC resonator	+Smaller area -Trade-off in switch size (switch loss vs. Parasitic Capacitance)	High-K transformer LC resonator	+high quality factor +Good Phase noise -Only one resonance mode	Self-switching inductor LC resonator	+Smaller Area -Trade-off in switch size (switch loss vs. Parasitic Capacitance)	Reusing internal turn of an inductor	+smaller area +No switch in tank for changing the mode	Tunable active inductor (TAI)	+Smaller area -poor phase noise -Large power consumption	Dividers, Mixers, and Multiplexers	+Small area -Large power consumption -spurious tone	
Table 2 Comparative analysis: Passive and Active Inductors

Performances	Passive Inductor (Spiral)	Active Inductor (Simulated: Active Device
Q-factor	Low Q: Q-factor can be improved by differential method but added cost	High Q: active inductor offers higher Q than the passive spiral inductor
Tunability	Fixed/Limited	Large tuning range
Die-Area	Large die-area	Small die-area
Power-Consumption	Zero	Significant: consumes power for generating active inductance, resulting to high Q that may offsets the power consumptions
Linearity	Good Linearity	Poor Linearity: driven under large-signal condition, causing shift in operating point, distortions, and impedance fluctuations
Noise	Superior: good phase noise performance	Poor : poor phase noise performance
EMI	Significant: Due to EM coupling in spiral inductors	EMI insensitive
Floor-Planning	Poor: large die- area makes difficult floor-planning	Not required

In this paper, design techniques towards minimizing the phase noise of the active inductor VCOs are discussed while maintaining a small real estate area and low power consumptions.

A. Active Inductor: State-of-The-Art

Active inductors are commonly implemented using transistors and associated circuitry (inductor-less passive components). Active devices (Transistors: Bipolars/FETs) exhibit 0^0 or 180^0 phase difference between output currents and input voltages/currents, therefore, at least one capacitor is required for the realization of an active inductor (since its V-I has 90^0 phase difference). By appropriate conversion, the port voltage can be imparted to lead the port current by 90^0, which is the intrinsic property of an inductor. This conversion is typically done using Gyrator (two transconductors connected back-to-back resulting inductive impedance) (Fig. 3).

The input admittance looking into port 2 of the gyrator is

$$Y = \frac{I_{in}}{V_2} = (sC_2 + G_{02}) + \left[\frac{1}{s\left(\frac{C_1}{G_{m1}G_{m2}}\right)+\left(\frac{G_{01}}{G_{m1}G_{m2}}\right)}\right] \quad (1)$$

From (1), equivalent RLC networks (Fig.3) is given by

$$R_p = \frac{1}{G_{02}},\ C_p = C_2, R_s = \left(\frac{G_{01}}{G_{m1}G_{m2}}\right), L_{eq} = \left(\frac{C_1}{G_{m1}G_{m2}}\right) \quad (2)$$

When either the input or the output impedances of the transconductors of Gyrator are finite, the synthesized inductors are no longer lossless and exhibit inductive property only in a specific frequency range. The performance of active inductor can be characterized by maximum usable frequency f_0 and Q-factor, can be characterized by

$$f_0 = \frac{1}{2\pi\sqrt{(L_{eq}C_p)}} = \frac{1}{2\pi}\sqrt{\frac{G_{m1}G_{m2}}{C_1C_2}} = \sqrt{f_1 f_2} \rightarrow f_{1,2} = \frac{G_{m1,2}}{C_{1,2}} \quad (3)$$

Where f_0 is the self-resonant frequency of the gyrator and $f_{1,2}$ is the cut-off frequencies of the transconductors.

The Q-factor of a conventional passive LC resonator at a given frequency is independent of the current swing passes through the resonator and can be described by

$$Q(\omega) = \frac{\omega_0}{2}\left[\frac{\partial\phi(\omega)}{\partial\omega}\right]_{\omega\to\omega_0} \quad (4)$$

where $\varphi(\omega)$ is the phase of the LC resonator impedance.

Unlike passive LC resonator, the inductance of the active inductors varies with the current/voltage passes through the inductors. Therefore, definition of Q-factor given in (4) does not hold well for active inductors, an alternative definition that accounts for the swing of the voltage/current can be given by

$$\overline{Q_a(\omega)}_{\omega\to\omega_0} = \left[\frac{\omega}{2(I_{max}-I_{min})}\int_{I_{min}}^{I_{max}} Q_a(\omega.i)\,di\right]_{\omega\to\omega_0} \quad (5)$$

where I_{min} and I_{max} are the minimum and maximum currents of the transconductors of active inductors, and $Q_a(\omega,i)$ is the instantaneous quality factor at frequency ω and channel current i provides an effective mean to quantify the Q-factor of active inductor when operated in a large-signal conditions, especially in tunable LC resonator oscillators.

B. Active Inductor: Realizations and Constraints

The realization of active inductor is mostly influenced by the fabrication technology and cost factor for available devices characteristics and FOM. For example, in CMOS technology, coupling capacitor is usually not available, hence, transistors may be connected directly for satisfying both DC biasing and RF signal flow at the same time. In RF/mixed-signal CMOS technology and other RF processes: GaAs and SiGe BiCMOS; MiM and poly-poly capacitors are generally available for signal coupling, and there is more design freedom [12]. Fig. 4 shows the typical implementation of an active inductor (AI) using SiGe HBTs in common emitter cascode topology.

We report SiGe HBTs AI in cascode topology (Fig.4). As shown in Fig. 4, transistors Q_1 (common emitter) & Q_2 (common base) are connected in cascode to provide high impedance. The O/P is feedback to the base of Q_1 through CB transistor Q_3 & Q_5, Q_5 is used as a voltage variable resistor. The base of Q_3 is grounded through R_3 that controls the –ve resistance of the AI, and Q_4 is used as a current source.

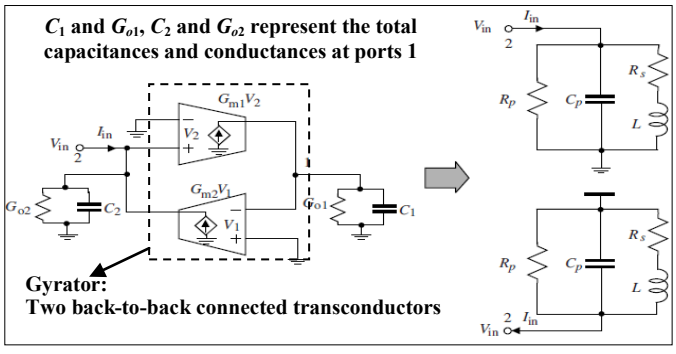

Fig.3 Typical realization of active inductor topology using a Gyrator

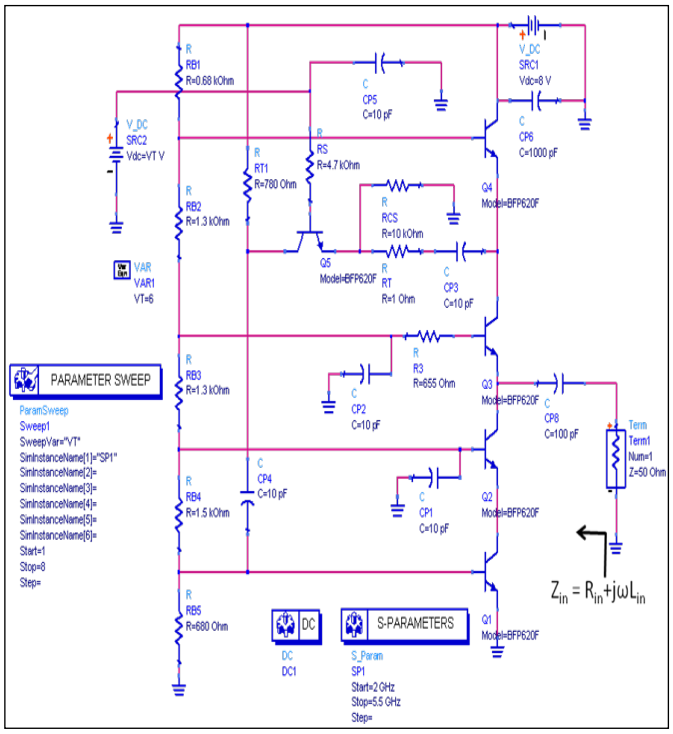

Fig.4 A typical schematic of active inductor using cascode topology

Fig. 5 shows the equivalent circuit model of active inductor (Fig. 4), for simplification of the analysis, all the transistor parameters are assumed to be identical ($C_{be1} \approx C_{be2} \approx C_{be3} = C_{be}$ and $g_{m1} \approx g_{m2} \approx g_{m3} = g_m$). The transistors Q_1 to Q_4 are biased at (2V, 6 mA), inductive property can be given by

$$L_{in} = \frac{1}{\omega}\left\{\frac{\omega C_{be}R_3(g_m+\varphi\gamma)-(\omega C_{be}-\varphi\delta)}{(g_m+\varphi\gamma)^2+(\omega C_{be}-\varphi\delta)^2}\right\} \quad (6)$$

$$R_{in} = \frac{(g_m+\varphi\gamma)+\omega C_{be}R_3(\omega C_{be}-\varphi\delta))}{(g_m+\varphi\gamma)^2+(\omega C_{be}-\varphi\delta)^2} \quad (7)$$

where

$$\gamma = g_m - (\omega C_{be})^2(R_{cs}+R_T),\ \delta = \omega[g_m C_{be}(R_{cs}+R_T)+C_{be}],$$
$$\varphi = \frac{{g_m}^3 R_{CS}}{\gamma^2+\delta^2}$$

Fig. 6 shows the typical variation of inductance and series loss resistance with the applied tuning voltage V_T at 8 GHz.

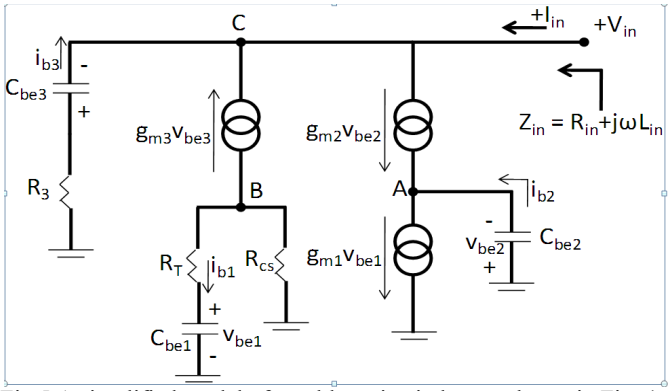

Fig.5 A simplified model of tunable active inductor, shown in Fig. 4

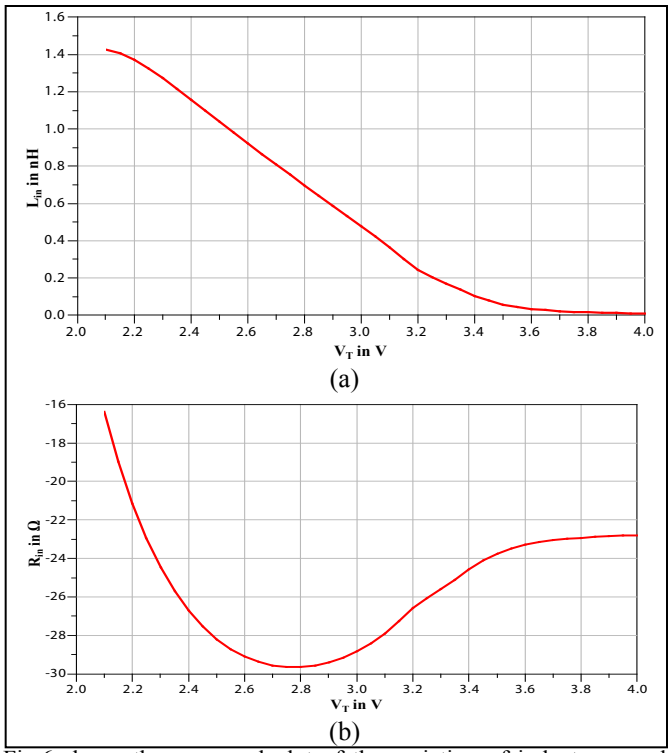

Fig.6 shows the measured plot of the variation of inductance and series resistance at 8 GHz for the tunable active inductor shown in Fig. 4. : (a) variation of inductance with respect to tuning voltage, and (b) shows the measured plot of the variation series loss resistance with respect to tuning voltage

III. Multi-Mode Multi-Band TAIO

Fig. 7 shows the equivalent representation of tunable active inductor oscillator (TAI) circuit. The steady-state oscillation condition for series feedback active inductor oscillator as shown in Fig. 7 is given by

$$Z_{osc}(I_L,\omega)+Z_L(\omega)=0 \Rightarrow Z_{osc}(I_L,\omega)=R_{osc}(I_L,\omega)+jX_{osc}(I_L,\omega) \quad (8)$$

$$R_{osc} = \left[\frac{\frac{1}{R_2}}{\left(\left(\frac{1}{\omega L_2}-\omega C_2\right)^2+\left(\frac{1}{R_2}\right)^2\right)}\right] - \left[\frac{-gm\left(\left(1-\omega^2 C_{b'e}L_1\right)\left(\frac{1}{\omega L_2}-\omega C_2\right)-\omega C_{b'e}\right)\left(\left(\frac{1}{\omega L_2}-\omega C_2\right)^2+\left(\frac{1}{R_2}\right)^2\right)-\frac{\omega^2 C_{b'e}C_{ce}}{R_2}\left(2\left(1-\omega^2 C_{b'e}L_1\right)\left(\frac{1}{\omega L_2}-\omega C_2\right)-\omega C_{b'e}\right)}{\omega C_{ce}\left(\left(\frac{1}{\omega L_2}-\omega C_2\right)^2+\left(\frac{1}{R_2}\right)^2\right)\left(\left(\left(1-\omega^2 C_{b'e}L_1\right)\left(\frac{1}{\omega L_2}-\omega C_2\right)-\omega C_{b'e}\right)^2+\left(\frac{1-\omega^2 C_{b'e}L_1}{R_2}\right)^2\right)}\right] \quad (9)$$

$$X_{osc} = \left[\frac{\left[\frac{-1}{\omega C_{ce}}\left(\frac{1}{\omega L_2}-\omega C_2\right)^2+\left(\frac{1}{\omega L_2}-\omega C_2\right)-\frac{1}{\omega C_{ce}}\left(\frac{1}{R_2}\right)^2\right]\left[\left(\left(1-\omega^2 C_{b'e}L_1\right)\left(\frac{1}{\omega L_2}-\omega C_2\right)-\omega C_{b'e}\right)^2+\left(\frac{1-\omega^2 C_{b'e}L_1}{R_2}\right)^2\right]}{\left[\left(\frac{1}{\omega L_2}-\omega C_2\right)^2+\left(\frac{1}{R_2}\right)^2\right]\left[\left(\left(1-\omega^2 C_{b'e}L_1\right)\left(\frac{1}{\omega L_2}-\omega C_2\right)-\omega C_{b'e}\right)^2+\left(\frac{1-\omega^2 C_{b'e}L_1}{R_2}\right)^2\right]}\right] + \left[\frac{\omega C_{b'e}\left(\frac{1}{\omega L_2}-\omega C_2\right)\left[\left(1-\omega^2 C_{b'e}L_1\right)\left(\frac{1}{\omega L_2}-\omega C_2\right)-\omega C_{b'e}\right]+\frac{\left(1-\omega^2 C_{b'e}L_1\right)}{\omega R_2 C_{ce}}g_m\left[\left(\frac{1}{\omega L_2}-\omega C_2\right)^2-\left(\frac{1}{R_2}\right)^2\right]-\frac{\left(1-\omega^2 C_{b'e}L_1\right)}{R_2}\frac{\omega C_{b'e}}{R_2}}{\left[\left(\frac{1}{\omega L_2}-\omega C_2\right)^2+\left(\frac{1}{R_2}\right)^2\right]\left[\left(\left(1-\omega^2 C_{b'e}L\right)\left(\frac{1}{\omega L_2}-\omega C_2\right)-\omega C_{b'e}\right)^2+\left(\frac{\left(1-\omega^2 C_{b'e}L_1\right)}{R_2}\right)^2\right]}\right] \quad (10)$$

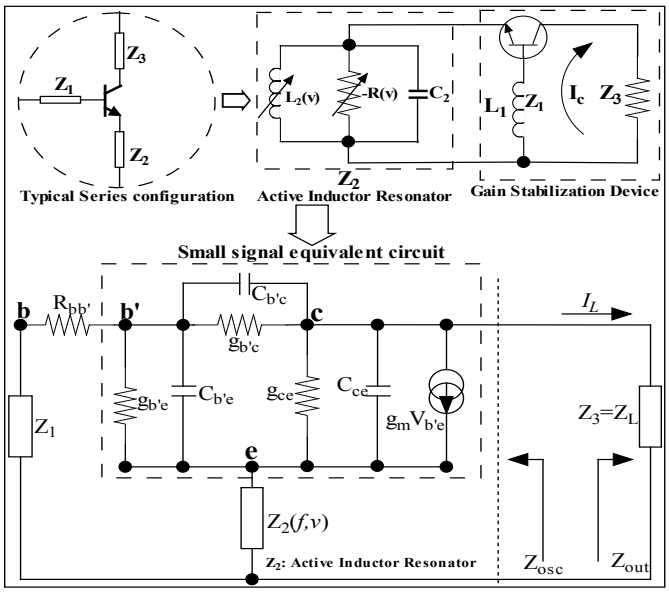

Fig. 7. A typical series feedback active inductor oscillator topology

For sustained oscillation $X_{osc} = 0$, (10) reduces to possible modes of oscillations:

$$\omega_1=\left[\frac{1}{L_2C_2}\right]^{1/2},\quad \omega_2=\left[\frac{1}{L_1C_{b'e}}\right]^{1/2},\quad \omega_3=\frac{1}{C_{b'e}C_{ce}}\left[2C_{b'e}C_{ce}\left(\frac{g_m}{R_2}\right)-\left(\frac{g_m}{R_2}\right)^2-8C_{b'e}^2\left(\frac{1}{R_2}\right)^2\right]^{1/2} \quad (11)$$

For dominant mode oscillation condition, negative dynamic resistance associated with R_{osc} can be described by solving (7) and (9), and the value of R_{osc} can be optimized in such a way that only desired fundamental mode (ω_1) of oscillation sustains the growth under the constraints of not enough gain supported by R_{osc} for other degenerate modes (ω_2 and ω_3). Fig 8 shows the typical simplified schematic of TAI oscillator of n^{th} order that can be reconfigurable with respect to multi-mode and multi-band wireless systems. As shown in Fig 8, the topology of multi-mode multi-band active inductor VCO is sensitive to mode-jumping and jitter and exhibits inferior phase noise performance in comparison to commercially available spiral inductor LC resonator based oscillator topology for a given DC power consumptions and figure-of-merit (FOM).

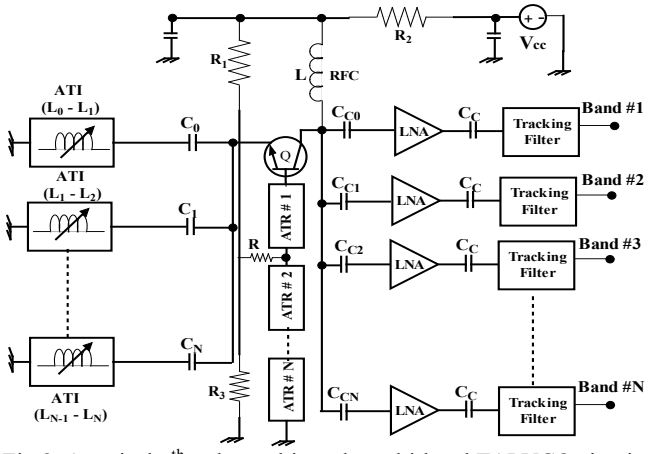

Fig.8. A typical n[th] order multi-mode multi-band TAI VCO circuits

In addition to this 1/*f* noise associated with active that forms active inductor under large signal drive level can become the bottleneck and restricts the applications. The novel and cost-effective approach is to incorporate self-injection-locking mechanism for improving the noise dynamics of inductor-tuned oscillator circuit for a given FOM. This can be realized by incorporating phase shifter network in the feedback path that improves the 1/*f* noise, including linearization of the large signal drive-level characteristics of the realized inductor as shown Fig. 4.

The goal for improving 1/*f* noise characteristics is paramount for enabling seamless transition from varactor-tuned LC resonator oscillator topology to inductor-tuned oscillator wireless applications. Nevertheless, the advantages of integration in small chip area (typically less than 10 % area of equivalent spiral inductor based RFIC VCO) make inductor-tuned VCO technology as a cost-effective alternative for RFIC/MMIC VCOs solutions for current and later generation of wireless systems [1]-[12].

IV. Examples And Validation

Fig.9 shows the typical schematic of self-injection-locked inductor-tuned Colpitts Oscillator realized by incorporating phase shifter network in the feedback path that improves the 1/*f* noise, including linearization of the large signal drive-level characteristics of the simulated realized inductor.

Fig.10 shows the CAD simulated phase noise plots with and without injection-locked inductor-tuned oscillators for giving brief insights about the improvement in phase noise performance. It can be seen from the phase noise plots (Fig. 10) that the phase noise of the inductor-tuned oscillator without injection locking is approximately -41dBc/Hz @ 10 kHz offset from 1.9 GHz the carrier frequency. When the inductor-tuned oscillator is locked, the phase noise drops to - 58dBc/Hz @ 10 kHz offset from the carrier frequency.

As shown in Fig. 9, self-injection locking mechanism improves phase noise typically 17 dB @ 100 kHz and 10 dB @ 1 MHz offset from carrier frequency 1.9 GHz. This observation is justified as injection-locking is more effective at lower offset (less than 100 kHz) and starts to degrade when the offset frequency exceeds 1 MHz due to broadband thermal noise trades with locking range for a given strength of injection level and phase shifts.

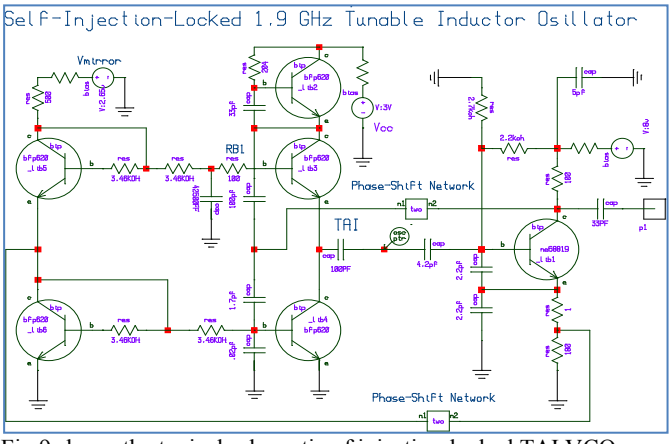

Fig.9 shows the typical schematic of injection-locked TAI VCO

Fig.11 shows the measured phase noise plots of injection-locked inductor-tuned oscillator circuit as shown in Fig. 9. It can be seen from the phase noise plot shown in Fig. 11 that the measured plot shows superior performance and vary more than 10 dB as compared to CAD simulated phase noise plot (Fig. 10), reason being unknown package parasitic and convergence problem (CAD tools) in presence of injection-locking signal which is fed through delay line phase shifter network into realized inductor circuit.

For validation of this approach, triple-band (0.9-1.8/1.8-3.6/3.6-6.9 GHz) TAIO is fabricated using SiGe HBTs on PCB substrate with ε_r of 3.38 and a thickness of 22mils (microstripline), however, this topology is amenable for integration in chip form.

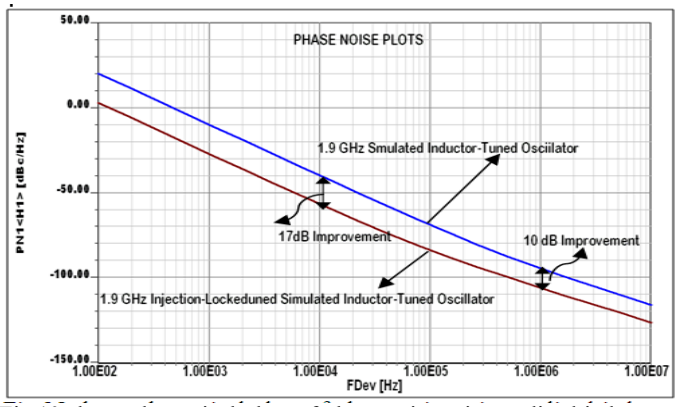

Fig.10 shows the typical plots of phase noise using realized inductor and injection-locked realized inductor.

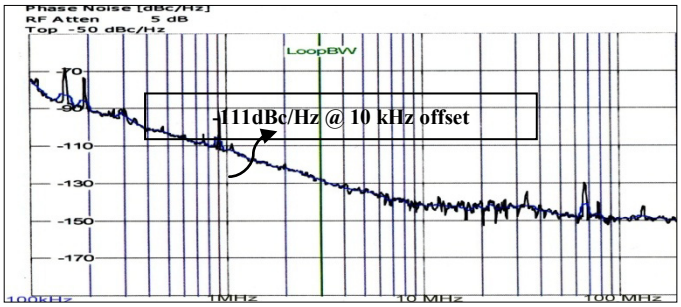

Fig.11 shows the measured phase noise plots of injection-locked inductor-tuned oscillator circuit as shown in Fig. 9.

The broadband injection-locking scheme shown in Fig. 12 can be realized by phase shifter network in conjunction with varying the realized inductance for optimum drive-level and dynamic range. The locking range of the injection-locked inductor-tuned oscillator can be described in term of maximum change in frequency for a given operating conditions. The frequency of TAIO (Fig. 12) is tuned by varying the inductance (Fig.4) as

$$f_0 = \frac{1}{2\pi\sqrt{LC}} \rightarrow f_0 + \Delta f = \frac{1}{\sqrt{(L+\Delta L)C}} \approx f_0\left[1 - \frac{1}{2}\frac{|\Delta L|}{L}\right]_{\Delta L \ll L} \quad (12)$$

$$|\Delta f| \cong f_0\left[\frac{1}{2}\frac{\Delta L}{L}\right]_{\Delta L \ll L} \quad (13)$$

where ΔL and Δf, is the maximum change of the inductance of the inductor (shown in Fig. 4) due to injection-locking signal (realized using delay-line phase shifter as shown in Fig. 12), and maximum frequency shifts that translates to locking range of the inductor-tuned oscillator.

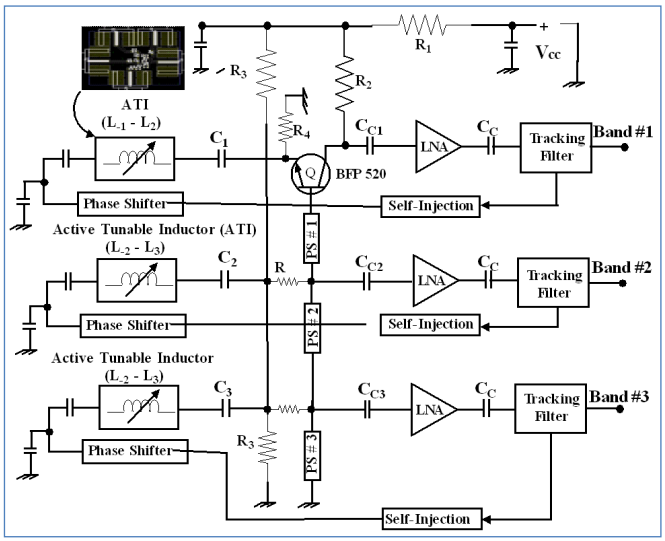

Fig.12 schematic of self-injection locked triple-band TAIO

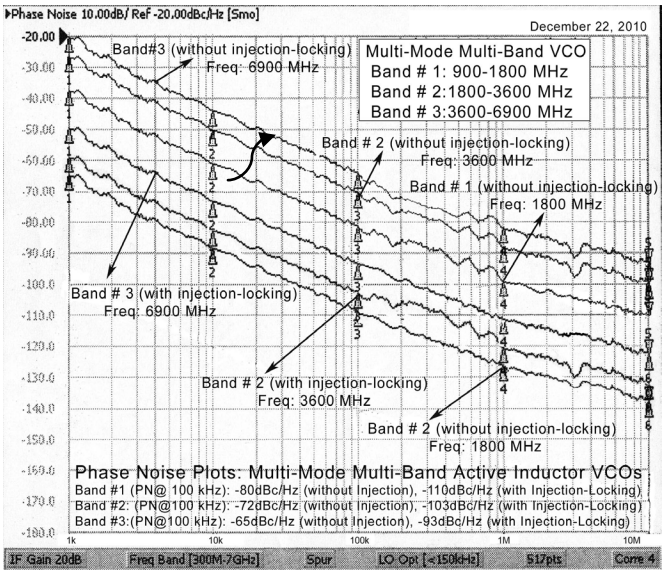

Fig.13 Measured phase noise plots of SiGe HBTs TAIO (Fig. 4)

From (13), the locking range is directly proportional to the maximum amount of the change of the inductance caused by the injected locking signal. For a varactor-tuned injection-locked LC oscillator, the locking range can be described by

$$|\Delta f| \cong f_0 \left[\frac{1}{2}\frac{|\Delta C|}{C}\right]_{\Delta C \ll C} \qquad (14)$$

where ΔC is the maximum amount of the change of the capacitance of the varactor caused by locking signal.

For a given oscillator circuit topology, operating condition, and figure-of-merit, it is important to note that the maximum change of ΔL is higher than ΔC and can be given by

$$\left[\frac{\Delta L}{L}\right]_{\Delta L \ll L} > \left[\frac{|\Delta C|}{C}\right]_{\Delta C \ll C} \qquad (15)$$

From (15), injection-locked inductor-tuned oscillator has a superior ability to adjust and coarse its frequency to follow the locking signal, resulting comparatively higher locking range as compared to varactor-tuned oscillator circuits.

The reason for higher locking range is less impact of injection signal on voltage output nodes of the varactor-tuned oscillator, resulting insignificant change in the capacitance (ΔC) of the varactor devices. On the contrary, inductance of the inductor-tuned oscillator is more sensitive to injected signal, and therefore, significantly varies current of the active device that forms the inductor circuit (Fig. 4). Fig.13 shows the measured phase noise plots with and without injection-locked inductor-tuned oscillators for giving brief insights about improvement in phase noise performance. It can be seen from Fig. 13 that the self-injection locked TAIO offers 15-25 dB better phase noise performance. The measured phase noise plots shown in Fig. 13 for band #1 (0.9-1.8 GHz), band #2 (1.8-3.6 GHz), and band #3 (3.6-6.9 GHz) are typically better than –110 dBc/Hz, -105 dBc/Hz, and -93 dBc/Hz respectively at 100 kHz offset from the respective carrier frequencies. The circuit works on 2V, 18 mA and gives O/P power typically better than -3dBm over respective bands.

The emerging applications of TAI topology continue to be unfolded along with the inception of new design techniques for improving phase noise and dynamic ranges. In spite of the drawbacks such as noise and linearity, active inductors have a significant advantage over passive inductors in terms of die-area, Q-factor, and issues regarding EMI and floor planning.

V. Conclusion

A design strategy centered on improving the locking range and broadband tunability of the realized inductor using SiGe HBTs is discussed, and validated through an example of triple-band injection-locked inductor-tuned oscillator circuit for multi-band multi-standard RF communication systems.

***Abstract*— We report a 4.596 GHz frequency synthesis based on a 2.1 GHz Solid Mounted Resonator (SMR) voltage controlled oscillator (VCO). The SMR source exhibits a power consumption of about 18 mW, a chip size of 2mm^2 and a phase noise of − 89 dBc/Hz at 2 kHz offset frequency. A synthesizer is constructed from this source to generate a low noise 4.596 GHz signal. The synthesizer is preliminary used as a local oscillator in a compact Cs atomic clock based on Coherent Population Trapping (CPT).**

I. Introduction

Chip Scale Atomic Clocks (CSAC) based on CPT are passive atomic frequency standards and need a high-performance local oscillator (LO) combining an extremely reduced volume, power consumption, frequency-temperature dependence as well a low phase noise not to degrade the clock short term frequency stability [1].

In general, LOs proposed for CSACs are frequency-multiplied low power consumption temperature-controlled (TCXO) or microprocessor-controlled (MCXO) crystal oscillators. Nevertheless, it can be useful to avoid this frequency multiplication process degrading the source phase noise and power consumption. In that sense, Brannon et al. proposed the development for CSAC applications of microwave oscillators based on quarter-wavelength ceramic-filled coaxial resonators [2]. In another way, a great challenge is to realize fully-packaged MEMS oscillators based on bulk acoustic wave resonators (BAW) due to their small size and high Q-factor [3]. Among them, Film Bulk Acoustic Resonators (FBAR), High-overtone Bulk Acoustic Resonators (HBAR) and Solid Mounted Resonators (SMR) are potential candidates. Romisch and Lutwak developed a low power 4.596 GHz Colpitts oscillator for Cs CSAC applications [4]. Yu et al. demonstrated a HBAR-based 3.6 GHz Pierce oscillator with a phase noise of -67 dBc/Hz at 300 Hz fourier frequency, a power consumption of 3.2 mW and a free-running frequency stability of 1.5×10^{-9} at 1 second [5]. A great issue in such oscillators is their high thermal frequency sensitivity. Several solutions were proposed to reduce the frequency-temperature dependence of FBAR [6], [7] and HBAR [8].

This paper presents an original SMR oscillator-based 4.596 GHz frequency synthesis. Such sources have been proposed recently [9]. Section II describes the 2.1 GHz SMR VCO. Section III presents the frequency synthesis to generate the 4.596 GHz signal. Section IV shows the successful detection of CPT resonances using the 4.596 GHz synthesized signal.

II. The SMR-based voltage controlled oscillator

Fig 1 shows the schematic structure of the Solid Mounted Resonator (SMR).

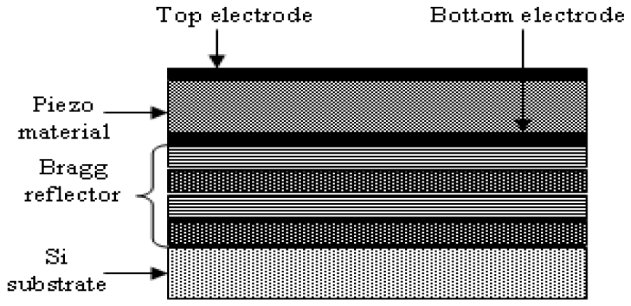

Fig. 1. *Cross-section of the Solid Mounted Resonator.*

It consists of a metal-piezo (Mo-AlN)-metal layered sandwich. The resonator is constructed over a Bragg reflector acoustic mirror structure using alternating layers of low and high acoustic velocity. The Bragg reflector is made of Tungsten (W) and silicon oxide (SiO_2). The so-called "frame" technique [10] is used to confine the acoustic energy in the useful thickness mode.

A quality factor value of 1176 at the series resonance frequency f_s of 2.083GHz is obtained. The Q-factor of the parallel resonance frequency f_p is 502 at 2.125GHz.

The VCO is based on a common-base configuration architecture [11]. The active circuit is a SiGe:C heterojunction bipolar transistor (HBT) using BiCMOS7RF 0.25μm technology processes from ST Microelectronics.

The fine frequency tuning of the oscillator is achieved by an adjustable voltage control supply added to the bias voltage. The coarse frequency tuning is achieved by a DDS circuit. The core oscillator uses a hybrid method by wire-bonding

978-1-61284-110-6/11/$26.00 ©2011 IEEE

the BiCMOS chip (1mm x 1 mm) and the Solid Mounted Resonator (0.35mm x 0.3mm).
The oscillation frequency variation as a function of the voltage tuning is 260 kHz/V. The measured output power variation is 0.5dBm/V.
Fig. 2 reports the variation of the VCO output frequency and power versus the resonator temperature.

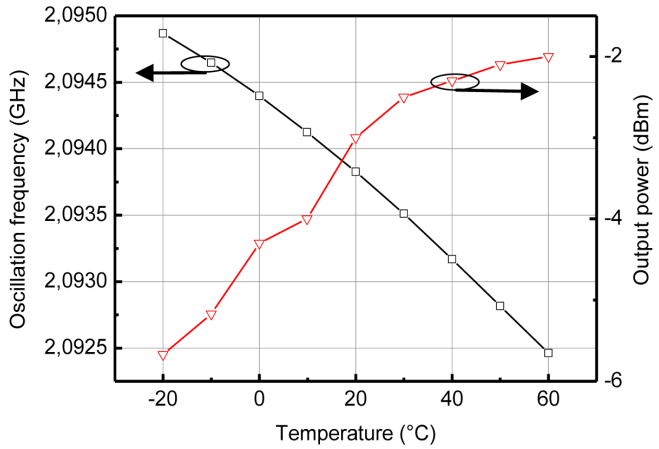

Fig. 2. *Oscillation frequency and output power of the SMR VCO as a function of the temperature.*

The frequency-temperature dependence is found to be -14 ppm/°C. The variation of the VCO output power versus the temperature is 3.6 dBm in the -20-60°C temperature range.

Fig. 3 shows the phase noise performances of the SMR VCO.

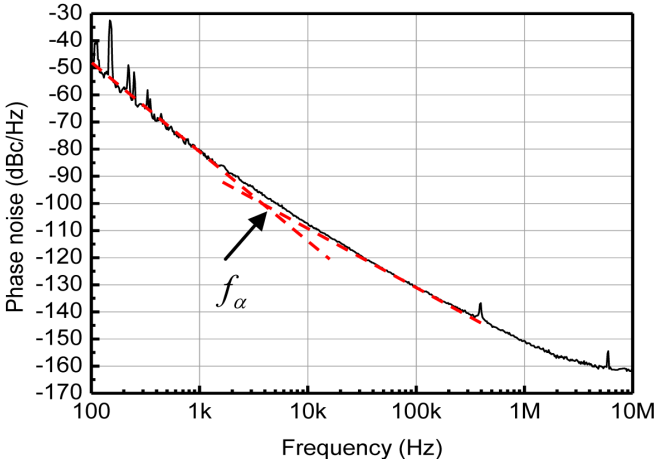

Fig. 3. *Phase noise of the SMR VCO.*

The VCO phase noise is -160 dBc/Hz for $f > 3.5$MHz and is -82 dBc/Hz at 1 kHz offset frequency. A very slight degradation of the VCO phase noise, lower than 1.5 dB, is obtained at f=2 kHz when the voltage control is increased while no significant variation is observed at f= 100 kHz.

III. THE 4.596 GHZ FREQUENCY SYNTHESIS

The description of the 4.596 GHz frequency synthesis based on the 2.1 GHz SMR VCO is described in [11]. The generation of the 4.596 GHz signal is realized by first frequency-doubling the VCO frequency at 4.2 GHz. Simultaneously, a signal of 396 MHz frequency is generated by mixing (mixer M1) the 384 MHz and 12 MHz signals from two Direct Digital Synthesis (DDS) DDS2 and DDS1 respectively. Eventually, the 4.596 GHz signal is obtained by mixing the 4.2 GHz and the 396 MHz signals using the mixer M2.
A synchronization clock signal (77MHz) for DDS and a FPGA is delivered by tracking and frequency dividing the SMR oscillator signal. A Frequency Shift Keying (FSK) modulation at a bit rate of 1kHz and frequency deviation of 3kHz is generated. This modulation is used to lock the final VCO output frequency on the atomic transition frequency. A useful 9.3 MHz RF signal is extracted from the synthesis to characterize easily the atomic clock frequency stability when it is locked. The output power is measured to be about 0 dBm at 4.596 GHz.
Fig. 4 reports phase noise performances of the free-running 2.1 GHz SMR VCO, of the DDS2 and the 4.596 GHz frequency synthesis output. The frequency synthesis phase

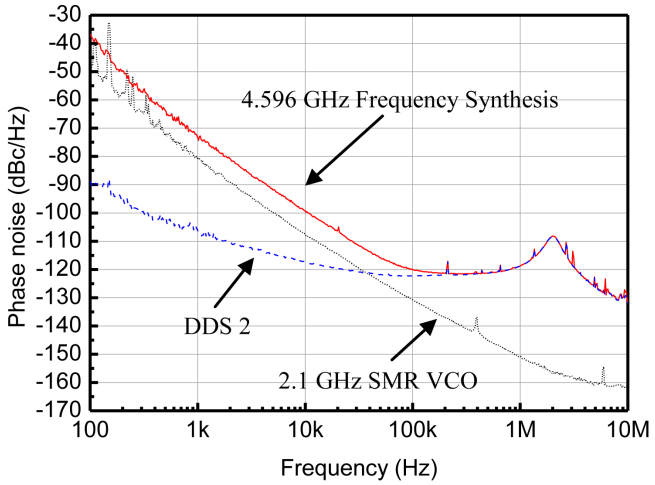

Fig. 4. *Phase noise performances of the 2.1 GHz SMR VCO, of the DDS2 and of the 4.596 GHz output signal of the frequency synthesizer.*

noise is clearly limited by the DDS2 phase noise at a level of -120 dBc/Hz and -132dBc/Hz at 1MHz and 10 MHz offset frequencies respectively for $f > 150$kHz. The phase noise of the 4.596 GHz signal is -76 dBc/Hz and -100 dBc/Hz at f = 1kHz and 10 kHz respectively.

IV. APPLICATIONS TO A MINIATURE CPT ATOMIC CLOCK

The SMR-VCO-based frequency synthesis is used as a local oscillator in a compact CPT atomic clock described in [11]. The CPT resonance was successfully detected. Fig. 5 shows the Allan deviation of the free-running oscillator and locked oscillator.

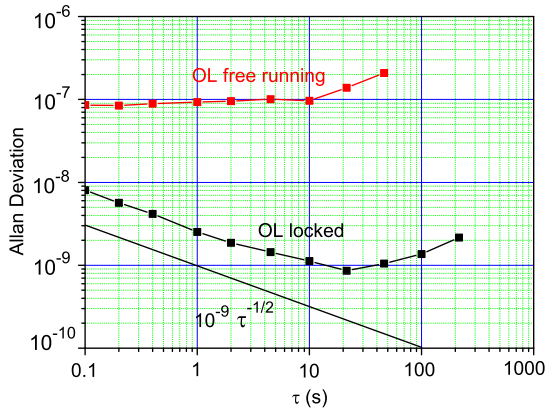

Fig. 5. *Allan deviation of the SMR VCO in free-running or locked configurations.*

In the free-running regime, it is measured to be 9.5×10^{-8} at 1 s integration time and increases after 10 s averaging time. In the locked regime, the BAW oscillator signal fractional frequency instability is measured to be $2.5 \times 10^{-9}\ \tau^{-1/2}$for integration times up to 20 s. This represents an improvement by a factor 38 and 83 compared to the unlocked regime at 1 s and 10 s respectively. In the present case, the clock short term frequency stability limitation is mainly attributed to huge temperature variations in the laboratory room affecting the SMR VCO free-running frequency through its frequency-temperature dependence as well as a clock frequency-locked loop (FLL) bandwidth too small. Unfortunately, this result could not be optimized because of time constraints.

V. CONCLUSIONS

A 2.1 GHz SMR voltage-controlled oscillator with a phase noise of $-$ 89dBc/Hz at f=2 kHz and $-$131dBc/Hz at f=100kHz was presented. The frequency-temperature dependence is $-$14ppm/°C over a range of $-$20°C to 60°C while its power consumption is 18 mW. An original analog-digital 4.596 GHz frequency synthesizer based on the designed SMR VCO was developed. The SMR VCO-based frequency synthesizer was preliminary successfully locked to the CPT resonance of Cs atoms in a mm-scale vapor cell.

ACKNOWLEDGMENT

This work was supported by ANR-MHAST. The authors would like to thank B. Verbeke and C. Begue for their help in electronics.

Abstract— **Adaptive mode-coupled harmonically tuned voltage-controlled SAW oscillators (VCSOs) are versatile performers in phase-locked reference sources, can be supplied in standard and custom frequencies through 5 GHz at a fraction of the size and power consumption of multiplied references. The typical measured phase noise @ 10 kHz offset from the 5 GHz carrier is -140 dBc/ Hz with 500 kHz tuning and RMS jitter less than 10 femto seconds. To author's knowledge, the reported 5 GHz VCSO offers about 10 dB superior phase noise performances as compared to commercially available SAW and crystal multiplied sources for a given size, cost, and power-consumptions.**

I. INTRODUCTION

Reference signal sources set the spectral standards for a wide range of phase-locked-loop (PLL) applications, from clock translators in instrumentation to radar systems. Traditional references sources, such as crystal, ceramic, or surface-acoustic-wave SAW) oscillators, are based on high-quality-factor (high-Q) resonators [1]-[48]. They are generally limited to about 3 GHz and must be multiplied to provide higher reference frequencies. And with multiplication comes degradation in phase-noise, power consumptions, and harmonic performance. In this paper, degenerated adaptive mode-coupling and regenerative noise filtering is being incorporated to achieve excellent spectral performance at fundamental frequencies 3 GHz and above.

In contrast to other high-frequency reference-source solutions, such as crystal-oscillator-based references which employ oscillators, gain blocks, and filtering networks that add to high development costs and reliability concerns, the reported adaptive mode-coupled harmonically tuned VCSO circuits provide simpler, more reliable solutions that save space and power consumption. The novel approach includes a methodology to enhance the mode-injection locking range, and to reduce or eliminate the amount of filtering needed to suppress sub-harmonics and higher-order harmonic products. The approach also reduces the susceptibility to microphonics while retaining low phase noise and a moderate tuning range to compensate for short-term and long-term effects of thermal drift and aging [3]-[11]. The reported reference sources are ideal for use as clock translators for high-speed analog-to-digital converters (ADCs) and direct-digital-synthesizer (DDS) clocks, offer superior figure-of-merit (FOM) in terms of performance, price, and product delivery to satisfy both the technical and current business needs of designers and buyers. So, whether oscillators are used at their specific frequency or tuned to higher frequencies using multipliers or PLLs, the need for accurate, affordable, low-phase noise and stable performance never changes.

II. VCSO TOPOLOGIES

VCSOs (Voltage Controlled SAW Oscillators) are widely used in wireless applications, since the technology features very low phase noise at fixed frequencies through about 1 GHz. However, VCSO circuit operating above 1 GHz and above is generally realized using multiplier approach which is power hungry, large size, and offers degraded phase noise performances. Historically synthesizer developers have relied on crystal based multiplied reference oscillator featuring excellent phase noise performance at 3 GHz and above frequencies. Although, frequency multiplier crystal oscillator can offer low phase noise performance at 3 GHz and above frequencies but at the cost of large size, high noise floor and high power-consumptions. The most dramatic change will occur when optimum loop bandwidth extends to a few megahertz, where reported adaptive mode-coupled harmonically tuned VCSOs noise performance supersede the performance of the conventional SAW and multiplied crystal oscillator at 3 GHz and above.

Furthermore, these characteristics, accompanied with reduced size, power consumption, cost, drift, and jitter inherent to the VCSO topology shown in Fig.1, is likely to secure their domination in the foreseeable future at higher frequency synthesizers and reference frequency standards for the applications in current and 4th generation communication systems.

Fig. 1 shows the typical block diagram of the novel VCSO using adaptive mode-coupled harmonically tuned mechanism with more than 500 kHz tuning for compensating the thermal drift without using heating device, and fabricated in tiny SMD packages (0.5x0.5 inches).

The typical measured phase noise @ 10 kHz offset from the 5 GHz carrier is -140 dBc/ Hz, with RMS jitter less than 10 femto seconds (Fig.2). The reported 5 GHz VCSO offers about 5-10 dB superior phase noise performances as compared to commercially available SAW and crystal multiplied sources for a given size, cost, and power-consumptions.

III. Multiplied Frquency Crystal Oscillator Circuit

As briefly discussed above, designers have often relied on multiplying a low-noise crystal oscillator to achieve higher frequency 1 GHz and higher output signals. The harmonic frequency crystal oscillator approach can provide excellent phase noise, but tend to consume a great deal of power, generate high levels of noise, and are large in size. Commercially available crystal oscillators at 100 MHz and below are available with phase noise of -160 to -176 dBc/Hz offset 20 to 100 kHz from a 100-MHz output.

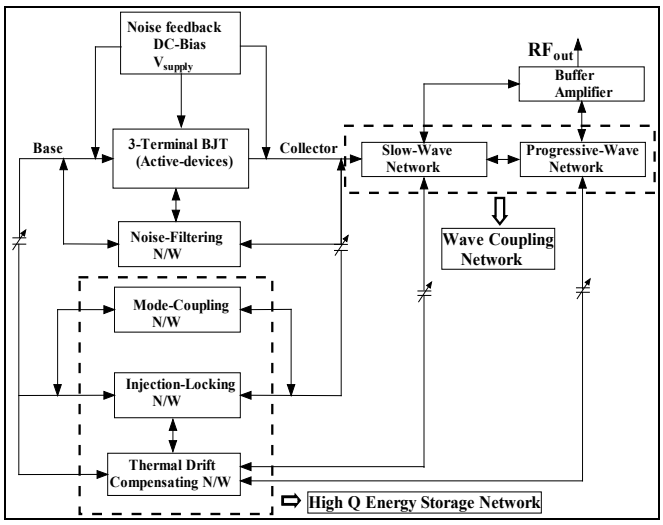

Fig.1. This block diagram shows the functional parts of an adaptive mode-coupled harmonically tuned VCSO for low cost high frequency sources.

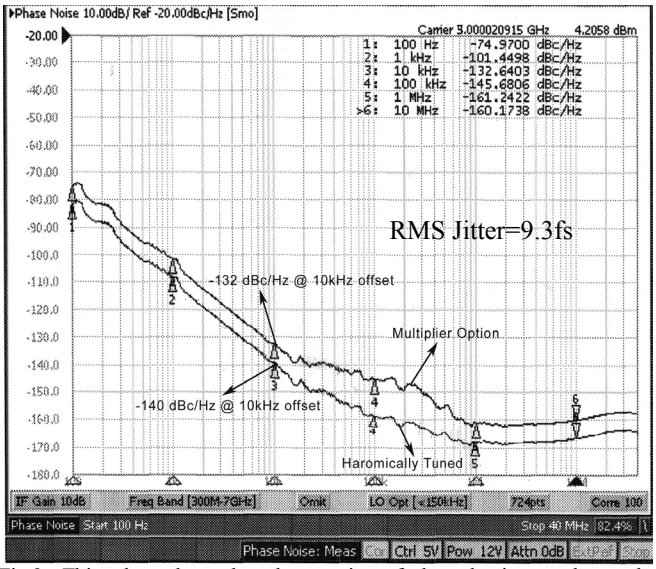

Fig.2. This plots show the phase noise of the adaptive mode-coupled harmonically tuned VCSO was measured at a carrier frequency of 5 GHz and with oscillator bias supply of 30 mA and +12 VDC.

When multiplied 10 times to obtain 1 GHz frequency source, the phase noise of crystal oscillators translates to -140 to -156 dBc/Hz offset 20 to 100 kHz from 1 GHz but can degrade the noise floor by as much of 20 dB.

The availability of low-cost, low-noise voltage controlled saw oscillator (VCSO) clears the way for small, low-noise synthesizers. Part of using these sources involves modeling the surface acoustic wave resonators under large signal drive conditions for the better insights about noise dynamics at close-in phase noise, then developing manufacturable methods for producing high-purity and temperature stable oscillators in chip form.

Fig. 3 compares fundamental 1 GHz VCSO phase noise at 1 GHz to that of a commercially available multiplied crystal oscillator circuit. It can be seen from Fig.3 that fundamental 1 GHz VCSO supersedes the phase noise performance as much as 20 dB at 100 kHz offset from the carrier as compared to commercially available multiplied 1GHz VCXO. The primary drawback of VCSOs is their inability to be tuned by means of tuning varactor diode, therefore, unable to compensate the frequency drifts due to ageing and changes in operating temperature for reference sources applications. Accordingly, there is a need for frequency agile SAW resonators for VCSO applications.

IV. Tunable SAW Resonator For VCSO Circuit

SAW (surface acoustic wave) devices are generally used in frequency ranges above that of the BAW (bulk acoustic wave) crystal such as the AT cut. The SAW involves only the surface of the substrate used. The frequency is set by the distance between the electrode "fingers" (Fig.4). Quartz, LiTaO3, and LiNbO3 are common substrates for such devices. Initial accuracy is dependent on the accuracy of the printing of the "fingers". Initial accuracy can be in the ±50 to 200 ppm range. The approximate temperature constant of quartz is 0.03 ppm/^{0}C² and -20ppm/^{0}C² for LiTaO3.

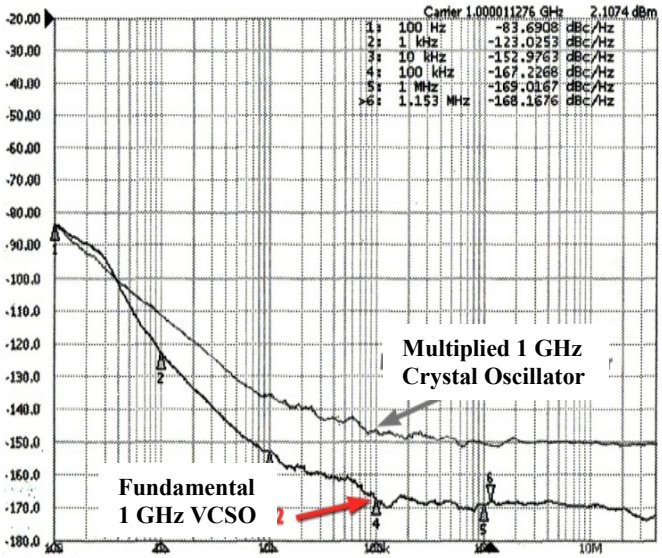

Fig.3. This phase noise plot compares the performance of a 1-GHz VCSO with 1-GHz achieved by multiplying a crystal oscillator.

Upper frequencies of 3.5 GHz are currently obtainable. The lower end is limited primarily by size, since the AT becomes more practical. Currently, surface acoustic wave (SAW) resonator based oscillators are used for high frequency signal sources, which have cost, availability, and frequency stability issues.

The shift to multi-band 3G phones has increased the demand of Surface Acoustic Wave (SAW) filters per handset. This implies a substantial increase in the filtering functions, thereby increasing the filter count in handsets. Combinations of multiband, multimode models are expected to use increasing number of SAWs. As more phones operate on multiple bands, manufacturers are expected to require more SAW filters, thereby increasing the overall SAW filter market size. The research service notes the following product segments: SAW filters, SAW resonators and SAW oscillators. SAW oscillators are widely used in wireless applications, since the technology features very low phase noise at fixed frequencies through about 3 GHz. SAW resonator oscillators are also known for their low microphonic noise (tolerance to vibration), high quality factor (Q), and low jitter.

Generally, it is highly desirable for reference frequency sources to exhibit ultra low phase noise characteristics. This is usually accomplished by using high Q quartz crystals and SAW resonator devices. Unfortunately, SAW resonator based oscillators have several disadvantages, including a limited operating temperature range and limited tuning range (which limits the amount of correction that can be made to compensate for the tolerances of other components in the oscillator circuitry). Coupling a varactor diode or other capacitive element to a high Q-factor frequency controlling element, such as SAW device, does not result in a tunable, low phase noise VCSO circuits. To overcome this limitation, VCSO have been implemented that couple together two or more SAW devices in order to achieve a wider tuning range and low phase noise.

The simplified approach is to reduce the quality factor of the SAW by introducing series or parallel loss resistors. However, the use of multiple SAW elements increases the complexity and the cost of the VCSO circuits [48]. Fig. 5 shows the arrangement of tunable SAW resonator network based on the design tradeoffs between the phase noise and the tuning characteristics of the VCSOs.

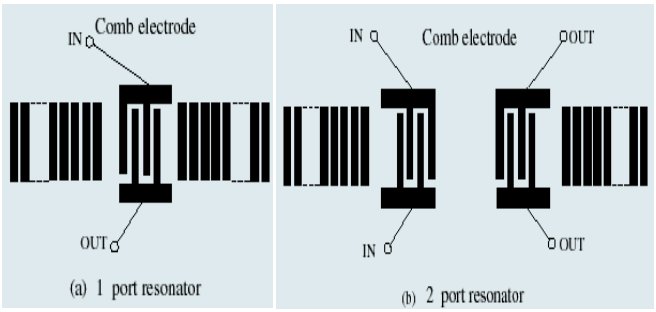

Fig.4 This shows the typical representation of surface acoustic wave resonator: (a) 1-port SAW Resonator, and (b) 2-port SAW resonator

Although, the frequency of VCSO can be changed over a fairly wide range by means of varying the capacitances (C_1, C_2, C_3, C_4, and C_5 as shown in Fig. 5), but the parameters of the oscillator circuit (Fig.6) are changing drastically.

This creates serious problems in terms of phase noise and tuning linearity. For low phase noise, it is necessary to keep the reactance slope as steep as possible by maximizing the phase derivative and group delay [$\partial\varphi/\partial\omega$] of the coupled SAW resonator network. For tuning linearity, it is necessary to keep the reactance slope as straight as possible over the desire operating frequency range. If the reactance curve is too shallow, VCSO (Fig. 6) circuit becomes susceptible to noise and stability perturbation. Furthermore, the straighter the reactance curve is, the greater is the tuning linearity in the desired frequency range.

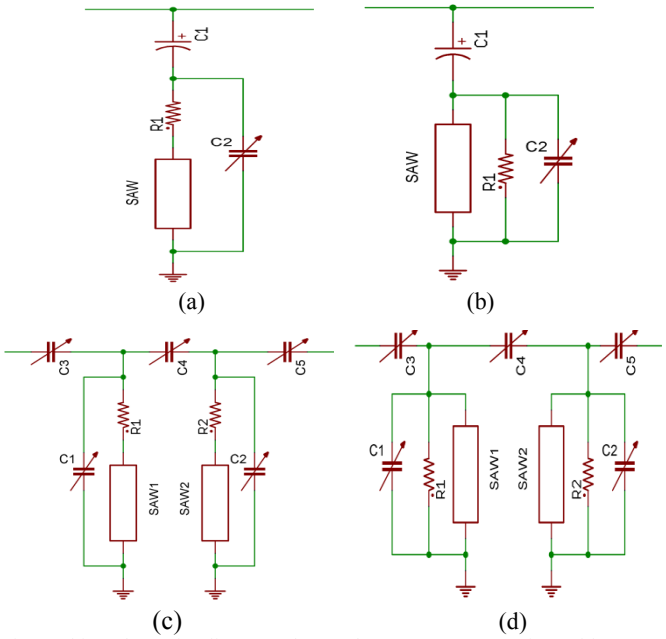

Fig.5 This schematic diagram shows the arrangements of tunable SAW resonator networks: (a) series resistance in conjunction with SAW resonator, (b) parallel series resistance in conjunction with SAW resonator, (c) series resistance in conjunction with capacitively coupled SAW resonator, and (d) parallel resistance in conjunction with capacitively coupled SAW resonator.

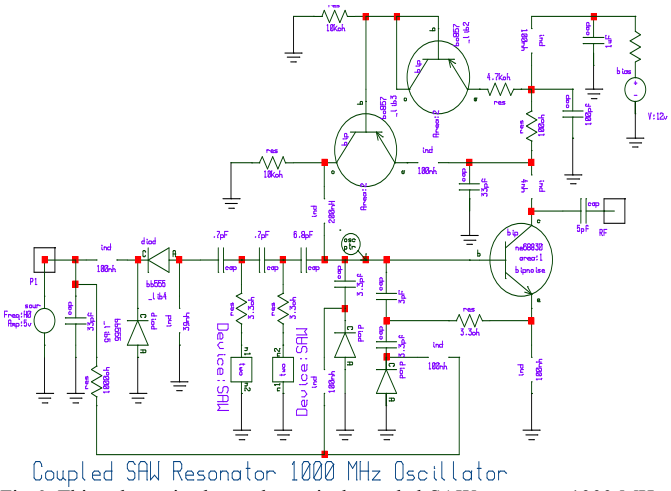

Fig.6. This schematic shows the typical coupled SAW resonator 1000 MHz oscillator

To overcome these problems, a novel technique is to incorporate additional inductor (L) parallel to the SAW resonator that resonates with the C_0 (the internal and package capacitance of SAW resonator) as shown in Fig. 7. Additionally, the value of inductor L2 and C (Fig.7) is adjusted in order to shift the resonance to that of intrinsic SAW resonator (without insertion of L and C) frequency (i.e. 1GHz). This enables the reactance curve linear and steep over the operating frequency range from 999.3-999.8 MHz (Fig.8).

An objective of this paper is to improve the tuning characteristics (on the order of +/-400 PPM) of the SAW resonator without compromising phase noise performance by cascading the mode-coupled harmonically tuned network to compensate the frequency drift caused due to change in operating temperature (-40 to +85 degree Celsius) (Fig.9).

As shown in Fig. 9, the cascaded mode-coupled harmonically tuned VCSO circuit minimizes the phase noise with more than 2 MHz tuning, resulting cost-effective solution. The typical measured phase noise is –152dBc/Hz at 10 kHz offset from the carrier with jitter less than 6fs, this is the reasonably low phase noise solution for this class of inexpensive VCSO solutions (Fig. 10).

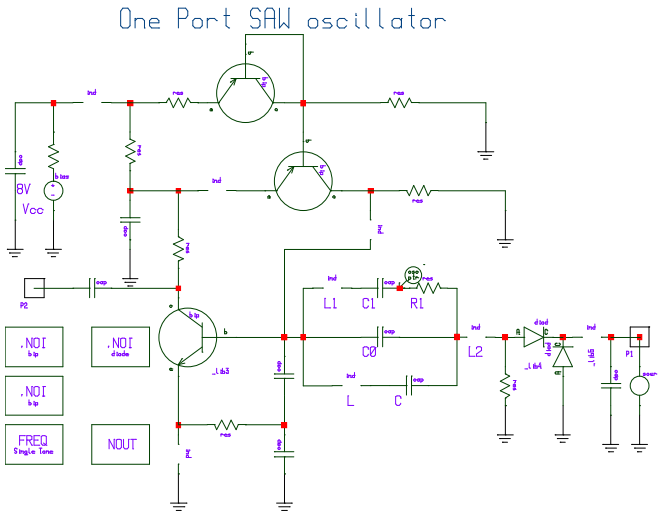

Fig.7. This schematic shows the typical tunable SAW resonator oscillator

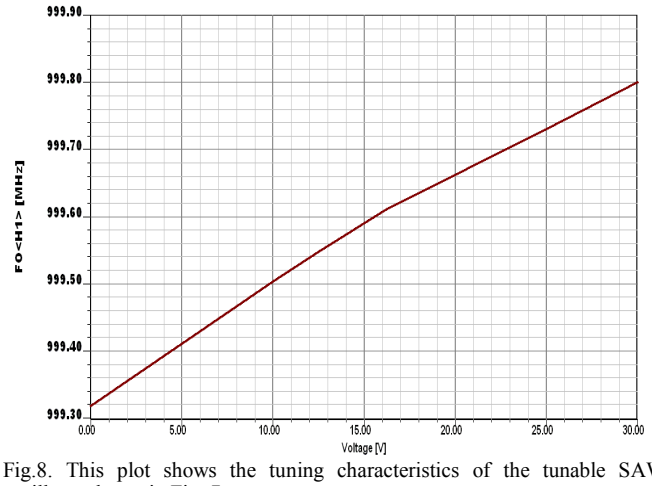

Fig.8. This plot shows the tuning characteristics of the tunable SAW oscillator shown in Fig. 7.

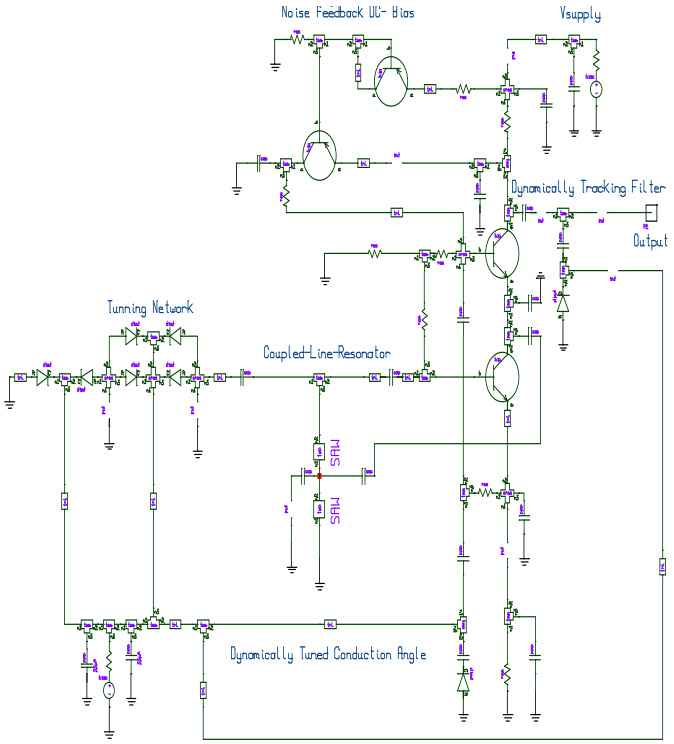

Fig.9. This schematic shows the cascaded mode-coupled harmonically tuned tunable SAW resonator oscillator

V. Example And Validation

The experimental results demonstrate the new design approach for ultra low phase noise VCSO for reference frequency standard applications.

Figure 11 shows the schematic of mode-coupled tunable 1 GHz SAW oscillator. The CAD simulated phase noise confirms the improvement in performance at 1 kHz and higher offset frequency from the carrier (Fig. 12).

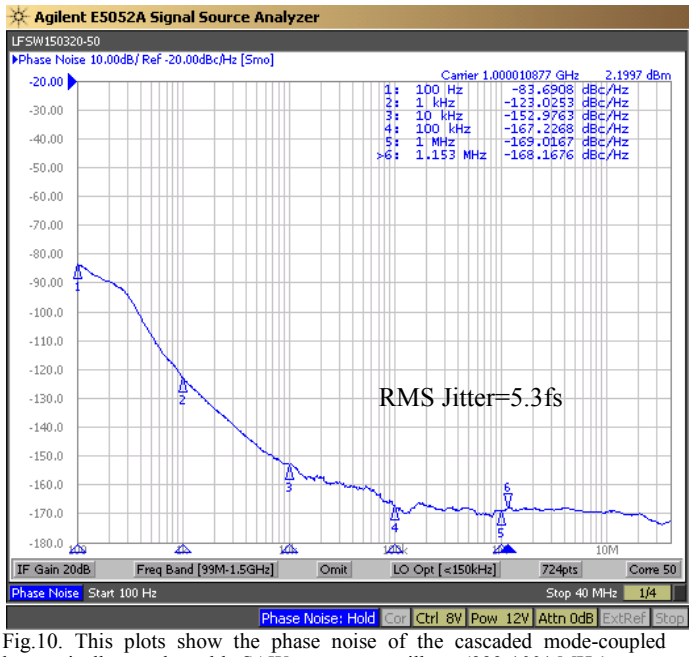

Fig.10. This plots show the phase noise of the cascaded mode-coupled harmonically tuned tunable SAW resonator oscillator (999-1001 MHz)

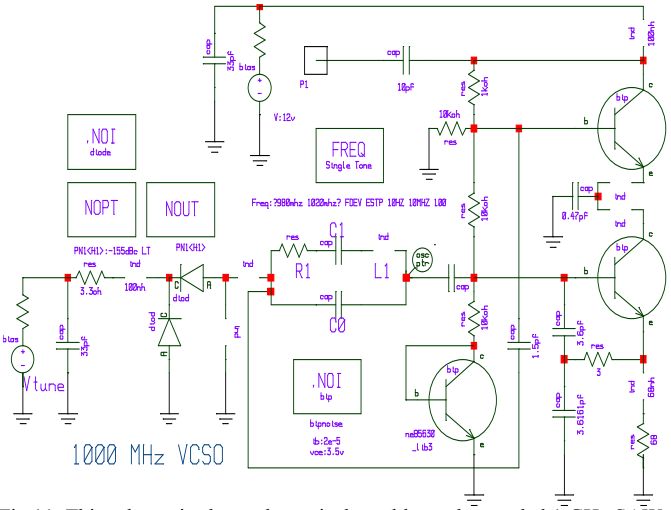

Fig.11. This schematic shows the typical tunable mode-coupled 1 GHz SAW resonator oscillator

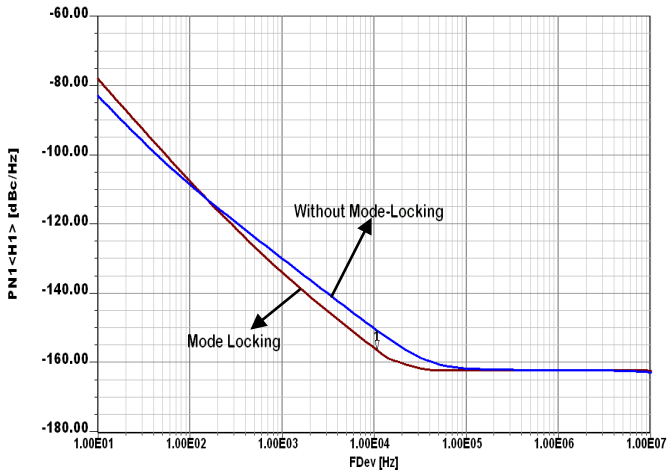

Fig.12. This plots show the phase noise of the mode-coupled tunable 1 GHz SAW resonator oscillator

Figure 13 shows the schematic of hybrid mode tunable 1 GHz SAW oscillator. For comparative analysis and brief insights about the various topologies, Figure 14 shows the measured phase noise plots of tunable SAW oscillators.

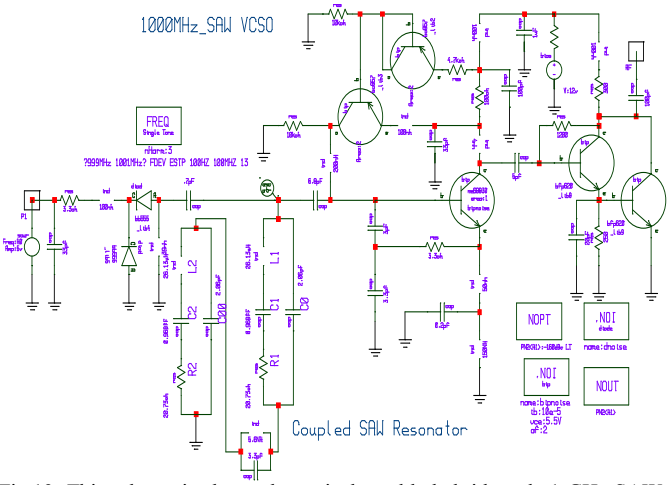

Fig.13. This schematic shows the typical tunable hybrid mode 1 GHz SAW resonator oscillator

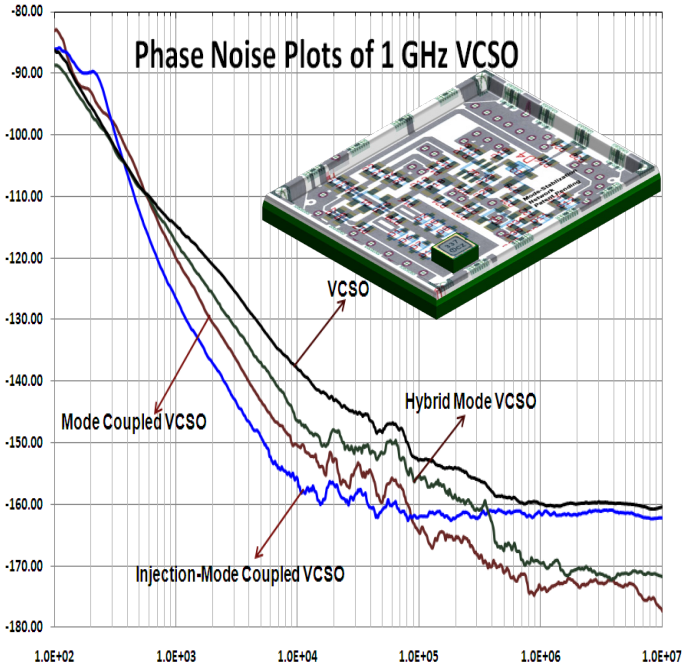

It can be seen from Fig.14, injection-mode coupled VCSO offers promissing phase noise with 1 MHz tunung to compensate the ageing and frequency drift. The drawback of this approach is vibration sensitive VCSO circuit, care must be taken for the application where g-sensitive criteria is important yard stick. By proper packaging and securing the SAW resonator in the cavity using double layer PCB for compensating the temperatrre charateristics, including g-insensitive solutions.

VI. Conclusion

The new ultra low phase noise VCSOs offer significant promise in terms of performance, price, and product delivery to satisfy both the technical and business needs for reference frequency sources for synthesizer applications.

***Abstract*—We recently demonstrated a Cryogenic Sapphire Oscillator (CSO) presenting a short term frequency stability better than 3×10^{-15} for 1 s $\leq \tau \leq$ 1,000 s and achieving 4.5×10^{-15} for one day integration [1], [2]. This CSO was designed and built in the frame of a research contract funded by the European Space Agency (ESA). It incorporates a pulse-tube cooler instead of a bath cryostat – thus eliminating the need for regular supplies and manual transferring of liquid helium. The advent of reliable and cryocooled CSO opens the possibility to implement such an ultra-stable reference not only in metrological laboratories with liquid helium facilities but also in remote sites like base stations for space navigation, VBLI antenna sites, ...**

In a new project: ULISS (Ultra-Low Instability Signal Source), funded by Regional and European Institutions, we are developping a new cryocooled oscillator specially designed to be transportable. The ULISS oscillator will be compared and tested in various laboratories, observatories and industrial companies throughout Europe.

In this paper we present the status of the ULISS project and the last frequency stability and phase noise characterisations of the current CSO working for more than one year in our lab.

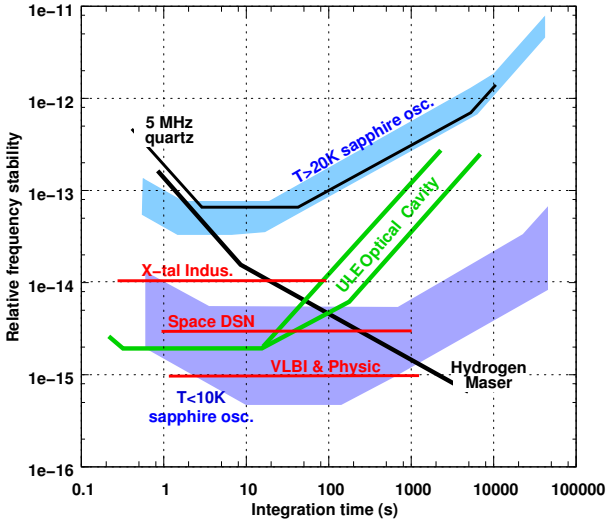

Figure 1. Relative frequency stability of some clocks and oscillators.

I. INTRODUCTION

The ever-increasing need for better time synchronization in number of High-Tech and scientific applications calls for the development of new frequency references of improved stability. The figure 1 shows the relative frequency stability as a function of the integration time τ for various clocks and reference oscillators as well as the needs newly expressed by various users:

The blue area in the figure 1 represents the typical performance of microwave oscillators incorporating a dielectric sapphire resonator cooled in a liquid helium bath. The Cryogenic Sapphire Oscillator (CSO) can exhibit the highest short-term frequency stability ($< 1\times10^{-15}$ for 10 s$< \tau <$ 100 s). CSO is the only available technology able to meet the requirements expressed by various users (red lines in Fig.1). Few liquid helium cryogenic sapphire oscillators have been built in a small number of worldwide research laboratories [3], [4], [5], [6]. Some of these instruments have been used as local oscillator for atomic fountain clocks [7] and for fundamental physical experiments [8]. Nevertheless they are still experimental prototypes that are difficult to implement outside a well-equipped laboratory. Moreover the liquid helium cryostat has to be refilled periodically adding a heavy maintenance constraint. Yet, various applications could benefit of the performances offered by the cryogenic sapphire oscillator:

- Space: The interplanetary navigation is based on microwave signal exchanges between the space vehicle and a ground station equipped with a high stability timing reference. Ranging and Dopplertracking resolutions are limited by the clock instabilities. To be able to met the stability requirements for the future space missions, the European Space Agency (ESA) sponsored the construction of a cryocooled–CSO. This project (ELISA project [9]) coordinated by the Femto-ST Institute was finalised in April 2010. The cryocooled–CSO achieves better than 3×10^{-15} frequency stability over 1 s to 1,000 s while insuring at least one year autonomy.

- Metrology: primary frequency standards. In an atomic clock, a local oscillator (LO) is frequency locked on the resonance frequency of an atomic transition. The best current atomic clocks using cold atoms operate sequentially. Indeed time is needed to cool the atoms before sensing the atomic transition. During this period of time no information is available for the frequency of the LO which is then free-running. Consequently the overall clock frequency stability is degraded by the short-term instability of the LO. Better than 1×10^{-14} over 1–100 s is required.

- Metrology: frequency stability certification. National Metrological Institutes have in charge to maintain the

standards and to establish certifications for industrial products and laboratory instruments. The frequency stability is one of the major characteristics of the signal source that could impact on the security and performances of number of systems. It is then a metrological quantity that has to be measured with the best resolution available. A standard presenting frequency stability better than 1×10^{-14} over 1–1,000 s will notably increase the current calibration capability making it compatible with all current industrial requirements.

- Very Long Baseline Interferometry: VLBI allows data from widely separated radio telescopes to be combined to get exceptional astronomical measurement resolution providing each radio telescope is equipped with an ultra-stable clock.

- Industry of high performance clocks and oscillators: To estimate, without ambiguity the frequency performances of state-of-the-art oscillators and clocks requires an ultra-stable reference. Some industrial companies making high performance quartz oscillators are interested by a versatile frequency reference of less than 1×10^{-14} frequency instability.

- Fundamental Physics. Special Relativity is one basic pillar of modern physics. Each basic theory has to be tested as its best, because it is so fundamentally important. The best tests of Special Relativity are based on ultra-stable oscillators for which we are locking for a frequency variation as a function of the speed and orientation of the laboratory. The frequency fluctuations of the oscillator limit the measurement resolution.

For all these applications, the autonomy and reliability of the frequency reference are major requirements. In all cases, liquid helium bath has to be rejected.

II. The ULISS project

Our work on the field of cryogenic oscillators was initiated 15 years ago, in the former Laboratoire de Physique et de Métrologie des Oscillateurs (LPMO) which becomes part of the Time and Frequency Department of the Femto-ST Institute at its creation in 2004. The project ELISA funded by ESA represents the outcome of all these efforts: the objective set by ESA was plenty fulfilled and we demonstrated for the first time the possibility to use a cryocooler while maintaining a state-of-the-art frequency stability.

We think that today the cryocooled–CSO technology is mature enough to be proposed as a reliable frequency reference for various applications. The ULISS (Ultra-Low Instability Signal Source) project answers our wish to see the CSO–technology used by other. This project is funded by the Fonds Européen de Développement Régional (FEDER), the Région de Franche-Comté and OSEO. It has been offically launched the 1st of March 2011 and contains two main parts:

- We are building a new CSO specially designed to be transportable by road. The new oscillator will be transferred (by road) successively to several potential users' sites. It will be tested in the real experimental conditions and critical result analysis will be carried out with the user. Hence the potentiality to improve their experiments as well as the reliability and autonomy of the CSO will be clearly demonstrated. These international tests will also give the opportunity to establish precisely the requirements specific to each potential user.

- A business unit: ULISS® has been created and is currently managed by the Université de Franche-Comté with the objective to commercially propose the CSO technology. The first purpose of this entity is the implementation of the first prototype, i.e. ELISA, in the ESA ground station situated in Malargüe (Argentina).

Visit our web site: www.uliss-st.com.

III. CSO performances

The CSO architecture is depicted in the figure 2. The heart of the instrument is a Whispering Gallery Mode Sapphire resonator stabilized at its thermal inversion point, i.e 6.1K. Such a low temperature is achieved in a closed–cycle Pulse–Tube Cryocooler specillay designed to ensure a high thermal stability ($\pm$1mK) and a low level of mechanical vibration: axial displacement less than 2 μm at the PT cycle frequency ($\approx 1Hz$). The CSO is designed to oscillate at 9.99 GHz $\pm$5 MHz. The difference with the 10 GHz round frequency is compensated by a low noise DDS. VHF and RF signals are synthetized from the stabilized 10 GHz [10]. The system is complemented with a Phase–COmparator (PCO) enabling to lock the synthized outputs to an incoming 100 MHz signal.

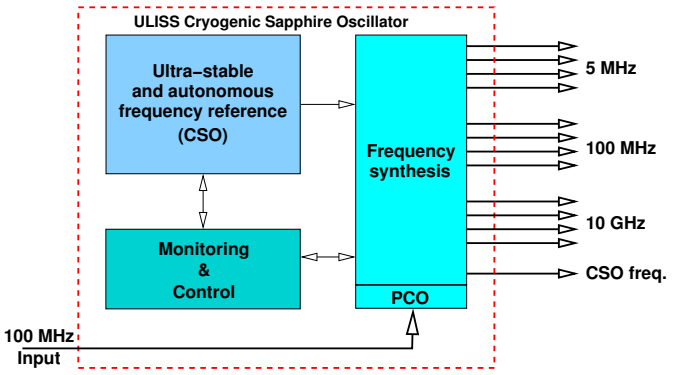

Figure 2. ULISS CSO architecture

The typical frequency stability performance of the CSO is shown in the figure 3. It is compared with the ADEV of other frequency references as active and passive Hydrogen Maser. The CSO bridges the gap between (unstable) high spectral purity oscillators and H maser. Here, we show fully conservative results. In all our measurements we do not remove drift, drift rate etc and we show the total noise of two

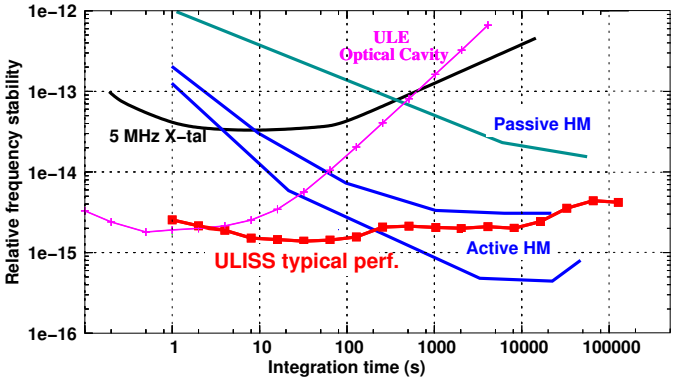

Figure 3. ULISS typical stability compared to some other clocks and oscillators.

oscillators, instead of taking away 3 dB under the assumption of two equal units.

IV. An example of application

As a Metrology laboratory associated with the Laboratoire National d'Essai et de Métrologie (LNE), a first evident application for us is the characterization of ultra-stable oscillators. Short term frequency stability of Quartz X-tal oscillator progresses only very slowly for more than 10 years and seems limited to $0.5 - 1 \times 10^{-13}$. In the X-tal oscillator, the location of the main source of noise is still not known and could be the quartz resonator frequency fluctuations and/or the sustaining amplifier phase noise. Even if some effort have been deployed to improve the resolution of measurement set-ups [11], [12], the limiting cause has still not be revealed. The ambiguity of the results remains due to the fact that the current instruments do not allow for the characteristaion of individual oscillator or resonator.

The CSO overcomes this issue, and offers an unprecedented resolution in the short term frequency stability measurement. Owing to the Uliss high stability, the frequency-stability measurement of most oscillators becomes straightforward as demonstrated by the experiment schematized in figure 4:

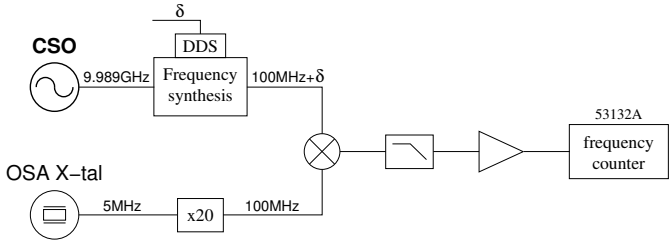

Figure 4. Simple measurement set-up used to evaluate the ADEV of a state-of-the-art X-tal oscillator.

An ultra-stable quartz X-tal oscillator from Oscilloquartz (modele 8607-B) [13] is simply compared to the CSO. The measurement is made at 100 MHz to ensure a sufficient resolution at short integration times. The beatnote frequency is adjusted by acting on the DDS command to optimize the counter operation. The raw result of this comparaison is shown in figure 5. 1s gate time samples have been recorded during 4,800 s, and ADEV computed without any post-treatment.

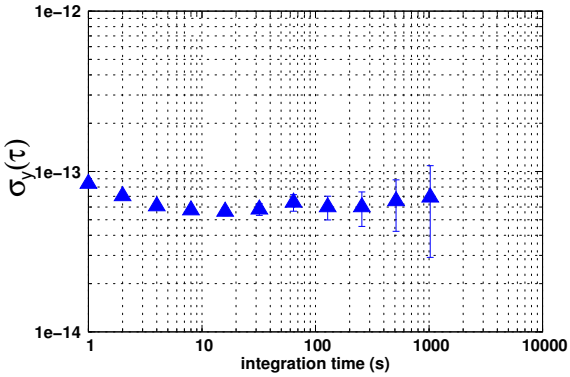

Figure 5. Relative frequency stability of a new Oscilloquartz 5 MHz X-al oscillator as measured with the CSO.

As revealed by the CSO, the short-term frequency stability of this X-tal oscillator constitutes a world record. The measured ADEV is limited by a flicker floor of 5×10^{-14} and still remains better than 8×10^{-14} at $\tau = 1,000$ s.

V. Acknowledgements

The authors want to thank M. Jacques Chauvin from Oscilloquartz to provide ultra-stable X-tal oscillator and to participate to the measurement compaign.

The ULISS team wish to express acknowledgements to the "Fond Européen de développement Régional " (FEDER), "le Conseil Général de Franche–Comté" and OSEO for their support.

***Abstract*—This paper presents improvements on a multi-channel time interval measurement for Time Comparison. The measurement has eight channels and measurements the time interval between nine clocks at the same tine. The measurement design is based on a commercially available GPX ASIC from acam-messelectronic gmbh provides a maximum of 86ps resolution per channel. In this measurement precision the measurement range of system is less than 10us and goes beyond the requirement of the time comparison. We extend the measurement range to endless by the internal start re-trigger and external interrupt. The architecture details of this system as shown in figure 1. We also develop a software runs on pc can control the measurement and display the measurement result in real time. We analyze the resolution variation of the measurements and the present linearity plots finally. The calculate results indicate that the precision per channel just a little decline after the measurement range was extended.**

I. INTRODUCTION

Time comparison is crucial in many areas of research and application such as timekeeping, navigation and positioning, laser distance measurement and so on. Multi-channel, high-resolution and low-power time interval measurement is demanded by time comparison for measuring time intervals between several received time signals to the standard time reference signal.

We developed a multi-channel time interval measurement based on time digital converter for comparing time between the reference clock and other clocks in a certain project. Time digital converter (TDC) is one of the most important tools to measure time intervals precisely [1] between several time signals. We used a commercially available time to digital converter to provide a two-level resolution for expediting progress of the measurement. Measurement system is communicated with personal computer (PC) by serial interface, this configuration provides a simply and efficient way of using the software running in the PC controlled the measurement, displaying the experimental results and storing these data in the hard disk of PC [2]. Such design is easy and efficient and convenient to modify. The experimental results are presented and the performance of this measurement is discussed in the end.

II. DESIGN

In order to measure the intervals between the reference clock and other clocks in the time standard assembly, we had developed an eight channel time interval measurement based on the TDC-GPX time to digital converter ASIC. The measurement is comes in 2U form factor for an optimized proprietary backplane bus. The selection of TDC-GPX for the time comparison of our project was motivated by the existing experience with it.

The principle of high resolution of the TDC-GPX is based on digital tapped delay line within the phase-locked loop. The line is composed of a number of delay cells, i.e. logic gate unit, each having the same propagation delay. It can be picoseconds resolution by modern CMOS technology. The use of the PLL ring oscillator can be regarded as a multiphase clock driving the clock inputs of the edge-triggered D-type flip-flops of the associated register, as shown in figure 1. Then the delay time can be precisely determined by counting the number of logic gate that start signal pass through.

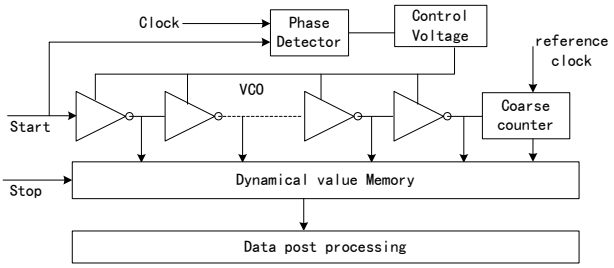

Figure 1. the principle of high resolution of the TDC.

This chip provides 8 channels with a typical resolution of 81ps least significant bit and can be slightly adjusted. The double-pulse resolution is 5.5 ns with 32-fold multi-hit capability, resulting in a peak hit rate of 182 MHz per channel. Over all channels a continuous rate of 40 MHz can be achieved.

It measures the time difference between each of the eight stop inputs and one common start input uses digital delay line techniques, and the total measuring range is 17 bit. In order to keep delays in the internal delay locked loop constant of this chip, it also had a phase locked loop circuit for the core voltage to compensating temperature drifts and manufacturing tolerances. The interval measurement results are stored in internal FIFOs of the chip, which are read out by a 28-bit parallel port clocked with 40 MHz.

Fig 2 depicts the proposed major part of the measurement according to the block diagram. The hardware architecture of the system consists of a power supply circuit, a pretreatment circuit, a time to digital converter circuit, a main-controller circuit, a reference frequency standard, power and resolution adjustment circuit and some other circuits.

Supported by the National Natural Science Foundation of China

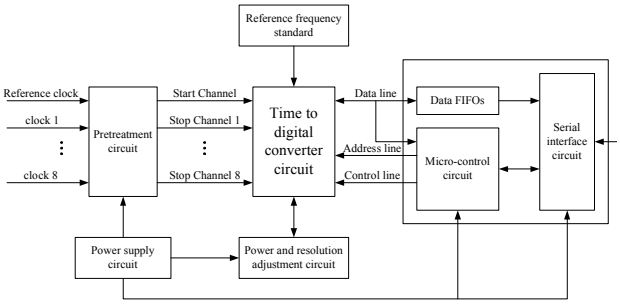

Figure 2. the hardware architecture

The pretreatment circuit has nine input interface and nine output interface. The time signal of clock was converted to TTL signal or LVTTL signal. So that it could be measured by the time to digital converter. The power supply circuit provides 3.3V direct current to pretreatment circuit, power and resolution adjustment circuit, micro-control circuit, serial interface circuit and so on.

The time to digital converter circuit is the core of the hardware of measurement which includes a high-resolution measurement circuit based on TDC-GPX. The principle of high resolution measurement part is based on digital tapped delay line within the phase-locked loop [3]. The TDC circuit consists of a start input channel and eight stop input channel which can accept TTL or LVTTL signals by the SMA connector.

The main-controller circuit consists of data FIFOs, micro-control circuit and serial interface circuit. This circuit connects to the TDC circuit by data bus include address line, data line, control line and some flag bit output lines and so on. The micro-control circuit is based on a 32-bit micro-controller which working frequency is up to 40 MHz [4]. The operation to the TDC circuit is directly accomplished by this micro-controller such as power-up reset, configuration of the registers, initiating measurement of input signal and readout the measurement result. The data FIFOs was a 28 ×100 Bit register. The results of time intervals were pre-stored individually in the register and are read out all together by the personal computer. The interface with the computer becomes very simple using the serial interface circuit, control data and measurement results transmit between the main-control circuit and personal computer by the serial RS232 interface.

The reference standard circuit provides a 40 MHz sine wave frequency signal as reference clock signal of the TDC circuit which is converting four times by the 10MHz high resolution frequency signal. The jitter of the reference was controlled less than 80ps. Because the jitter of the reference clock signal has a direct affection on precise measurement when the internal start retrigger signal of TDC circuit is used.

In principle the high resolution of the TDC circuit is derived from the internal gate propagation times. The logic gate propagation time depends upon voltage, temperature and the manufacturing process, the resolution of the TDC is not known and must be calculated via calibration measurements [5]. In addition, the resolution is not stable with the swing of voltage and temperature. So a power and resolution adjustment circuit is indispensable to adjust quartz-accurately and absolutely temperature stable and regulates the core voltage of the TDC, so that the resolution of TDC is set exactly to the programmed value [6].

Furthermore the implemented software consists of three main components, the device driver, the firmware of micro-controller and an application program runs on PC. The block diagram of software as shown in fig. 3.

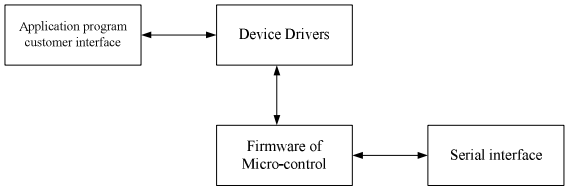

Figure 3. The software architecture block diagram.

The device driver is basic segment of the software which communicates with the measurement through the computer bus to the measurement hardware. When an application software program invokes a routine in the driver, the driver should issues commands to the device. Once the device sends data back to the driver, the driver may invoke routines in the original calling software. Driver provides the interrupt handling required for the serial interface and is hardware-dependent and operating-system-specific.

The firmware is involved with very basic low-level operations without which the measurement would be completely non-functional. It resides in the ROM or RAM of the micro-controller, and directly operates the time to digital circuit and so on. The firmware implements the power-up reset, the registers configuration, enabling the measurement and readout the measurement data from the time to digital circuit.

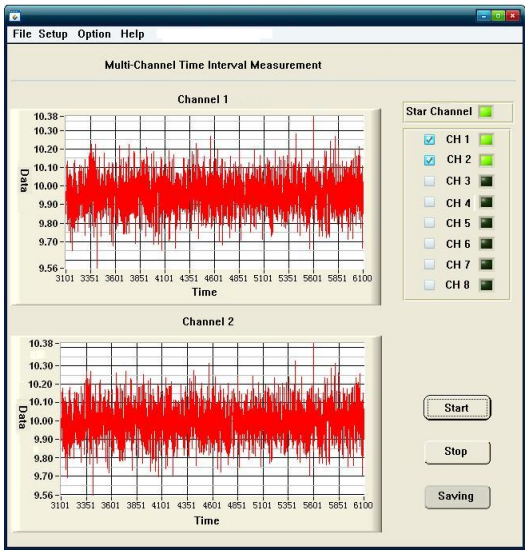

Figure 4. The customer interface of application program

The customer interface of application program as showed in fig. 4. It automatically detects when the measurement device is being prepared, initializes the serial communication and starts the data acquisition. The software displays the result of the measurement which read from the firmware and plots the

graphics of these data, save all the measurement result in the hard disk of the personal computer.

III. EXPERIMENTAL RESULT

Measurements have been carried out with the help of master clock of national service center in order to check if the measurement conforms to the requirements with regard to resolution and measurement range for time comparison.

For the resolution and range measurement, the master clock of NTSC produces 10Mhz sine wave frequency was reduplicate four times by the measurement circuit as the reference clock. A 1pps signal synchronized with the master clock as the start signal. And the 1pps output from master clock is divided into the two same signals and added some time delay. The two divided 1pps are connected to two stop channel respectively. The TDC is configured as the I-mode and the resolution is actually 130ps and the measurement range is from 200 ns to 30s. It accepts only one stop event per channel, therefore the next measurement is made after Master-Reset.

A. Short measure range

The short measure rang result as shown in figure 5. The delay between the start pulse and stop pulse is 1251275835 ns (include the delay of cable and channel) and the measurement time is 1200 second. The mean of result is 1251275836.479 ns; the maximum positive offset from mean is 0.39 ns and the maximum negative offset from mean is 0.42 ns. The standard deviation of the result is 134 ps.

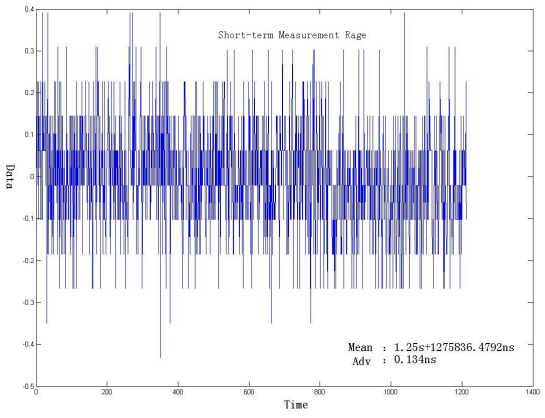

Figure 5. The short-term measure rang result

B. Long measure range

For the long measure rang test, the delay between the start pulse and stop pulse is 29S + 51 ns (also include the delay of cable and channel); the measurement time is 14000 second. All the results are shown in figure 6. The statistical results are showed that all of the readings are between the maximum 29S + 52.8ns and the minimum 29S + 50.1ns. The mean of result is 29S + 51.3237 ns and the standard deviation of the result is 316ps.

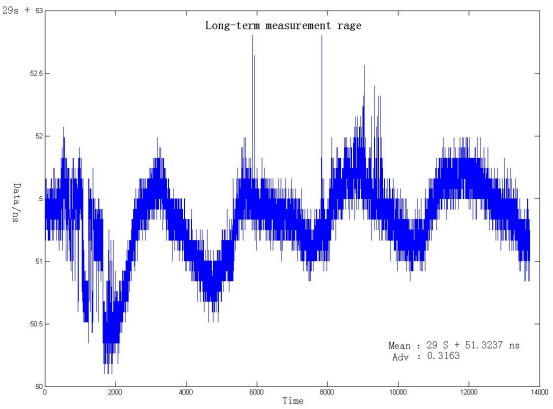

Figure 6. The long-term measure rang result.

IV. CONCLUSION

The measurement has eight input channels plus a common channel and realizes common-start and common-stop operations. It can provide a maximum of 134ps resolution per channel with the measurement range approximately 1.25 second and a maximum of 316ps resolution per channel with the measurement range approximately 30 second. The experimental result show that the resolution per channel was a little decline along with measurement range was extended from 1s to 30s. We will improve the precision of this multi-channel time interval measurement with a large measurement range and extend the measurement rage to endless in the future work.

***Abstract*—Building optical fiber-based systems presents different challenges than free-space architectures due to the inherent vibration sensitivity of the fiber and the associated components. A survey of the vibration sensitivity of an assortment of commonly used fiber-based optical components is presented to identify problematic parts of a fiber-based design. The measurement of vibration sensitivity is challenging due to the difficulty of separating the sensitivity of the components from the measurement apparatus itself. The noise introduced by the interconnecting fibers bridging between the stationary measurement system and the vibrating device under test can dominate and mask the noise of the device being measured. We propose and demonstrate a novel technique to measure the vibration sensitivity of fiber-based optical components. It uses a common-arm counter-propagating frequency-shifted interferometer that cancels the vibration-induced phase noise of the interconnecting fibers. The proposed technique improves the vibration-induced phase noise floor by more than 30 dB compared to a conventional frequency-shifted Mach-Zehnder interferometer and allows measurement of low vibration sensitive devices.**

***Index Terms*— optical fiber, interferometer, phase noise, vibration sensitivity**

I. Introduction

There is a growing need for low phase modulated (PM) noise and low vibration sensitive oscillators for many applications such as radar, navigation, spectroscopy, and timing. In recent years, ultra-low PM noise microwave signals have been generated by dividing optical signals from stabilized lasers. This division from the optical to microwave domain has resulted in extremely low PM noise of -101 dBrad^2/Hz or lower at 1 Hz offset from a 10 GHz carrier [1]. Opto-electronic oscillators (OEO) have also been used to generate low noise microwave signals by use of a modulated optical carrier [2]. Presently, the lowest PM noise has been achieved only in quiet, low-vibration laboratory environments. The vibration sensitivity of an OEO is on the order of 10^{-8} to 10^{-10} per g (1 g is the acceleration of gravity near the earth's surface, approximately 9.8 m/s^2), and arises mostly from the length fluctuation of the OEO's long optical fiber that acts as a resonator [3-5]. Extensive work involving vibration insensitive Fabry–Pérot cavities have been reported [6-8]. However, there is little information on the vibration sensitivity of fiber-based optical components [9-11]. The focus of this paper is to study the noise performances of an assortment of such optical components under vibration.

A conventional frequency shifted Mach-Zehnder interferometer (MZI) for measuring vibration sensitivity of fiber-based optical devices is shown in Fig. 1. During the course of setting up a measurement of vibration sensitivity, the interconnecting fibers (F_1 and F_2 in Fig. 1) that deliver the optical signal to and from the device under test (DUT) were so sensitive to vibration that the measurement of a given device could not be made with assurance. Since these delivery fibers cross between the stationary reference frame and the moving frame of the vibration actuator, they undergo not only vibration due to the actuator, but also bending and stretching between the two frames. Mechanical distortion of the core and surrounding cladding causes fluctuations in the phase of the optical signal passing though the fiber [3]. Many fiber-based optical components are connected via integrally included optical fiber 'pigtails' (F_A and F_B in Fig. 1). The sensitivity of these pigtail fibers cannot be ignored and must be viewed as an integral part of the DUT. The effect of these pigtail fibers are not to be confused with, and should be separated from, the delivery fibers that connect the DUT on the vibration actuator to the measurement interferometer. Unfortunately, in many cases the delivery fibers that bridge the stationary and vibratory frames undergo larger phase fluctuations than those experienced by the DUT being evaluated. In this letter, we propose and experimentally demonstrate a novel scheme for reducing the vibration effect on the interconnecting delivery fibers while measuring the vibration sensitivity of an assortment of optical fiber-based components. Sections II and III constitute the technical portion of this paper. Section II describes the setup for reducing the vibration effect on the interconnecting fibers while measuring a component under vibration. Section III discusses measurements results of the optical component's vibration sensitivity.

II. Measurement Methods

In order to measure the vibration sensitivity of a component accurately, it is important to know the noise floor of the measurement system. The initial measurement technique employed to measure the PM noise, and hence the sensitivity of optical components to vibration, is shown in Fig. 1. It consists of a frequency-shifted MZI with an erbium-doped

fiber laser at 1550 nm as the optical source. A 40 MHz acousto-optic modulator (AOM) is connected to the reference path of the interferometer, shifting the frequency of the laser by 40 MHz and translating the output of the MZI from baseband to radio frequency for analysis. The DUT, mounted on a vibration platform, is inserted in the non-shifted measurement path of the MZI. The lengths of the two paths are kept almost equal, to minimize differential delay. Finally, the 40 MHz beat at the output of the photo-detector (PD) is amplified and measured on a direct-digital PM noise measurement system. All fibers used in the system are single-mode SMF-28.

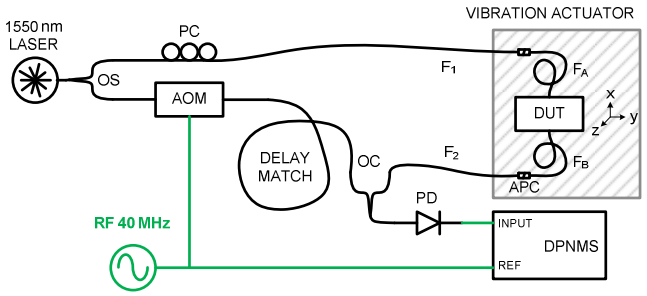

Fig. 1. Block diagram of a conventional frequency-shifted MZI for residual vibration sensitivity measurement of optical devices. PC: Polarization Controller, OS: Optical Splitter, OC: Optical Combiner, AOM: Acousto-Optic Modulators, PD: Photo detector, APC: Angled Physical Contact Connector. DUT: Device Under Test, DPNMS: Digital Phase Noise Measurement System, F_1, F_2: Interconnection Fibers, F_A, F_B: DUT Fiber Pigtails. Green lines represent radio frequency signals and black lines represent optical signals. The z-axis is perpendicular to the page.

Traditionally, vibration sensitivity is given by Γ_y, which is defined as the ratio of fractional frequency fluctuations to acceleration. For devices such as resonators and delay lines, fluctuations in the length (l) or delay (τ) are often normalized as $\delta l/l$ or $\delta\tau/\tau$. The vibration-induced phase fluctuations observed for short fibers are not necessarily proportional to their lengths. Therefore, an alternate vibration-phase sensitivity, Γ_φ, for two-port devices can be defined as [12]

$$\Gamma_\varphi = \sqrt{\frac{S_\varphi(f)}{S_g(f)}} \quad \text{rad/g}, \qquad (1)$$

where, $S_\varphi(f)$ is the double-sideband phase noise in rad^2/Hz and $S_g(f)$ is the root mean square (rms) acceleration power spectral density (PSD). Vibrational effects that are distributed with length are best described using Γ_y. Localized or spot effects due to vibration should not be normalized by total length and can be described with Γ_φ. Conversion to the traditional Γ_y can easily be made with use of the carrier frequency.

To determine the noise floor of the conventional MZI measurement system under vibration, the DUT is removed, and fibers F_1 and F_2 are connected and secured to the vibration platform. For this test, a random white vibration profile of $S_g(f)$ = 1 mg^2/Hz is used for 10 Hz $\le f \le$ 1000 Hz. The vibration phase sensitivity of the conventional MZI is shown by the top green curve in Fig 3. The noise floor due to the bending and stretching (length fluctuations) of interconnecting fibers was excessive and thus prohibited the measurement of low-vibration sensitive devices. A different approach was therefore necessary that compensated for fibers F_1 and F_2 while retaining sensitivity of the DUT connected between them. A novel technique using a common-arm counter-propagating frequency-shifted Mach-Zehnder interferometer (CACP-MZI) is proposed and shown in Figure 2. In this new method the conventional MZI is modified with the addition of four circulators. Two of these circulators, A and D, are mounted on the stationary measurement system, and the remaining two circulators, B and C, are mounted on the vibrating platform. The optical signal is split into two paths by use of a 50/50 coupler. The forward measurement signal path, represented by the blue arrows, propagates through the circulators A, B, the DUT, C and, D as shown in Fig 2. Similarly, the reverse reference path represented by the red arrows is frequency-shifted by the AOM and propagates through circulators D, C, B and A respectively, while bypassing the DUT. The forward and reverse signals combine at the PD, creating a 40 MHz beat signal that is then analyzed. The noise introduced from the flexing interconnecting fibers, F_1 and F_2, is common to both the forward measurement and reverse reference paths and thus cancels in the MZI, producing a lower noise floor. It should be noted that in CACP-MZI, there is a short uncompensated signal path between ports 2 - 3 of circulator B, ports 1 - 2 of circulator C and fiber F_3 that contributes to the noise floor.

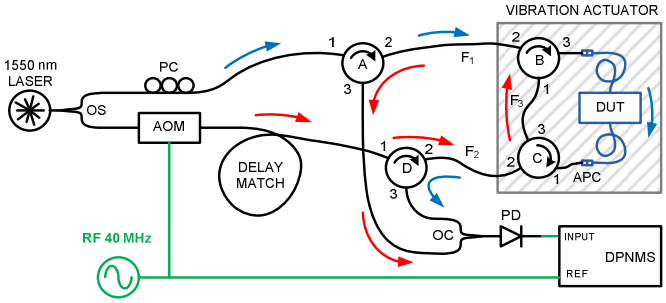

Fig. 2: Common-arm counter-propagating frequency-shifted interferometer for measuring vibration sensitivity of fiber-based optical devices.

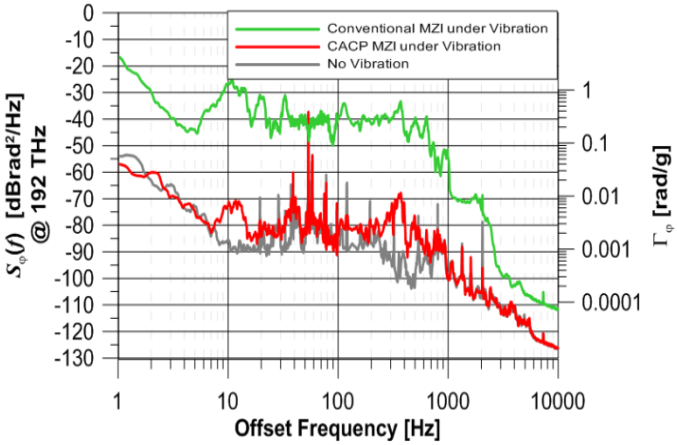

Fig. 3. The vibration sensitivity and residual phase noise floor of the conventional MZI and CACP-MZI under vibration. A random vibration with $S_g(f)$ = 1 mg^2/Hz is used for 10 Hz $\le f \le$ 1000 Hz. The bottom gray curve shows the noise floor measured under no vibration.

The noise floor for CACP-MZI system is measured under the same vibration condition as that of conventional MZI by replacing the DUT with 10 cm of SMF-28 fiber between ports 3 and 1 of circulators B and C. The noise floor for CACP-MZI (shown in red in Fig. 3) is limited primarily by the noise floor under no vibration. An improvement of more than 30 dB over conventional MZI noise floor is observed.

III. Test Results

The optical components considered for vibration sensitivity testing are listed in Table I and shown in Fig. 4. The fiber pigtails associated with these components are all 9/125/250 µm SMF-28 fiber. The buffer type and length for each DUT measured are indicated in Table I. For these DUTs, the associated buffer consisted of one of three types, namely, 900 µm tight buffer, 900 µm loose tube, and 3 mm jacketed buffer shown in 5a.

TABLE 1 - Devices considered for vibration test

Device Under Test	Buffer Type	Pigtail Length (m)
Power Splitter	900 um Loose Tube	1
Circulator	900 um Loose Tube	1
Etalon Filter (Finesse ~ 100, BW = 0.9 nm)	900 um Tight Buffer	1
Erbium-doped Fiber Amplifier (Gain = 23 dB, P1dB = 17 dBm)	900 um Tight Buffer	2
80 MHz AOM	3 mm Jacketed	2
Fiber potted in RTV Silicone	250 um Bare Fiber	0.1

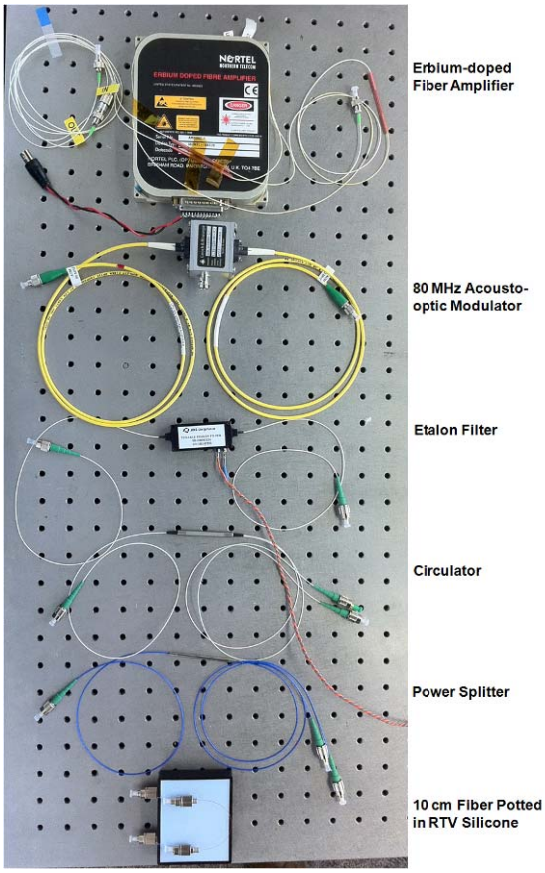

Figure 4. Picture of fiber-based optical components considered for the vibration tests at 1550 nm.

In order to understand the sensitivity contribution of the pigtail fibers to the DUT, we first measure Γ_φ of 1 m long optical patch cords of each buffer type. The patch cord is coiled in a 10 cm diameter and is taped on the shaker. For this test, $S_g(f)$ = 100 µg^2/Hz from 10 Hz $\leq f \leq$ 1000 Hz is used. For each fiber patch cord, Γ_φ varied depending on the amount of stress induced by the tape securing the fiber coil. Under different mounting conditions, about one to two orders of magnitude variation in Γ_φ is observed for a given fiber. The min-max plots showing this variation of Γ_φ for these three kinds of patch cords are shown in Fig. 4. The result indicates that the loose tube fibers, when constrained with mounting tape, can be less sensitive to vibration than the tight buffered fibers.

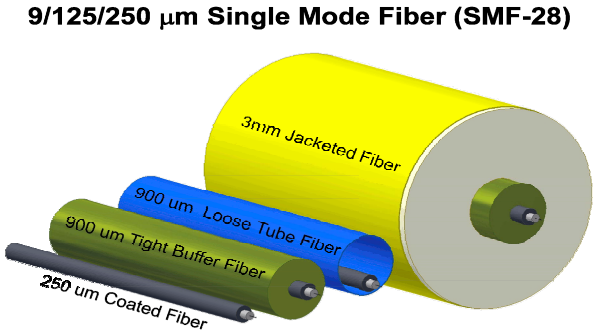

Figure 5a. Depiction of 9/125/250 µm SMF-28 fiber with different buffer types.

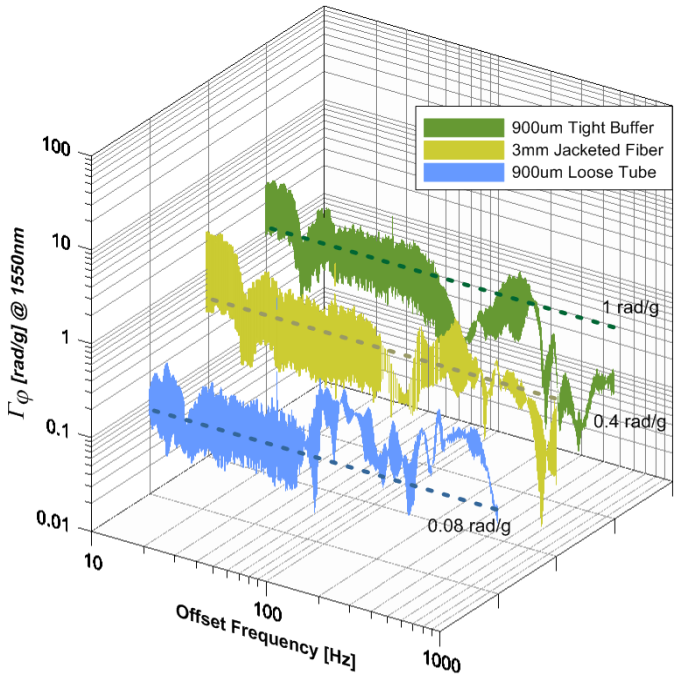

Fig. 5b. Min-Max plot showing the variation of the vibration sensitivity of 1 m long optical patch cords. The resonances above 100 Hz are contributions from the custom built vibration actuator and are not features of the DUT.

Next, the vibration sensitivity of fiber-based optical components are measured under the same vibration conditions, and results are shown in Fig. 6. The vibration is applied only along the z-axis, as shown in Fig. 1. Comparing Fig. 5b and Fig. 6 indicates that the vibration sensitivity of the power splitter, the Etalon filter and the AOM arises mostly

from the fiber pigtails, whereas for the circulator and the EDFA, their high sensitivity comes from the device itself, and not from the fiber pigtails. We also tested a 10 cm bare fiber potted in room temperature vulcanized (RTV) silicone. The sensitivity to vibration is found to be nearly two orders of magnitude worse than a non-potted bare fiber of the same length.

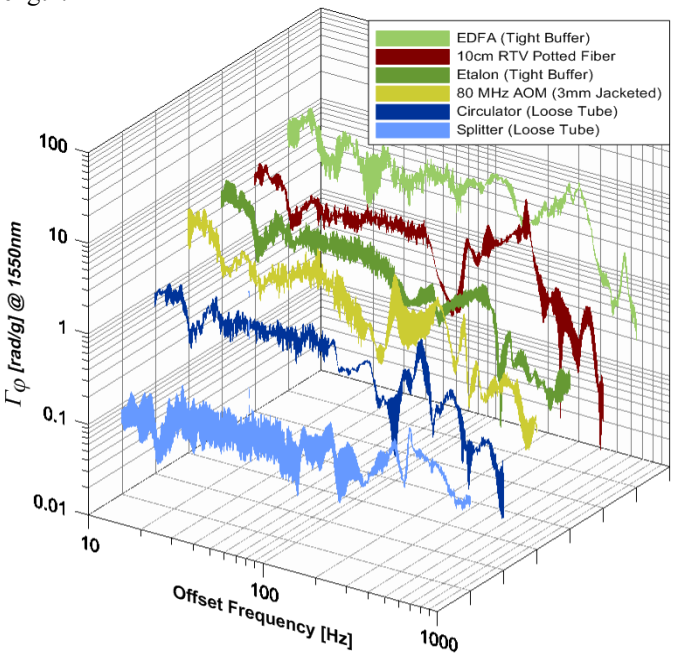

Fig. 5. Min-Max plot of the vibration sensitivity of the various optical components listed in Table I.

IV. Conclusions

We propose and demonstrate a technique to measure the vibration sensitivity of optical fiber-based components. It uses a common-arm counter-propagating MZI, that reduces the vibration-induced PM noise of the interconnecting fibers used in the measurement system. To our knowledge, this is the first implementation of this novel topology. This technique improves the vibration-induced noise floor typically by 30 to 40 dB compared to that of a conventional MZI approach. The proposed system has a sensitivity of nearly 1 mrad/g at 192 THz; therefore, it allows the measurement of low-vibration sensitive optical components. Vibration sensitivity of many optical components is dominated by the sensitivity of the associated fibers pigtails.

Constraining the optical fibers to prevent movement is often necessary for repeatability and consistency in fiber-based systems. Stress induced in the fiber due to this constrainment can dramatically increase vibration sensitivity. Different types of buffers used to protect the fiber from other environmental effects can either transmit or isolate the mounting stress to the underlying bare fiber. Loose tube buffering has shown less sensitivity to mounting stress than other buffer types.

Careful design of fiber-spool geometry has been used to minimize vibration sensitivity for long lengths of fiber [11]. The sensitivity of the spool has been reduced to levels approaching, or possibly below, the sensitivity due to the interconnecting fibers. If a vibration-insensitive spool of 1 km length were constructed, the connecting 3 mm jacketed fibers (Γ_φ = 0.4 rad/g) would limit the overall fractional vibration sensitivity of the spool to $\Gamma_y = 7\times10^{-11}$/g.

Methods similar to CACP-MZI can also be implemented either with polarization or frequency division multiplexing to combine the reference and measurement path in a common fiber. These common-arm MZI methods may find additional applications when it is critical to separate environmental noise of the delivery fibers from a remote fiber-based sensor.

In the future, a similar technique will be used to reduce the vibration sensitivity of coaxial cables in the microwave frequency range [12].

The Use of Multi-variance for Likelihood Weighted Drift Estimation in a Disciplined Oscillator Algorithm

Gregory Weaver, Mihran Miranian, Jeffrey Garstecki
Space Department
Johns Hopkins University Applied Physics Laboratory
Laurel, MD, USA
gregory.weaver@jhuapl.edu

***Abstract*—Our recent research at JHU/APL has focused on advancing algorithms and software control developments for a next generation, disciplined USO based clock system. This research shows promise that incorporating an in-situ control system for removing USO deterministic frequency error based on multi-variance methods and a Bayesian maximum likelihood estimation (MLE) process could mitigate the burden of post processing spacecraft clock data.**

We found the effects caused by sudden frequency changes and perturbations could be diminished with a dynamic, multi-variance algorithm used to augment the drift estimation process. We used the complementary aspects of the Allan and Hadamard variance to form an MLE function. We then used the output of the MLE function to drive the weighted decision process of a simulated frequency correction control algorithm.

Our paper will discuss the mathematical approach used to formulate the multi-variance MLE and discuss our findings on its implementation in the disciplining algorithm developed from the research. Using laboratory collected USO data, we will show simulated USO timekeeping performance to a maximum time interval error of < 1 μs over 70 days of operation and discuss the impact of frequency anomalies and short term rate changes to the behavior of the multi-variance approach.

I. Disciplined System for Improved USO Timekeeping

The Johns Hopkins University Applied Physics Laboratory (JHU/APL) has been providing ultra-stable oscillators (USOs) for decades for use in mission critical space applications where best performing frequency stability of less than 3E-13 in the 1 to 1000 s time interval is required for deep space science data return. The New Horizons mission and the Gravity Recovery and Interior Laboratory (GRAIL) are two most recent examples. The New Horizons mission to Pluto and the Kuiper Belt will use the frequency stability of the on-board USOs for a radio science experiment (REX) to determine any residual atmosphere that may exist from Pluto's most recent perihelion. The GRAIL mission will use the frequency stability of the USO in a Dual One Way Ranging (DOWR) instrument deployed in each of two tandem flying spacecraft to map the gravitational field of the Moon.

As described in these two examples, USOs are generally used as very-low phase noise frequency sources in science instruments. However, years of frequency data collected by ground mission operations has consistently shown that the frequency drift associated to quartz resonator aging over long periods of space operation can become good enough for consideration as timekeeping references. For example, frequency data collected from USO A on the New Horizons spacecraft determines a current frequency drift of -3.4E-12/day for a total accumulated frequency change of -19E-9 after 1800 days since launch, shown in Fig. 1 [1]. Also noticeable in Fig. 1 is a slow monotonic improvement in frequency drift with few frequency perturbations or anomalies, the most observable at day 400 from ionizing radiation associated with the spacecraft's encounter with Jupiter's magnetopause [2]. Such regular occurrence in USO performance for long-term frequency stability has motivated JHU/APL to support research into the development of a disciplined USO timekeeping system (TKS).

A disciplined USO TKS uses a remotely located reference of higher accuracy, in our case the master clock of ground

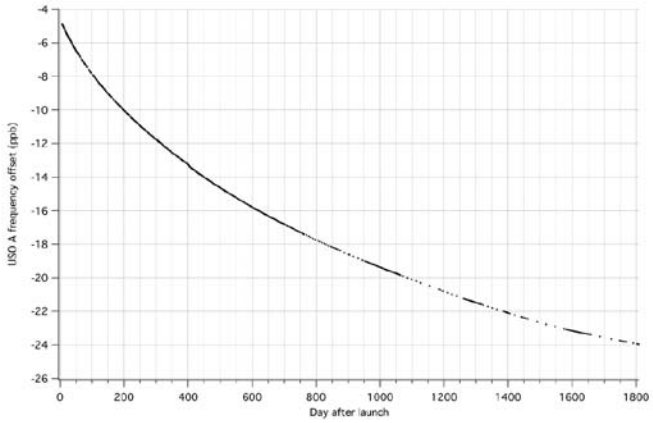

Figure 1. New Horizons USO A frequency since launch, Jan. 19 2006

control operations, to periodically correct the frequency of the USO output and maintain synchronization of the spacecraft to mission time. A disciplined USO TKS must perform two important functions. First, it must be able to transfer and then hold synchronization to mission time within some maximum time interval error (MTIE). Second, it must correct the USO frequency by removing its error during the time interval when access to the ground control master clock is not available. In USO's, this error can be partitioned between changing environmental conditions and dynamic drift (aging). These error contributions must be uniquely characterized to the USO frequency source in use. The information of the characterized USO is then used by the clock model of the disciplining control system to reduce the frequency error effects on the accumulated time.

Fig. 2 describes a notional system block diagram of our disciplined USO TKS. Our recent research shows, through simulation on archived USO test data, a possible USO timekeeping performance of less than 1 μs over 70 days of operation. This simulated performance improvement was accomplished through the development of three key technologies, indicated within the red dashed area of Fig. 2:

Steering algorithm for frequency drift correction using multi-variance based maximum likelihood estimator (MLE) function,

Clock model interface to control the operation of a Diophantine frequency synthesizer (DFS) [3],

Virtual state machine (VSM) autonomy controller to supervise the update implementation to the clock model DFS interface and alarm possible incidences of frequency perturbations or anomalies, as determined by the MLE algorithm [4].

This paper will discuss the theory, development and implementation of the MLE function from our research. We will describe our use of a three-state clock model derived in [5] and forward how its separation of deterministic frequency coefficients from Gaussian noise diffusion coefficients motivated our use of the dynamic Allan and Hadamard variances to detect USO frequency anomalies and perturbations.

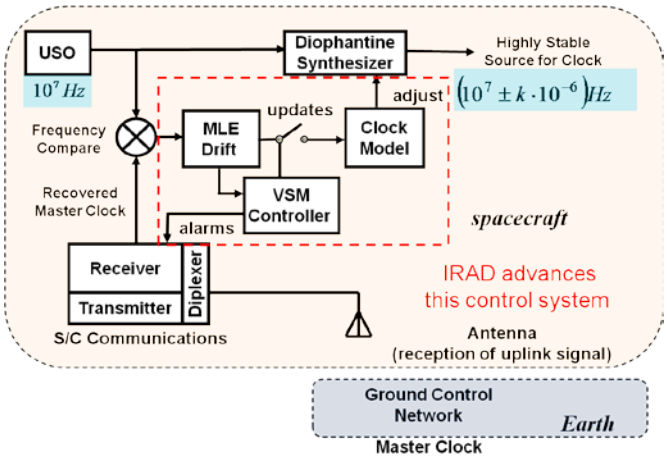

Figure 2. Block diagram of JHU/APL disciplined USO system

The information from these two related statistics was used to form a measure of likelihood that the frequency data collected over the most recent USO characterization interval was representative of previous clock model innovations. Dependent on this measure of statistical likelihood the influence of the data was selectively weighted for updating the clock model. It was found that the higher order power law noise of spectral density $S_y(f)$ proportional to f^{α}, where α is less than -2 are indicative of USO frequency data that is highly influenced by short-term frequency instability and should not be used with high significance in the clock model innovation. It was also found that a dynamic test comparing the statistics of the most recent characterization interval to a cumulative moving average could be used to check for the incidence of increased white FM, $\alpha = 0$, caused by outlier phase pops and frequency jumps.

II. The Clock Model and Its Relationship with the Allan and Related Variances

We use the title of [5] for this section heading as it clearly presents the motivation of our work in the construction of the MLE function to be described later in the paper. In [5], the authors derive a description of a three-state clock model, $d\mathbf{X}(t)$, from a generalized set of stochastic ODEs that represent the standard rate algebra of a clock with frequency offset, drift and a linear change of drift (μ_1, μ_2, μ_3 respectively). Gaussian noise diffusion processes are assigned to each equation with diffusion coefficients for white FM, random walk FM and random run FM (σ_1, σ_2, σ_3 respectively). The authors continue by showing that the solution of this set of strictly linear equations can be found in a closed form with a useful separation of the deterministic and stochastic parts:

$$\mathbf{X}(t) = \mathbf{\Phi}_{t,0}\mathbf{X}(t_0) + \mathbf{B}_t\mathbf{M} + \mathbf{G}_t, \tag{1}$$

where the matrix $\mathbf{\Phi}_{t,s}$ drives the transition $\mathbf{\Phi}_{t\to s,0}$, $\mathbf{M}$ is a vector of μ_1, μ_2, μ_3 and $\mathbf{G}_t$ is a vector that innovates only the stochastic part of $\mathbf{X}(t)$. Moreover, the authors develop an approach, offered by the separation of the deterministic and stochastic parts, to produce the clock model mean, $E[\mathbf{X}(t)]$, expressed in terms of a distribution of the vector $\mathbf{M}$ and clock model covariance, $E[\mathbf{G}_t\,\mathbf{G}_t^{\mathrm{T}}]$, expressed in terms of the distribution of the diffusion coefficients (σ_1, σ_2, σ_3). The mean, shown in (2) and the covariance, shown in (3) of the clock model are reproduced from [5], as follows:

$$E[\mathbf{X}(t)] = \begin{bmatrix} c_1 + (c_2+\mu_1)\,t + (c_3+\mu_2)\,\dfrac{t^2}{2} + \mu_3\dfrac{t^3}{6} \\ c_2 + (c_3+\mu_2)\,t + \mu_3\dfrac{t^2}{2} \\ c_3 + \mu_3 t \end{bmatrix} \tag{2}$$

$$E[\mathbf{G}_t\mathbf{G}_t^T] = \begin{bmatrix} \sigma_1^2 t + \sigma_2^2\frac{t^3}{3} + \sigma_3^2\frac{t^5}{20} & \sigma_2^2\frac{t^2}{2} + \sigma_3^2\frac{t^4}{8} & \sigma_3^2\frac{t^3}{6} \\ \sigma_2^2\frac{t^2}{2} + \sigma_3^2\frac{t^4}{8} & \sigma_2^2 t + \sigma_3^2\frac{t^3}{3} & \sigma_3^2\frac{t^2}{2} \\ \sigma_3^2\frac{t^3}{6} & \sigma_3^2\frac{t^2}{2} & \sigma_3^2 t \end{bmatrix}. \quad (3)$$

In subsequent sections of [5], the authors use the definitions of the Allan, $\sigma^2_y(\tau)$, and Hadamard, $H\sigma^2_y(\tau)$, variances expressed as expectations of the mean and covariance of $\mathbf{X}(t)$ to find the relationship of the clock model deterministic and stochastic coefficients to these two variances. The Allan, shown in (4) and the Hadamard, shown in (5) are reproduced from [5], as follows:

$$\sigma_y^2(t_k,\tau) = \left(\frac{\sigma_1^2}{\tau} + \frac{\sigma_2^2\tau}{3} + \frac{\sigma_3^2\tau^3}{20}\right) + \sigma_3^2\left(\frac{\tau^3}{3} + \frac{\tau^2 t_k}{2}\right) + \frac{\tau^2}{2}\left[c_3 + \mu_3(\tau + t_k)\right]^2 \quad (4)$$

$$H\sigma_y^2(\tau) = \frac{\sigma_1^2}{\tau} + \frac{\sigma_2^2\tau}{6} + \frac{11}{120}\sigma_3^2\tau^3 + \frac{\mu_3^2\tau^4}{6} \quad (5)$$

With respect to our work, two highly interesting observations can be made from (4) and (5). First, the deterministic linear change of drift coefficient, μ_3, is separable from the noise related parts of the statistics and contains contrasting information in the form of differing power law orders, τ in the case of the Allan deviation and τ^2 in the case of the Hadamard deviation. μ_3 is an important parameter for our interest in disciplining a USO since its dynamic behavior is the principle mechanism for the required periodic correction of our clock model process. Referring to Fig. 1, we expect that the μ_3 parameter should be small in respect to an update interval on the order of 12 to 24 hours. Therefore, we use this insight to form a piecewise comparative ratio, with the deviations segmented by octaves,

$$\mathrm{A} = \sum_{i=0}^{m}\frac{\sigma_y(2^{i+1}\tau,\mathrm{t_k})}{\sigma_y(2^i\tau,\mathrm{t_k})} \quad \mathrm{H} = \sum_{i=0}^{m}\frac{\mathrm{H}\sigma_y(2^{i+1}\tau,\mathrm{t_k})}{\mathrm{H}\sigma_y(2^i\tau,\mathrm{t_k})} \text{ to form } \frac{\mathrm{H}}{\mathrm{A}}, \quad (6)$$

where m is an integer limit to the number of $2^i\tau$, octave segments, that can be made in a t_k interval of data, such that $2^m\tau$ is accepted within the $\chi^2_{n,p}$ equivalent degrees of freedom, n, for a chosen confidence interval, p. We can then use this composite statistic to check dynamic intervals, t_k, for clock data where the relation $\frac{\mathrm{H}}{\mathrm{A}}$ exceeds a value, hypothetically indicating the incidence of a pronounced level of μ_3.

The second observation made from (4) and (5) is that as the deterministic coefficients of linear frequency drift approach zero, the power law relationships of $\sigma_y(t_k,\tau) \rightarrow H\sigma_y(\tau)$. In this manner, we are not so concerned about determining the level of the diffusion noise coefficients, σ_1, σ_2, σ_3, but that the relation $\frac{\mathrm{H}}{\mathrm{A}}$ approaches one. We interpret this result in two scenarios.

For a quartz-based USO, it is typically expected that c3 (or μ2) should always exist, but gradually diminish in a monotonic sense, as shown in Fig. 1, with some small value (slow function) of μ_3. So, in the very long term, the Allan deviation should approach the Hadamard and each of these identify the power law noises to a similar extent, although the Allan variance is twice as strong at identifying random walk FM, σ_2, than the Hadamard. For this scenario, the relation $\frac{\mathrm{H}}{\mathrm{A}}$ would start at a value less than one and evolve toward one. We consider this the nominal case.

The second scenario would be a slope reversal in the apparent drift of the USO. This sometimes is called "hockey-stick" aging where the drift starts in one sense (positive or negative) over an initial period in the order of a few weeks and then turns to the opposite sense over the longer term operation, usually in a yearly time frame. The cause for "hockey-stick" can be for various reasons, but it always means that two (or more) processes are competing in the composition of the USOs drift characteristic. These competing mechanisms may not be both intrinsic to the quartz resonator. For example slow temperature stabilization could overwhelm the apparent aging in the short term and then, once the system becomes quiescent, the resonator aging becomes dominant. It has been asserted that accumulated dose effects of ionizing radiation can be observed in space-based USOs as a competing process [6].

For our disciplining system, determining a possible "hockey-stick" drift evolution is highly desired as misidentifying this scenario as the nominal case would degrade the accuracy and the extent of autonomy of our USO timekeeping system. Our described work, then, concentrates on examining the dynamic behavior of the relation $\frac{\mathrm{H}}{\mathrm{A}}$ over data collection intervals, t_k to t_{k+1}. We venture from the basis of dynamic variance provided from [5] to formulate a maximum likelihood function (MLE) that we use to weight our periodic estimation of the deterministic coefficients, μ_1, μ_2, μ_3, and differentiate drift reversals and other short term frequency anomalies from the expected nominal case demonstrated in Fig.1.

III. A Maximum Likelihood Estimation Function (MLE) for Weighted Drift Estimation

Significant and elegant work has been accomplished, as in [7, 8 and 9] toward the use of multiple variances (multi-variance), Bayesian inference and the moment condition to separate, identify and determine the diffusion coefficients from a mixture of power law noises and deterministic drift in the spectral density of frequency sources such as USOs. We

adopted the notions of this work, in a less sophisticated approach, to construct a likelihood function using the relation $\frac{H}{A}$, along with our a priori knowledge about the evolution of $\frac{H}{A}$ from the two USO drift scenarios expressed in the previous section.

We consider our approach multi-variance in that $H\sigma^2_y(\tau)$ is shown in (5) to estimate the power law diffusion coefficients at different sensitivities than the $\sigma^2_y(\tau)$ in (4). In particular, the $H\sigma^2_y(\tau)$ assesses σ_1 for white FM the same as $\sigma^2_y(\tau)$; the $H\sigma^2_y(\tau)$ is half as sensitive for σ_2 random walk FM and about 1/3 as sensitive to σ_3 random run FM. In a strict multi-variance approach these definite relationships could be used to minimize uncertainty in power law identification and improve the accuracy of diffusion coefficient estimates. We did not perform this strict technique, rather simply opting for the unique identification of the $H\sigma^2_y(\tau)$ to the change of linear drift, μ_3, as a power of τ^4 and the knowledge that the classic, non-dynamic $\sigma^2_y(\tau)$ is not capable of resolving power law noises greater the random walk FM. As will be explained later in our implementation sections, we did use the aspect that the $H\sigma^2_y(\tau)$ and the $\sigma^2_y(\tau)$ react equally to white FM as a trap for phase pops and frequency jumps.

We consider our approach Bayesian, in that we estimate the extent of an unknown quantity, the change of linear drift μ_3, from measurements identifying μ_3 and the power law noises as found in the relation $\frac{H}{A}$. Further from the work of [5], we can express likelihood on the relation $\frac{H}{A}$ by setting μ_3 and certain power law noises to fixed values with an expectation of how μ_3 should evolve given our two a priori drift scenarios, the nominal case and the "hockey-stick" case. We did not perform the mathematics to derive the probability densities $p(\mu_3 \mid \frac{H}{A})$, $p(\frac{H}{A} \mid \mu_3)$ and the a prior probability density $\pi(\mu_3)$. However, we believe certain unique noise properties of the USO can nonetheless enable us to express the information provided by the relation $\frac{H}{A}$ into a Bayesian theory formulation.

Specifically, high quality USOs such as in New Horizons show a sharp contrast in the transition from flicker FM (F FM) with $\ln\tau^0$ dependency to linear drift with τ dependency in the Allan deviation. As the drift improves the extent of the flicker FM floor appears to increase with small evidence of random walk FM with $\tau^{1/2}$ dependency. This characteristic in USO noise offers the ability of the Allan deviation as segmented in (6) to highly distinguish USO drift from noise. This USO noise characteristic offers the additional advantage that we can place a high pass cut-off, through our selection of the base collection interval τ_0, to be aligned within the latter part of the flicker FM floor, nominally just high enough in frequency that the relation $\frac{H}{A}$ starts before the expected USO drift and nominally only considers noise with power law dependencies of $\tau^{\geq 0}$. We therefore will treat white FM as an anomaly in the expected result.

Finally we consider the $H\sigma^2_y(\tau)$ a sufficient variance as defined by the moment condition because its insensitivity to linear drift, $\mu 2$, provides for convergence for all power law noises up to random run FM. Also, since our timekeeping system is expected to act on daily or shorter updating periods, this places a low frequency limit that should cut-off the effects of higher order noises greater the random run FM.

We set four expected values, a minimum and a maximum for both the A and H defined in (6), to develop our Bayesian approach into a function that can operate as a maximum likelihood estimator (MLE) for the discrimination of the linear change of drift, μ_3. We construct the MLE with a bipolar selection effect for shifting the nominal case to the negative side of the function and the "hockey-stick" or high likelihood of μ_3 toward the positive. In this manner, we consider the positive indication in the hypothesis that μ_3 exists as anomalous to the expected nominal case and any use of the clock data collected in that update period should be deemphasized in the revision of the deterministic coefficients of the clock model. The four expected values are considered test limits, given as follows;

$$\mathsf{A}; \mathrm{E}_{\max}\left[\sum_{i=0}^{m}\frac{\sigma_y(2^{i+1}\tau, \mathrm{t}_k)}{\sigma_y(2^i\tau, \mathrm{t}_k)}\right] \Rightarrow 2m, \text{ drift} >> \text{noise} \quad (7)$$

$$\mathsf{B}; \mathrm{E}_{\min}\left[\sum_{i=0}^{m}\frac{\sigma_y(2^{i+1}\tau, \mathrm{t}_k)}{\sigma_y(2^i\tau, \mathrm{t}_k)}\right] \leq \sqrt{2}m, \text{ drift} < \text{noise} \quad (8)$$

$$\mathsf{C}; \mathrm{E}_{\max}\left[\sum_{i=0}^{m}\frac{\mathrm{H}\sigma_y(2^{i+1}\tau, \mathrm{t}_k)}{\mathrm{H}\sigma_y(2^i\tau, \mathrm{t}_k)}\right] \Rightarrow 4m, \mu_3 \text{ dominant} \quad (9)$$

$$\mathsf{D}; \mathrm{E}_{\min}\left[\sum_{i=0}^{m}\frac{\mathrm{H}\sigma_y(2^{i+1}\tau, \mathrm{t}_k)}{\mathrm{H}\sigma_y(2^i\tau, \mathrm{t}_k)}\right] \leq \sqrt{2}m, \sigma_2 \text{ or less} \quad (10)$$

Test limits A and B, (7) and (8), are the maximum and minimum expected values for the Allan deviation function A in (6). In test limit A, the expected value represents the result of the summed, octave-sectioned power law slopes where drift dominates over any other power law noises. Test limit B is the expected value of A in (6) where drift has diminished beyond $2^m\tau$ and only a random walk noise may

be evident. Again *m* is the maximum number of segments that can be statistically formed with a given confidence level in the update period, t_k. Test limits C and D, (9) and (10), are the maximum and minimum expected values for the Hadamard deviation function H in (6). Test limit C is the expected value when the change of linear drift, μ_3, dominates over any other power law slopes. Test limit D is similar to test limit B, but since H in (6) is insensitive to drift, D is also the likely expected result.

We use the test result limits set by A, B and C, D to construct a four zoned hypothesis based on the a prior knowledge about the two drift scenarios for USOs. Fig. 3 depicts this conception of our four hypothesis zones and the dynamic evolution of the USO drift scenarios. In Fig. 3, the four hypothesis zones are laid out in a quasi-coordinate manner with the dynamic evolution of the USO drift, as measured by the Allan deviation, shown in the vertical axis and unexpected changes in power law noise or the strong incidence of change of linear drift, μ_3 in the horizontal axis. The visualization of the dynamics of the USO drift and noise process is a vector moving from the nominal expected zone A, D (aging drift and low mostly- stationary noise processes) toward one of the other hypothesis zones. From our nominal case a priori scenario, such as shown in Fig. 1, we expect this vector to travel mostly vertical toward B.

The discrimination of the MLE function is then constructed to determine short term shifts of the visualized USO drift and noise process vector of Fig. 3 toward the horizontal axis. Such shifts are considered short-term anomalies and the significance of the clock data in the most recent t_k interval should be reduced in revising the clock model.

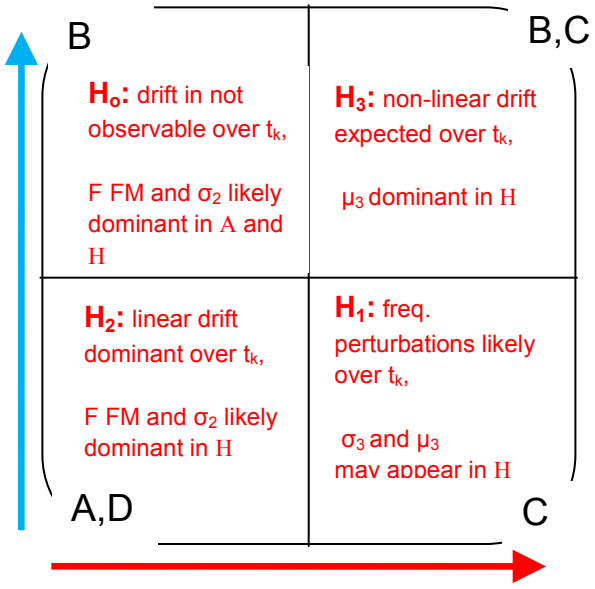

Figure 3. Four zones of MLE hypothesis based on USO drift evolution scenarios. Vertical blue arrow indicates nominal case evolution. Horizontal red arrow indicates "hockey-stick" case.

The test limits A, B and C, D, (7-10), and the four hypothesis zones H_0, H_1, H_2 and H_3 are assembled in the typical method of expressing an MLE function as the natural log of the test measurement ratios, in our case $\ln(\frac{H}{A})$ to provide a monotonic expression with the following formulations;

$$H_0 : \ln D - \ln B = 0, \quad \text{F FM or } \sigma_2 \text{ , drift not observable} \tag{11}$$

$$H_1 : \ln C - \ln A = \ln 2, \quad \sigma_3 \text{ or } \mu_3 \text{ , freq. perturbations likely} \tag{12}$$

$$H_2 : \ln D - \ln A = \ln \frac{1}{\sqrt{2}}, \text{ F FM or } \sigma_2 \text{ , linear drift dominates} \tag{13}$$

$$H_3 : \ln C - \ln B = \ln 2, \quad \mu_3 \text{ dominant , non - linear drift expected} \tag{14}$$

Fig. 4 graphically shows the MLE function $\ln(\frac{H}{A})$ as the relation $\frac{H}{A}$ changes from μ_2 drift dominated Allan deviation with low noise, as found by A of (6), moves to higher order μ_3 dominated linear change of drift as found by H in (6). Along the bipolar, monotonically increasing MLE function, the hypothesis zones are placed by the expected test limits (7-10) and their associated hypothesis definitions (11-14). Along the vertical secondary axis of Fig. 4 is placed the value of parameter W, which represents the assigned weighting to be applied to the update of the clock model coefficients, μ_1, μ_2, μ_3 using the function;

$$\mu_x(t_{k+1}) = \frac{W\mu_x(t_k) + \mu_x(t_{k+1})}{W+1} \tag{15}$$

The value of W in (15) gives the highest significance to the most recent clock data, t_{k+1}, when the MLE is less than $\ln\frac{1}{\sqrt{2}}$ or identified as likely in H_2, our nominal USO case.

The weighting function proceeds to de-emphasize the significance of the clock data in t_{k+1}as the MLE function moves positive. We assign a mid-grade weighting to W as the function transitions through zero, since the MLE function can have an ambiguity in the resolution of our two a priori scenarios in this region. In the nominal case, the drift slowly diminishes over a long time and it is expected that the MLE approach zero; as stated earlier, the power law noise of the Allan deviation should approach the Hadamard. However, in the "hockey-stick" scenario or with the introduction of a new competing drift process with a reversal in sign, the MLE function will also temporarily approach zero, but likely in the short term. We therefore diminish the possible outcome of the ambiguity by introducing a precautionary mid-grade significance. Above an MLE function value of zero, we give the data for t_{k+1} the least significance. Clearly with this approach, the number of weighting levels for W and the delimiter values associated to the MLE could be tailored.

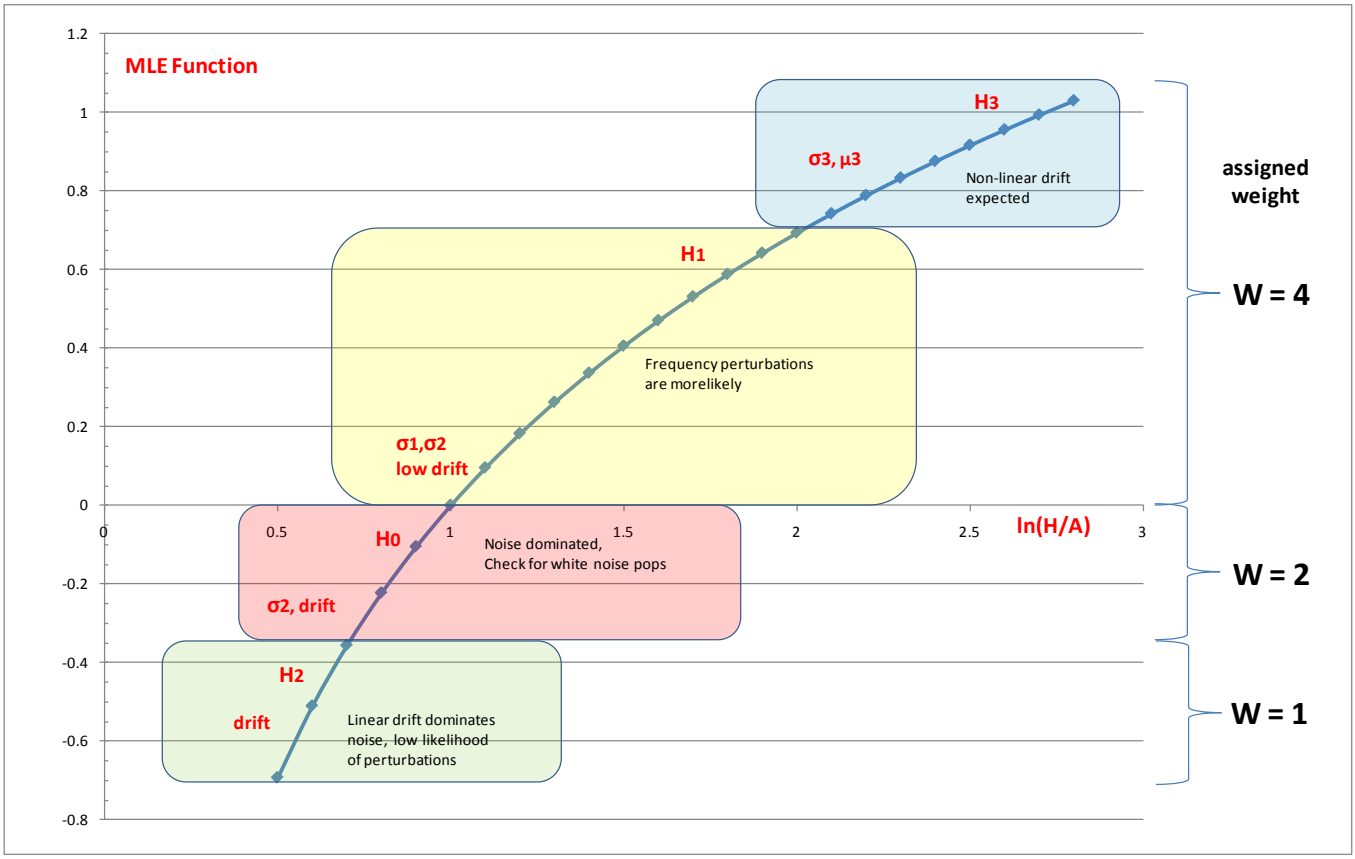

Figure 4. Graph of MLE function with hypothesis zones and weighting values for W on the secondary vertical axis

However, we chose to operate in this simple manner to examine how the process might work on real USO clock data, as will be discussed in the remaining sections.

But before we finish our paper with operational results, there is a special case we must consider in the MLE function associated with the incidence of white FM from phase pops or frequency jumps. We discussed earlier in this section that the base collection interval τ_0 was chosen to provide a high pass cut-off to filter the USO clock data so that the MLE function mostly operates on power law noises of $\tau^{\geq 0}$. Nonetheless in all real clock data, including the research USO data to be presented, there are instances of discontinuous phase and frequency that will issue large white FM noise into the collected data for that interval. Our MLE function is vulnerable to this condition since the Allan and Hadamard deviation are equally sensitive to white FM, σ1 in (4) and (5). Phase pops or frequency jumps that impart a white FM dominance into the data could wrongly place the MLE function into H_0 or H_2 and result in assigning the data more significance than desired.

We design a trap for this condition by using a dynamic analysis test, which compares the function A in (6) for the most recent collected data interval, t_{k+1} against a cumulative moving average of this function from previous intervals. A similar technique is used for H in (6). The expressions for this process are shown as follows;

$$\text{With } A(\tau, t_{k+1}, m) = \sum_{i=0}^{m} \frac{\sigma_y(2^{i+1}\tau, t_{k+1})}{\sigma_y(2^i\tau, t_{k+1})} \text{ and}$$

$$H(\tau, t_{k+1}, m) = \sum_{i=0}^{m} \frac{H\sigma_y(2^{i+1}\tau, t_{k+1})}{H\sigma_y(2^i\tau, t_{k+1})}$$

$$E\left[A(\tau, t_{k+1}, m) - \sum_{1}^{k} \frac{A(\tau, t_k, m)}{k}\right] = \pm\left|2-\sqrt{2}\right| \quad (16)$$

$$E\left[H(\tau, t_{k+1}, m) - \sum_{1}^{k} \frac{H(\tau, t_k, m)}{k}\right] = \pm\left|\sqrt{2}-1\right| \quad (17)$$

In (16) and (17) expected limits are set for the dynamic analysis tests. The limits are based empirically on our nominal dynamic drift scenario; the power law change from t_{k+1} to t_k is low compared to our update period. In (16), we expect the summed power law will change no more than one octave slope segment from drift to random walk FM. Likewise, in (17) the change is no more than one octave segment from random walk to flicker FM. In application to our research data, we only used the negative side of the test limits, such that when a result of (16) and (17) coincidentally fall outside the negative limits, we trap t_{k+1} as a white FM event and set W equal to 4. The A and H results for t_{k+1} are also not brought into the cumulative moving average of these functions.

IV. USO Frequency Data used in Research and Dynamic Analysis Results

We applied our theory of operation of the MLE function into an algorithm that would process periodically collected clock data. We set the processing period with a dynamic window variable called t_k, where t_k is set by an integer multiplication of the base τ_0 of the data measurement. For our research into the algorithm's effectiveness, we operated on 72 days of archived USO data. The USO data are phase measurements of a USO compared to a hydrogen maser with the USO maintained at 30 C in a space simulation environment with vacuum levels below 50 µtorr. The USO was powered on several days prior to the start of the data collection with vacuum pump down also occurring in this period. The phase collection measurement interval, τ_0, was 600 s.

Fig. 5 shows the relative frequency of the USO, in red, over the 72 day collection period with a fitted diffusion equation, $a+b(\tau_0 + c)^{½}$ shown in green. Fig. 6 shows the residual of the USO data with the fitted diffusion equation subtracted to more closely examine the dynamic behavior of the USO. The inspection of Figs. 5 and 6 reveals several aspects of the data that make it useful for our purpose of assessing the MLE based algorithm's performance in determining the μ_1, μ_2, μ_3 updates to our dynamic clock model for the purpose of disciplining the USO.

In Figs. 5 and 6, the USO data appears to contain the "hockey-stick" scenario of competing drift mechanisms. Additionally, the USO data contains various phase pops and short-term frequency perturbations that are traceable to anomalies in the vacuum and temperature control systems of the space simulation chamber, as sometimes occurs in long-term operation. The USO data also contains gaps in the data caused by discontinuity in the service provided by the maser signal. These gaps were subsequently filled into the data by least squares quadratic fits. The combined occurrence of all

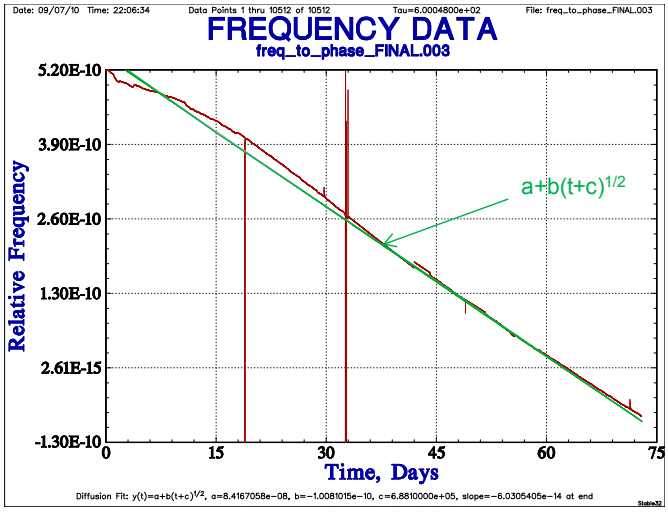

Figure 5. USO frequency data with diffusion equation

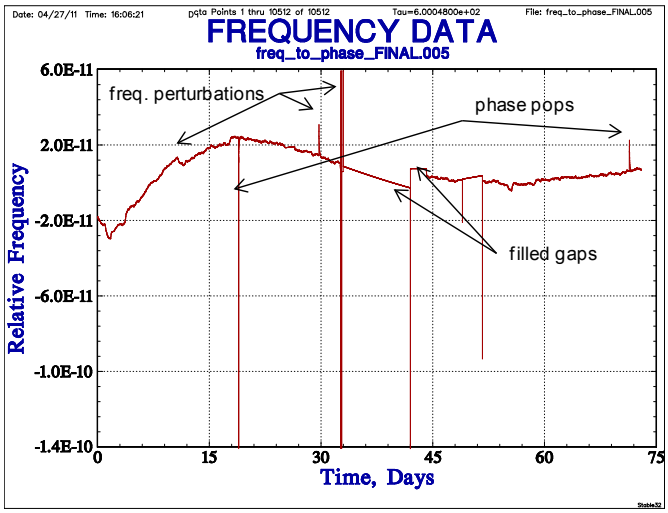

Figure 6. Residual frequency difference of USO data from diffusion equation

these data artifacts provides a challenging model for our disciplined USO algorithm research in contrast to the nominal scenario data such as shown in Fig. 1 from USO A of the New Horizons spacecraft.

We estimate the dynamic Allan and Hadamard variances for the USO data using one day windows, or t_k equal to $144(\tau_0)$. Fig. 7 shows the dynamic Allan deviation in a three dimensional presentation with τ and t_k (slices) shown on the floor projection and the frequency stability axis normal to this time plane. As discussed, we estimate the variance in τ by increasing octave sections from τ_0 to $2^5\tau_0$. Fig. 7 also shows a two dimensional inset with just the stability and t_k (slices) axis. The dynamic Allan deviation of the USO data shows a mostly constant drift with the stability proportional to τ. We observe the aspect of the "hockey-stick" process in the first fifteen t_k slices, noting the power law relationship dipping to lower order noise processes. We also see the effects of certain frequency anomalies coordinate with the indications shown in Fig. 6. These appear to have a mostly whitening effect as expected. The filled data gaps have an artificial appearance as the numerical noise from the calculated fits is not significant.

Fig. 8 shows similar results for the Hadamard deviation. In these presentations, we observe a mostly random walk FM. We also notice the effects of certain frequency anomalies similar to the Allan deviation of Fig. 7, although certain anomalies, such as t_k slices 29, 56 and 72 show indication of higher order noises expected with evidence of the linear change of drift, µ3. Figs. 9 and 10 show the density of the two point power law slopes for the Allan and Hadamard deviations, for each octave sections from τ_0 to $2^5\tau_0$. With careful inspection, the effect of the "hockey-stick" process in the first fifteen tk slices is apparent along with evidence of the frequency anomalies. These analysis results provide confidence that our MLE function should produce the effective discrimination desired.

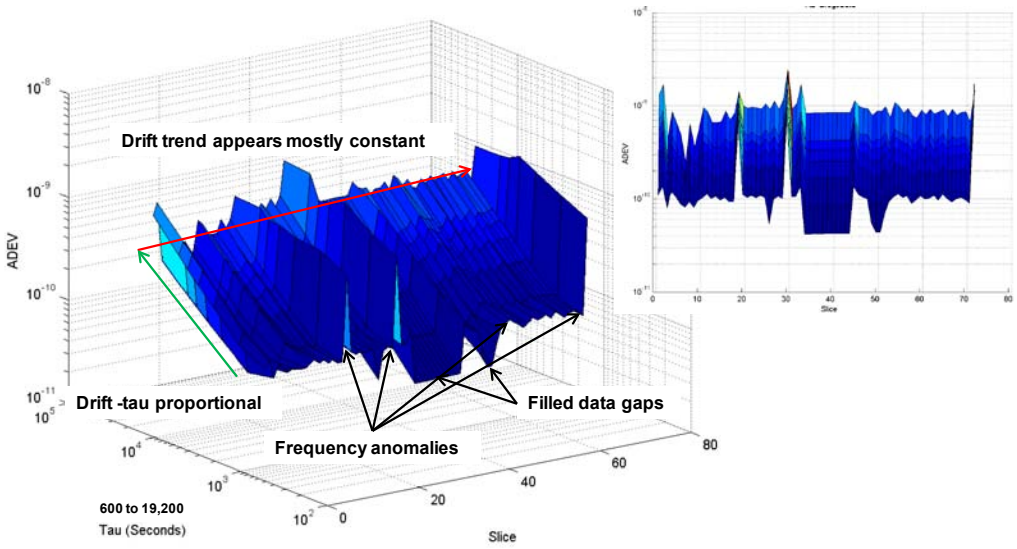

Figure 7. Dynamic Allan deviation: one day windows, $t_k = 144(\tau_0)$

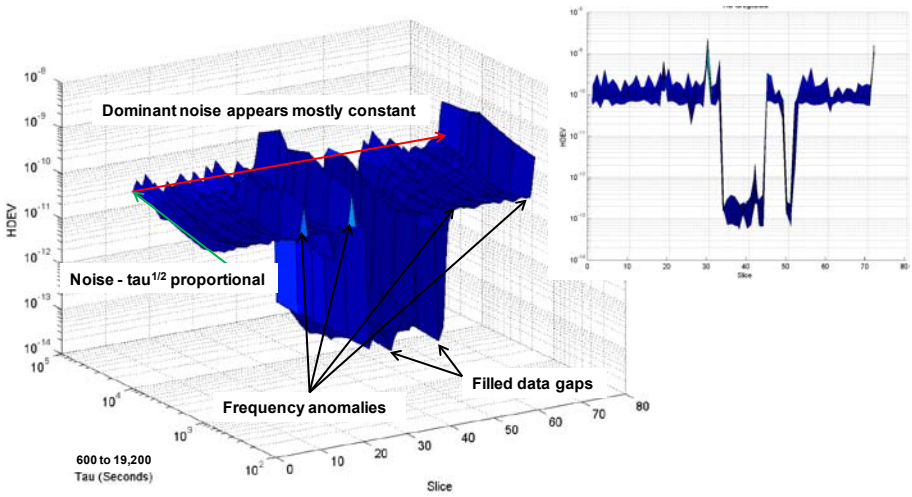

Figure 8. Dynamic Hadamard deviation: one day windows, $t_k = 144(\tau_0)$

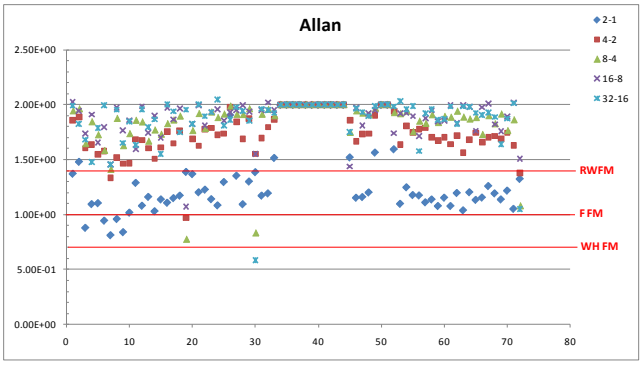

Figure 9. Density of octave power slopes for Allan deviation

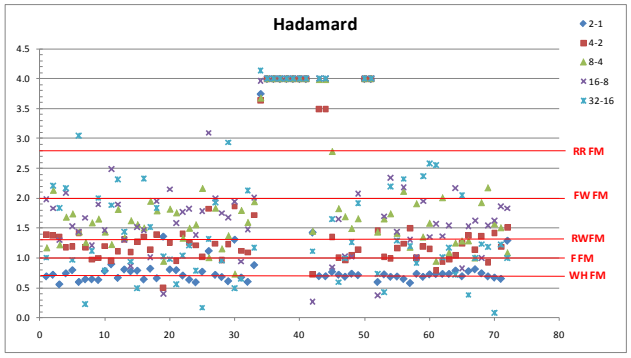

Figure 10. Density of octave power slopes for Hadamard deviation

We conclude by showing the performance of our MLE based algorithm operating on the USO data. Figs. 11 and 12 are similar in presentation as Figs. 5 and 6. However, in the case of Figs. 11 and 12, the green line represents the propagated clock model based on the MLE algorithm's calculation of the frequency offset, drift and a linear change of drift coefficients (μ_1, μ_2, μ_3 respectively). Fig. 12 shows the residual apparent corrected frequency with the propagated simulated frequency subtracted from the USO data. Finally, Fig. 13 shows the estimated timekeeping by converting the residual data from Fig. 12 to phase. The simulation indicates an effective timekeeping of the disciplined USO of about 1μs, including the effects of short-term frequency perturbations, phase pops and data gaps representative of the absence of a master reference clock. With the inclusion of a periodic phase adjustment, which would be available in our implemented system, the possible performance could maintain an MTIE of less than 1 μs over this same 72 day operation period.

***Abstract*—Long term reliability of piezoelectric micro-electro mechanical systems (pMEMS™) resonators and oscillators has been characterized for high performance frequency reference applications. In particular, high-*Q* piezoelectric bulk acoustic wave (BAW) resonators exhibit aging (frequency drift) within measurement system accuracy (±2ppm) under two long-term measurement conditions: over 9 months at 25°C, and over 1400 hours at 125°C.**

I. INTRODUCTION

Quartz crystal resonator oscillators have been used for frequency reference applications due to their excellent performance, such as high *Q*s and stable frequencies for the past few decades. Over the past few years, however, many efforts have been underway to replace quartz with other technologies with [1][2][3] or without MEMS resonators [4]. These disruptive technologies enable reductions of package sizes and cost, and in some cases enable significant improvement in performance and reliability. Among commercialized oscillator products based on MEMS resonators, electrostatically transduced vibrating resonator oscillators have been the first to be introduced into the timing markets. Compared to quartz counterparts, however, their performance needs to be improved especially for high-end frequency reference applications.

As a member of MEMS resonator family, pMEMS™ resonator has emerged as one of the strong candidates for replacing quartz technology for high-end timing and frequency reference products [1][5][6]. These pMEMS™ resonator oscillators have demonstrated short term frequency stability and phase noise on par with quartz crystal oscillators. However, for successful adoption in timing and frequency reference markets these pMEMS™ resonators and oscillators need to pass stringent qualification tests such as the ones specified by JEDEC standards [7] among others [8][9]. Robustness of these low phase noise oscillators has been demonstrated by subjecting these plastic packaged devices to a large range of reliability tests [7]. Focus for this paper is on aging, i.e., frequency drift over time.

Oscillator frequency drift over time is mostly a function of the resonator, i.e., quartz resonators or in this case pMEMS™ resonators. This paper presents the aging (frequency drift) test results of the pMEMS™ resonators and oscillators at both normal (25°C) and accelerated temperature conditions (125°C).

Figure 1. Teardown of a pMEMS™ oscillator sample in a plastic package

II. PMEMS™ RESONATOR

As the name implies, the pMEMS™ resonator is composed of a piezoelectric material with single crystal silicon, taking advantage of both worlds, i.e., combining advantages of piezoelectric quartz resonators with advantages of MEMS resonators. Specifically, pMEMS™ utilizes a piezoelectric material for its high coupling between electrical and mechanical interaction, and a single crystal silicon for the high quality factor as the main vibration body that dominates the frequency selective performance [1][6]. Figure 2 presents the schematic of a pMEMS™ resonator with a piezoelectric layer and a single crystal silicon layer. By electrically exciting bottom and top electrode layers using ac-electric signals, the piezoelectric material vibrates mechanically at the designed frequency transferring the acoustic wave energy to single crystal silicon layer. Making use of its excellent frequency selectivity, the single crystal silicon layer in turn bounces most of the acoustic energy back to the piezoelectric layer where

978-1-61284-110-6/11/$26.00 ©2011 IEEE

the acoustic energy changes into electric signals sensed at the top electrode. Due to the nature of silicon as the main element of the vibrating structure, this pMEMS™ resonator provides sufficient quality factors (Q's > 10,000)[1]. With the proper selection of the piezoelectric material as the transformer of the two energy domains, it eliminates the need for external DC biases required in capacitively transduced MEMS resonators [10][11], and enhances high energy transmission ratio enough to implement practical high frequency timing and frequency reference products.

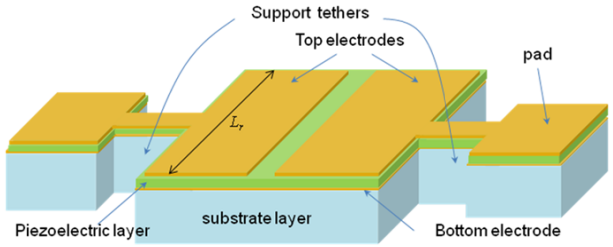

Figure 2. Perspective schematic view of a pMEMS™ resonator

For the aging reliability tests in this paper, very high frequency (>100 MHz) pMEMS™ resonators were selected. All the selected pMEMS™ resonators vibrate extensionally in lateral direction at the following frequency,

$$f_0 = \frac{1}{2 \cdot L_r}\sqrt{\frac{E_{eff}}{\rho_{eff}}} \qquad (1)$$

where L_r is the lateral length, E_{eff} the effective Young's modulus, and ρ_{eff} the effective density of the composite pMEMS™ resonator. Once the materials of pMEMS™ are set, the only parameter that determines the frequency is the lateral dimension of pMEMS™ resonator, meaning that the resonator frequency is easily designed by a single device layout and implemented with etchings of the composite material layers.

III. Setup for Reliability Tests

In order to accommodate multiple pMEMS™ resonators in a single aging setup, multiplexers, 3499A and 34980A from Agilent, are employed to switch both RF signals and low frequency temperature sensors, respectively. Each multiplexer for RF signals requires five quad dual switch modules (N2268A from Agilent), four of which were used for first stage of switching and the last one for multiplexing the first stage four switch modules. Each switch module has 50Ω characteristic impedance with SMA connections. The multiplexer for accurate temperature measurements required one low frequency switch module (34921A from Agilent), and it not only switches the RTD (Resistance Temperature Detector) sensors but also converts the RTD resistance reading to temperature data. Therefore, each set of multiplexers can take up to 16 units in parallel, and the implemented aging setup consisted of two sets of multiplexers and network analyzers. The overall measurement system shown in Figure 3 is controlled by an automatic program through GPIB interface to take measurements and extract data, such as resonance frequency, quality factor, insertion loss, etc., from each pMEMS™ resonator. Due to the high sensitivity of resonance frequency on temperature it is very important for the pMEMS™ resonators to be accurately measured with respect to surrounding temperature. Therefore, in this aging test setup, temperature data are measured from platinum RTD sensor readings at the time of frequency measurements and then later used to extract aging data.

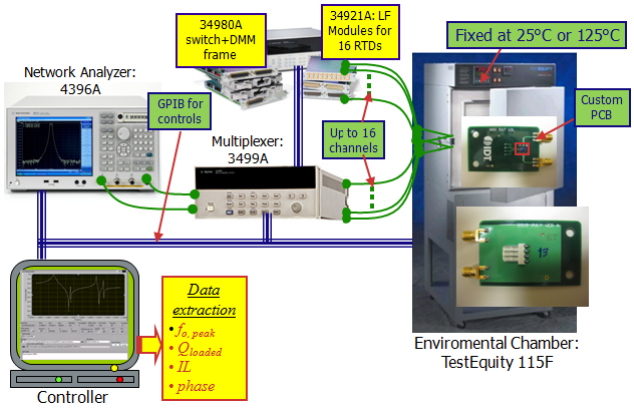

Figure 3. Schematic of Aging Test Setup

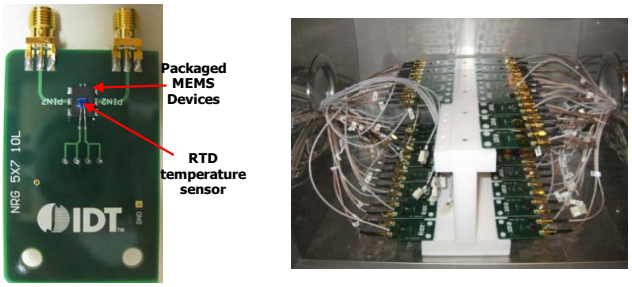
Figure 4 (a) shows a customized PCB board where a packaged pMEMS™ resonator / oscillator and a platinum RTD are soldered. Note that an RTD platinum sensor is epoxy-glued on top of the plastic package to measure the temperature at the time of a single frequency sweep as accurately as possible. Total of 32 boards were mounted to a Teflon rack and put into a temperature chamber shown in Figure 4 (b).



(a) Test board (b) Test boards on a rack

Figure 4. PCB test boards mounted on a rack inside temperature chamber

All the materials used in this setup can withstand high temperature of 125°C to cover acceleration tests. The reliability test systems have been set up at IDT's long term MEMS test lab shown in Figure 5.

Figure 5. MEMS lab for the long term aging tests of pMEMS™ resonators and oscillators at Integrated Device Technology, Inc.

IV. Results and Discussions

A. Aging of pMEMS™ resonators at 25°C

In the aging setup, ten pMEMS™ resonators were measured in the temperature chamber set to 25°C for approximately nine months, while their frequency data was recorded automatically with open-loop configurations. To extract the aging performance of the pMEMS™ resonators, the frequency fluctuations with respect to temperature variations within the temperature chamber were corrected using linear least square regression.

Figure 6 below presents the plot for extracted aging data for ten pMEMS™ resonators vibrating at high frequency. All of the ten pMEMS™ resonators regardless of the device locations have frequency variations less than ±2ppm for nine months.

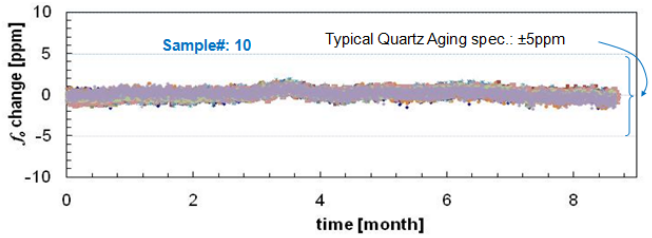


Figure 6. Aging measurements of 10 pMEMS™ resonators / oscillators over nine months at 25°C (Measurement accuracy ±2ppm).

Of the ±2ppm frequency changes, ±1ppm is attributed to the accuracy of the network analyzer. We observed the frequency changes with discontinuous quantum leaps, which correspond to the frequency resolution of the network analyzer at a given sweep span with a fixed number of data points. It is worth noting that the compensated frequencies are somewhat correlated with temperature fluctuations, suggesting that the rest of ±1ppm of the total ±2ppm frequency variation likely stems from two factors as follows.

1. Temperature gradient between the pMEMS™ resonator and an RTD sensor location: RTD temperature sensor measures the temperature on top of the plastic package not at the actual pMEMS™ resonator inside of the package.
2. Inaccurate timing of the temperature sensing: Temperature reading is based on the average by the integration of digital multi-meter 34980A, which means that the reading does not represent the temperature exactly at the time of resonance frequency detection. To make it worse, as the temperature easily changes ±0.02°C in a short period of time, there is an uncertainty in the measured temperature.

B. Acceleration tests for pMEMS™ resonators at 125°C

In order to accelerate the aging tests, ten packaged pMEMS™ resonators were placed for more than 1400 hours inside the temperature chamber set to 125°C which is the temperature required for accelerated burn-in tests in the JEDEC standards [7]. Figure 7 presents the extracted aging data showing less than ±2ppm frequency variation at 125°C. This suggests that the pMEMS™ resonators are very robust and can withstand high temperatures over long periods of time that exceeds any commercial application requirements.

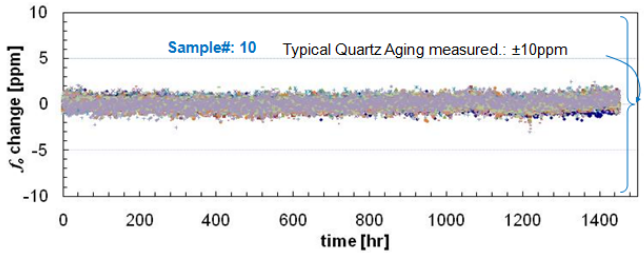

Figure 7. Accelerated aging measurements of 10 pMEMS™ resonators / oscillators over 1400 Hours at 125°C (Measurement accuracy ±2ppm).

For comparison, a typical AT-cut quartz crystal resonator was measured along with pMEMS™ resonators at 125°C. Since it was not easy to find quartz crystal resonators that were commercially available and rated for 125°C operation, a quartz resonator specified at 85°C was selected. The quartz measurements exhibit frequency drifts of ±10ppm with a negative slope over 1400 hours compared to ± 2ppm measured for pMEMS™ devices. These ±10ppm quartz oscillator measurements are comparable to burn-in test data published by multiple commercial crystal oscillator vendors.

V. Conclusions

Robustness of low phase noise pMEMS™ resonators and oscillators has been demonstrated by subjecting these plastic packaged devices to long term aging (frequency drift) tests. pMEMS™ devices exhibit aging (frequency drift) comparable to quartz at 25°C and significantly better at 125°C (accelerated tests). Long term reliability tests presented in this paper suggest that the pMEMS™ resonator oscillators are as robust as quartz resonator oscillators in the long-term at nominal temperatures (25°C) and much better over a wide temperature range.

Abstract—**Demands for high-speed multimedia data communications increasing telescopically, pushing wireless transmission data rate with 2Gbps or higher. In these high-speed data communication systems, the bit error rate (BER) characteristic is dependent on a phase noise performance of the VCO. To meet the above challenges, it is necessary for these systems to have high performance VCO with low phase noise, low cost, wide tuning range, and high DC-to-RF conversion efficiency. The tiny VCO developed using SWR (Slow Wave Resonator) and mode-coupling techniques support high DC-to-RF conversion efficiency and low phase noise in compact size and also easily amenable for integration in the IC (integrated circuit) form. The typical measured phase noise @ 10 kHz offset from the 12 GHz carrier is -110 dBc/ Hz with 5V, 30 mA DC bias using slow wave dynamics in multi-mode regimes.**

I. INTRODUCTION

Tunable oscillators are instrumental in the operation of many systems, from commercial communications to military radars. And, while many characteristics define the performance of a tunable RF/microwave oscillator, one of the more difficult parameters to optimize is phase noise, which is critical to the performance of so many systems. Communication systems rely on low-phase-noise signal sources such as tunable oscillators or phase-lock-loop (PLL) synthesizers for reliable voice communications and to ensure transmitted data integrity. Constraints on cost, size, power-efficiency, performances are particularly demanding. As data requirements increase beyond 2 Gb/s, the phase noise of one possible tunable source solution, the voltage-controlled oscillator (VCO), becomes critical for achieving acceptable bit-error-rate (BER) performance [1]-[22].

VCOs are versatile, tunable sources, their resonators can be formed in a variety of ways, including by printing coupled resonators. VCOs reported in this paper using printed coupled slow wave resonator (SWR) measure just 0.3 x 0.3 in. but can match the phase-noise performance of more expensive oscillators with high-quality-factor (high-Q) resonators. The SWR network approach also lends itself to semiconductor fabrication processes, to produce high-performance VCOs in integrated-circuit (IC) form. The tiny SWR VCOs reported in this paper are ideal sources for miniaturized PLL frequency synthesizers and provide outstanding bandwidth versus phase noise performances stability by locking in frequency to a reference source as part of a PLL frequency synthesizer. In addition to this, these novel VCO solutions are inherently immune to shock and vibration due to printed coupled resonators. It is to note that SWR design parameters (coupling coefficient, multi-mode sensitivity, and Q factor) can be obtained using full wave EM simulation. It has been found that degenerate modes play important role in improving the Q-factor, therefore, rigorous mathematical treatment is necessary for the minimization of the spurious and jitters in pass-band. The theoretical treatment and experimental validation of a new class of slow wave resonator suggests the possibility of cost-effective alternative of Dielectric and YIG resonator based signal sources [1]-[9] .

II. THEORY

As the frequency band for the wireless communication shifts higher, generation of the power efficient ultra low noise wideband and thermal stable compact signal sources with low cost become more and more challenging due to the frequency limitations of the active devices. The technique of harmonic generation has been proven to be a cost-effective solution to extend tuning range of the oscillator circuits [2]-[5]. These techniques are based on the nonlinearity of the transconductance of the active device under large signal drive conditions but it introduces distortions and has poor phase noise performances [6]-[7].

YIG oscillators are well known for broadband configurable signal source but at the cost of size, power and integrability in IC form [8]-[11]. In view of the limitations of known YIG resonators for integrability and power-effective operation, the present work describes a novel and innovative topology as slow wave resonator (SWR) VCO, which supports wideband tunability in compact size and easily amenable for integration in the integrated chip form. SWR VCO is planar structure and broadband in nature, and is well suited for MMIC fabrication with affordable price. With the potential to enable wide operational bandwidths, eliminate discrete resonators (YIG sphere), and produce high Q planar resonators for ultra low noise VCOs in the context of a planar fabrication process compatible with existing IC and MMIC processes, SWR VCO is widely believed to be promising technology to meet the present and future requirements [22].

To solve the frequency-agility issue, radio manufactures that serve the point-to-point and point-to-multi-point markets would prefer to use SWR VCO that could emulate

978-1-61284-110-6/11/$26.00 ©2011 IEEE

configurability, wideband tunability and low phase noise, yet eliminate the crude YIG based signal source; and deliver higher transmission speeds, cost and power-effective solutions for present and later generation of the communication systems [2].

A. Multi-Coupled Slow-Wave Resonator

A printed coupled resonator network realized by slow wave dynamics is attractive due to compact size and provides a wide spurious-free band. In addition to this, the physical layout of slow wave resonators enables the implementation of optimum EM couplings [10]. As a result, resonators are not only compact size due to slow wave effect but also exhibit high frequency selectivity, wider stop-band resulting from dispersion phenomena. In order to facilitate a broad yet precise description of the VCO topology and layout of the SWR structure is selected in such a way that it minimizes the effect caused by temperature and mechanical stresses, and supports uniform negative resistance over wide tuning range.

In slow-wave propagation, as its name implies, the electromagnetic wave is transmitted in the guided-wave media with a slower phase velocity, namely, shorter guided wavelength, at a specified operating frequency [8]. This is achieved by modifying electric and magnetic energy storage in the guided-wave media. Slow-wave resonators are attractive due to several reasons: the slow-wave effect makes them very compact and can support evanescent mode coupling for obtaining Q-multiplier effect at resonant condition, thus low phase noise signal source solutions. Additionally, the geometrical configuration of SWR resonators makes possible the implementation of compact layout and amenable for RFIC/MMIC realizations [9]-[10].

A slow wave structure is one of the concepts that can be used for reducing the size of the circuits, especially the length of the transmission lines. For the electrical circuits, the periodic shunt loading of the transmission lines can behave as a slow wave structure. This periodic shunt loading reduces the phase velocity, thereby increasing the effective electric length of the line. In conventional transmission lines, the phase velocity V_p is controlled only by the dielectric material and can be expressed as [14]

$$V_P = f \times \lambda = \frac{c_0}{\sqrt{\mu_r \varepsilon_{reff}}} \tag{1}$$

where c_0 is the velocity of light, μ_r is the effective relative permeability, and ε_{reff} is the effective relative permittivity.

From (1), by increasing the effective relative permittivity of dielectric material at a given operating frequency decelerate the propagation electromagnetic (EM) waves in a guided medium. The Slow Wave Effect can be realized by adding periodical shields that decelerate the propagation electromagnetic (EM) waves in a guided medium.

From (1), an equivalent inductance L_{eq}, equivalent capacitance C_{eq}, and propagation constant β can be described as

$$\beta = \omega\sqrt{L_{eq}C_{eq}} \Rightarrow V_P = \frac{1}{\sqrt{L_{eq}C_{eq}}} \tag{2}$$

From(2), both distributed inductance (L) and capacitance (C) along the transmission line in the guided medium can be increased for the realization of slow-wave effects owing to increase of the propagation constant β, consequently, the loss of the resonator can be reduced [8].

Fig. 1 shows the typical simplified topology of a single-coupled slow-wave resonator. This consists of a slow-wave resonator loaded at its near and far ends with series capacitors C_S. The resonator itself is made up of a transmission line of characteristic impedance Z_0 and electrical length 'θ', periodically loaded by shunt capacitors C_p. The electrical length θ of the unloaded transmission line is defined at frequency *f* as [10]

$$\theta = \beta d = \frac{2\pi f\sqrt{\varepsilon_{reff}}}{C} d \Rightarrow \quad \theta\big|_{f=f_0} = \theta_0 \tag{3}$$

where ε_{reff} is the effective relative permittivity , d is the physical length of the unloaded line, and C is the free space light velocity. At the center frequency f_0, the electrical length is θ_0. By using *ABCD* (cascade) matrices, the equivalent characteristic impedance Z_{eq} of a coupled slow-wave resonator can be easily extracted.

As shown in Fig. 1, the real estate of SWR layout is quite large, therefore not suitable for the application where size is the constraint. Fig. 2 shows the typical layout of the printed slow wave resonator, capacitively coupled between two arms of the resonator leads to the slow-wave effect. For unloaded transmission line there were no dispersion in the phase velocity, however, for the periodically loaded line the phase velocity is frequency dependant.

As illustrated in Fig. 3, the transmission line is periodically loaded with identical open stub elements for the realization of high Q-factor SWR structure. The input impedance Z_{in2} for a lossless line can be given by [9]

$$Z_{in2} = Z_0 \frac{Z_L + jZ_0\tan(\beta l)}{Z_0 + jZ_L\tan(\beta l)}, \quad where \quad Z_0 = \sqrt{\frac{L}{C}} \tag{4}$$

$$Z_{in2}\big|_{\tan(\beta l)\to 0} = \frac{Z_0 Z_L}{Z_0} \Rightarrow Z_{in2} \propto Z_L \tag{5}$$

where L and C are the inductance and capacitance per unit length of the line, Z_0 and β are the characteristic impedance and phase constant of the open stub, respectively.

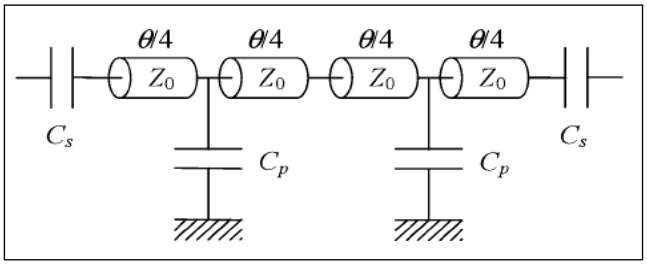

Fig. 1. A typical topology of a single-coupled slow-wave resonator loaded at the near and far ends with series capacitors C_s [10]

From (5), for infinitesimal value of $\tan(\beta l)$, the input impedance Z_{in2} is proportional to Z_L, therefore, $Z_{in2} \rightarrow \infty$ or 0 for corresponding $Z_L = \infty$ or 0. Under these cases, the slow-wave periodic structure loaded by Z_{in2} in Fig. 3(b) provides passband ($Z_{in2} \rightarrow \infty$) and stopband ($Z_{in2} \rightarrow 0$) characteristics.

As illustrated in Fig.3, the layout size is large and not attractive for tiny VCO applications. Fig. 4 shows the modified version of SWR, where transmission line is loaded by a square ring resonator with a line-to-ring coupling structure.

As depicted in Fig. 4(b), Z_{in3} is the input impedance looking into the transmission line l_b toward the ring resonator with the line-to-ring coupling.

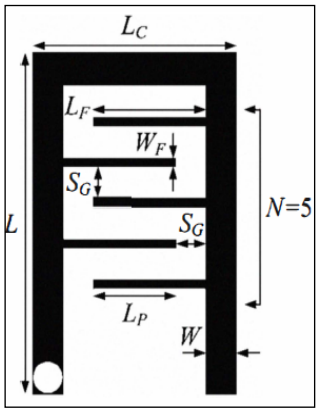

Fig.2 A typical slow wave printed coupled resonator (no of section, N=5) [8]

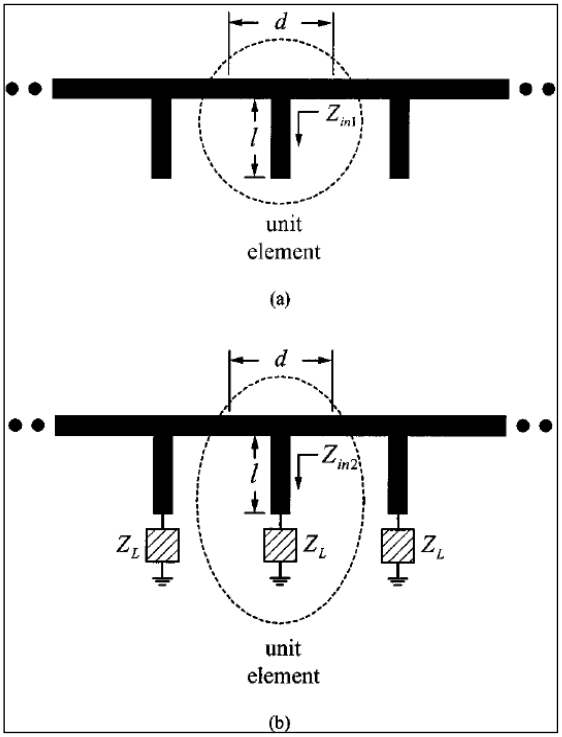

Fig. 3. Slow-wave periodic structure. (a) Conventional type. (b) With loading Z_L at open end [9].

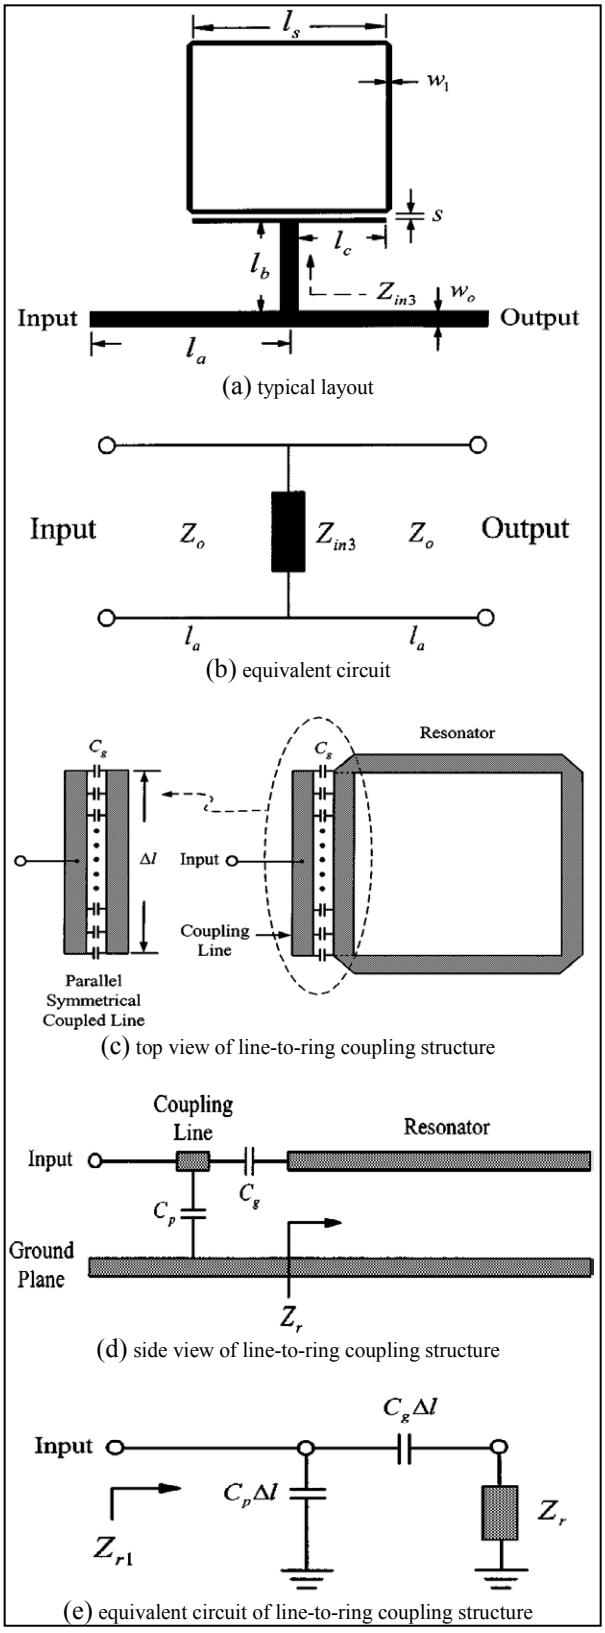

Fig. 4 Slow-wave ring resonator with one coupling gap (a) typical layout, (b) equivalent circuit, (c) top view of line-to-ring coupling structure, (d) side view of line-to-ring coupling structure, and (e) equivalent circuit of line-to-ring coupling structure [9].

The input impedance Z_{r1} looks into the line-to-ring coupling structure toward the ring resonator. The input impedance Z_{in3} is [9]

$$Z_{in3} = Z_0 \frac{Z_{r1} + jZ_0 \tan(\beta l_b)}{Z_0 + jZ_{r1} \tan(\beta l_b)} \quad (5)$$

Where

$$Z_{r1} = \frac{(Z_r + Z_g)Z_p}{(Z_r + Z_g + Z_p)}, \quad Z_g = \frac{1}{j\omega C_g \Delta l}, \quad Z_p = \frac{1}{j\omega C_p \Delta l}, \quad \omega = 2\pi f, \quad (6)$$

The parallel f_p and series f_s resonances of the slow wave ring resonator as shown in Fig.4 can be obtained by setting $|Y_{in3}| = 0$ and $|Z_{in3}| = 0$.

Figures 5(a), (b), and (c) show the typical block diagram and layout of the VCO using mode-coupled SWR, which validate a novel SWR (Slow Wave Resonator) approach, using a SiGe hetro-junction-bipolar-transistor (HBT) active device fabricated on low loss RF dielectric substrate material with a dielectric constant of 3.38 and thickness of 22 mils printed structure.

The SWR structure is modeled in 3-D EM (Electromagnetic) CAD simulator and incorporated into optimized nonlinear oscillator circuit to enable configurable and low phase noise operation over the band. This enables SWR structure to set up optimum standing waves (within the resonator) and the noise impedance transfer function over the tuning range by controlling m_{opt} (by optimizing injection locking) and β_{opt} (by optimizing mode tuning).

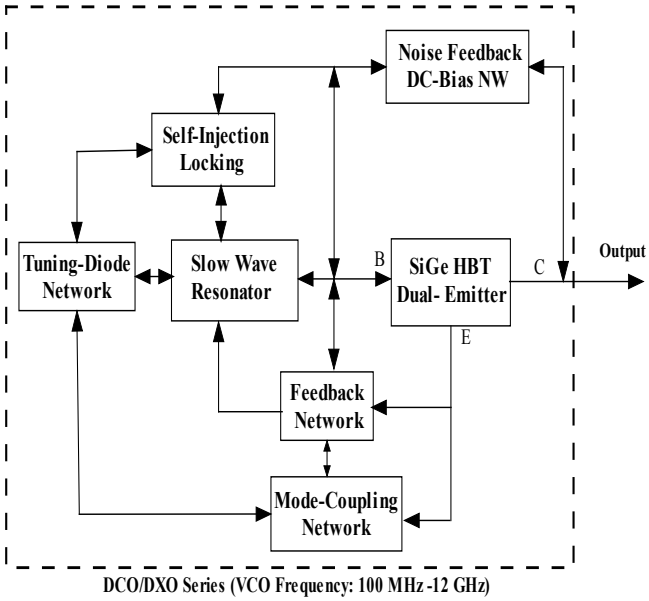
The nonlinear circuit contains the oscillator's active device, with S-parameters. This partitioning of the oscillator into its modeled component parts works quite well, and the combination of the S-parameters and the nonlinear circuit model agrees closely with the measured data in the circuits we already built. The S-parameters used for these transistors are large-signal S-parameters, which improve the optimization cycles using commercial CAD tools such as ADS 2010 (Agilent) and Ansys (Nexxim) to the limits allowed by physics.

B. High Q-Factor Slow-Wave Resonator VCO

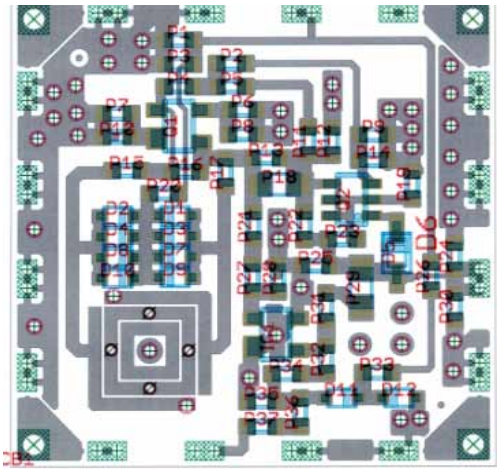
The *Q* (quality) factor of the Printed transmission line resonator can be enhanced by introducing slow wave coupling mechanism (electric/magnetic/hybrid).

Figure (6) illustrates the layout of the typical electric, magnetic, hybrid-coupling planar resonator networks, and oscillator circuits for comparative analysis. As described in Figure (6), the coupling dynamics can be characterized by proximity effect through the fringing fields, which exponentially decays outside the region; electric and magnetic field intensity tends to concentrate near the side having maximum field distribution. The coupling factor β (β_e: electric, β_m: magnetic and β_h: hybrid) can be described as

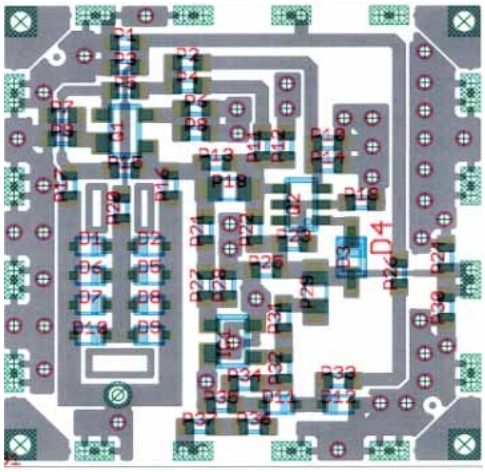
$$\beta_e \cong \frac{coupled-electrical \quad energy}{stored-energy \ of \ uncoupled-resonator} \cong \frac{f_{me}^2 - f_{ee}^2}{f_{me}^2 + f_{ee}^2} \cong \frac{C_{me}}{C} \quad (7)$$



(a) block diagram of SWR VCO



(b) layout mode-coupled SWR VCO



(c) progressive wave coupled SWR VCO

Fig.5. (a) A typical Block diagram of SWR VCO, (b) layout mode-coupled SWR VCO, and (d) layout of progressive wave coupled SWR VCO

$$\beta_m \cong \frac{coupled-magnetic\quad energy}{stored-energy\ of\ uncoupled-resonator} \cong \frac{f_{em}^2 - f_{mm}^2}{f_{em}^2 + f_{mm}^2} \cong \frac{L_{mm}}{L} \quad (8)$$

$$\beta_h \cong \frac{coupled-electro-magnetic\quad energy}{stored-energy\ of\ uncoupled-resonator} \cong \frac{f_{eh}^2 - f_{mh}^2}{f_{eh}^2 + f_{mh}^2} \cong \frac{CL_{mh} + LC_{mh}}{LC + L_{mh}C_{mh}} \quad (9)$$

where

$f_{ee} = \frac{1}{2\pi\sqrt{L(C+C_{me})}}$, $f_{me} = \frac{1}{2\pi\sqrt{L(C-C_{me})}}$, C_{me}: Mutual Capacitance

$f_{em} = \frac{1}{2\pi\sqrt{C(L-L_m)}}$, $f_{mm} = \frac{1}{2\pi\sqrt{C(L+L_m)}}$, L_{mm}: Mutual Inductance

$f_{eh} = \frac{1}{2\pi\sqrt{(L-L_{mh})(C-C_{mh})}}$, $f_{mh} = \frac{1}{2\pi\sqrt{(L+L_{mh})(C+C_{mh})}}$, L_{mh}: Hybrid Inductance

$f_0 = \frac{1}{2\pi\sqrt{LC}}$, f_0: Fundamental resonance frequency of uncoupled resonator.

The loaded quality factor Q_L of the coupled resonator network is given in terms of unloaded quality factor Q_o as

$$Q_L(\omega_0) = \frac{\omega_0}{2}\left[\frac{\partial\phi}{\partial\omega}\right] \quad (10)$$

$$[Q_L(\omega_0)]_{electrical-coupling} \cong 2\left[\frac{Q_0}{(1+\beta_e)}\right]_{\beta_e<<1} \cong 2Q_0 \quad (11)$$

$$[Q_L(\omega_0)]_{magnetical-coupling} \cong 2[Q_0(1+\beta_m)]_{\beta\to 1} \cong 2Q_0 \quad (12)$$

$$[Q_L(\omega_0)]_{hybrid-coupling} \cong 2\left[Q_0\frac{(1+\beta_{mh})}{(1+\beta_{eh})}\right]_{\beta_e<<1,\ \beta_m\to 1} \cong 2Q_0 \quad (13)$$

where $\frac{\partial\phi}{\partial\omega}$ is the rate of change of the phase, and Q_0 is the unloaded Q-factor of the uncoupled single open loop microstrip line resonator (Fig. 13). From (11), (12), and (13), there is trade-off between improving the Q factor and the permissible attenuation required (which is compensated by active device for oscillation build up). The coupling mechanism described in Figure (13) shows improvement in quality factor in comparison to single uncoupled planar resonator but drawback is limited tuning range (less than 1%). From (11), (12) and (13), loaded quality factor (Q_L) can be maximized by either lowering the value of mutual capacitance (C_m) and inductance (L_m) or maximizing the self-capacitance (C) and inductance (L), therefore, upper limit of the loaded Q- factor is dependent on the coupling β that can optimized by controlling the width of the transmission line (w), gap of the open line resonator (p), and spacing between the two open line resonators (d).

However, dynamic controlling and tuning the parameters w, p, and d at high frequency in IC technology is challenging task. For wideband tunability, the coupling factor β_j has to be dynamically tuned for low phase noise performances over the operating frequency band.

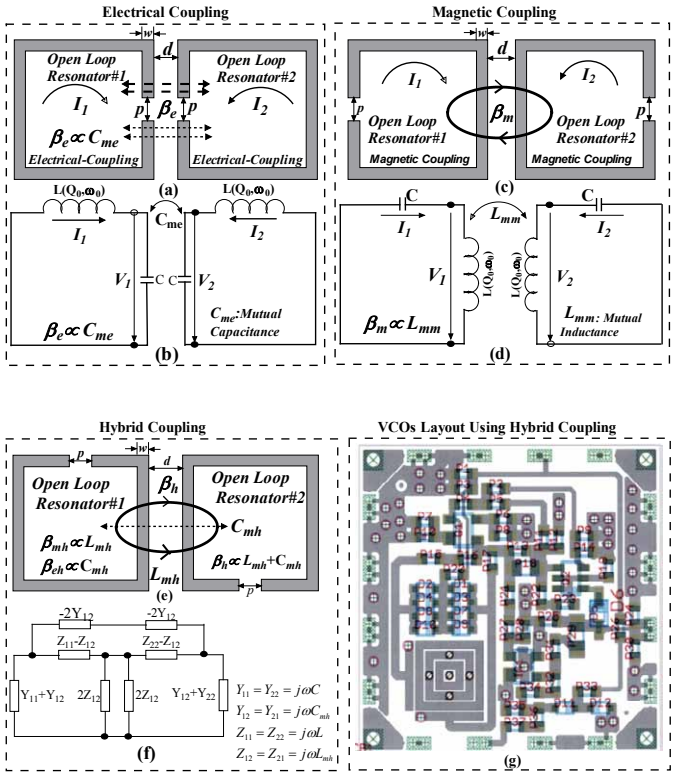


Fig.6. Typical simplified structure of open loop microstrip line coupled resonator networks:(a) Electrical coupling, (b) Equivalent lumped model of electrical coupling, (c) Magnetic coupling, (d) Equivalent lumped model of magnetic coupling, (e) Hybrid coupling, (f) Equivalent lumped model of hybrid coupling and (g) Layout of VCO using electric and magnetic coupling.

C. Phase Noise

The expression of phase noise can be given by [6, pp. 332]

$$\pounds(f_m) = 10\log\left\{\left[1+\frac{f_0^2}{(2f_mQ_L)^2}\right]\left(1+\frac{f_c}{f_m}\right)\frac{FkT}{2P_0}+\frac{2kTRK_0^2}{f_m^2}\right\} \quad (14)$$

$$\pounds(f_m) = 10\log\left\{\left[1+\frac{f_0^2}{(2f_mQ_0)^2m^2(1-m)^2}\right]\left(1+\frac{f_c}{f_m}\right)\frac{FkT}{2P_0}+\frac{2kTRK_0^2}{f_m^2}\right\} \quad (15)$$

where $\pounds(f_m)$, f_m, f_0, f_c, Q_L, Q_0, F, k, T, P_o, R, m and K_0 are the ratio of the sideband power in a 1Hz bandwidth at f_m to total power in dB, offset frequency, flicker corner frequency, loaded Q, unloaded Q, noise factor, Boltzman's constant, temperature in degree Kelvin, average output power, equivalent noise resistance of tuning diode, ratio of the loaded and unloaded quality factor and voltage gain. From (6), (7) and (8), m is given in terms of coupling coefficient as

$$m = \frac{Q_L}{Q_0} \cong \left[\frac{2}{(1+\beta_e)}\right]_{electrical} \cong [2(1+\beta_m)]_{magnetic} \cong \left[\frac{2(1+\beta_{mh})}{(1+\beta_{eh})}\right]_{hybrid} \quad (16)$$

By differentiating (16), with respect to m and equating to zero, local minimum value of phase noise for a given resonator and oscillator topology can be given by

$$\frac{\partial^2}{\partial m^2}[\pounds(f_m)]_{m=m_{opt}} = 0 \Rightarrow$$

$$\frac{d^2}{dm^2}\left[10\log\left\{\left[1+\frac{f_0^{\,2}}{(2f_mQ_0)^2m^2(1-m)^2}\right]\left(1+\frac{f_c}{f_m}\right)\frac{FkT}{2P_0}+\frac{2kTRK_0^2}{f_m^2}\right\}\right]=0\Rightarrow m_{opt}=0.5 \quad (17)$$

$$m_{opt}\to 0.5 \;\Rightarrow\; [\beta_e]_{opt}\ll 1,\quad [\beta_m]_{opt}\to 1,\quad 0<[\beta_h]_{opt}<1 \quad (18)$$

From (18), for low phase noise applications, m_{opt} and β_{opt} should be dynamically tuned and must converge in the vicinity of $m_{opt}\cong 0.5$ and $0<\beta_{opt}<1$ respectively for best phase noise performances.

From (18), broadband tunability and low phase noise performance is opposing requirements due to the problem of controlling the loop parameters, and the optimization of the time average loaded Q of the resonator over the band simultaneously. The novel mode-coupled SWR network allows for a substantial reduction in phase noise by dynamically optimizing impedance transfer function and coupling factor across the progressive medium [6].

The new approach to designing tunable oscillators with mode-coupled SWR yields compact VCOs that tune either optimized or wide bandwidths with excellent phase-noise performance, rivaling performance from high Q resonator oscillators with excellent phase noise performance, and in configurations that can be readily adapted to modern RF integrated circuit (RFIC) and MMIC semiconductor manufacturing processes. As an example for validation of this approach, Figures (7), (8), (9), and (10) shows the phase noise, tuning range, RF out power, and harmonics characteristics for tiny SWR VCO (4200-9400 MHz) shown in Fig. 6(g), fabricated on Rogers substrate material with a dielectric constant of 3.38 and thickness of 22 mils (PCB size: 0.3 x 0.3 x 0. 08 inches).

As shown in Figure 7, SWR VCO offers typical measured phase noise –105dBc/Hz at 100 kHz offset from the carrier frequency of 9 GHz with 3V, 25mA DC bias (power consumption: 75milli Watt). The reported novel SWR VCOs offer more than 2:1 tuning bandwidths (Fig. 8).

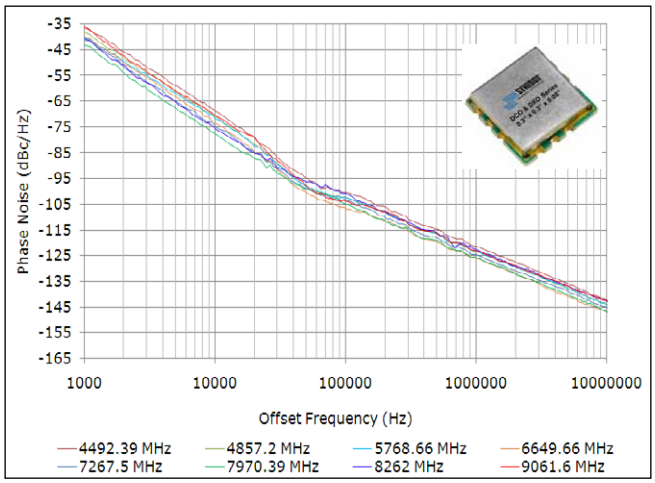

Fig. 7. This plot shows the measured phase noise of the SWR VCO tunes from 4500 to 9000 MHz for coupling dynamics $m_{opt}\cong 0.5$ and $\beta_{opt}\cong 1$.

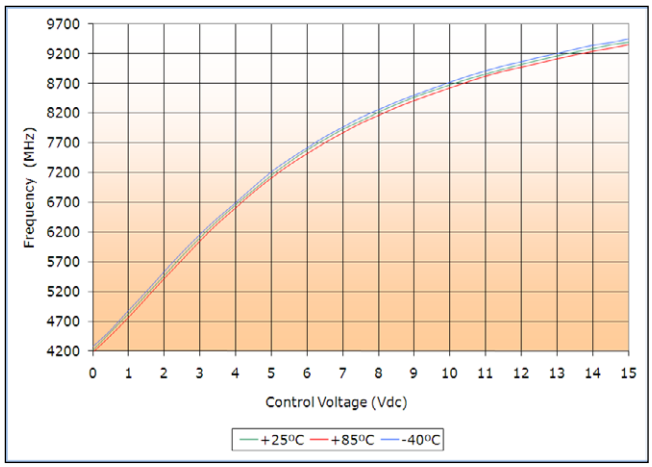

Fig.8. This plot shows the measured tuning characteristics of the SWR VCO tunes from 4500 to 9000 MHz for coupling factor $\beta_{opt}\cong 1$.

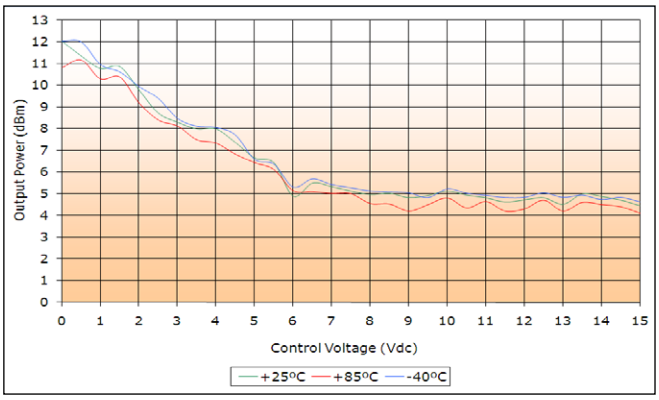

Fig.9 This plot shows the measured output power characteristics of the SWR VCO tunes from 4500 to 9000 MHz for coupling factor $\beta_{opt}\cong 1$.

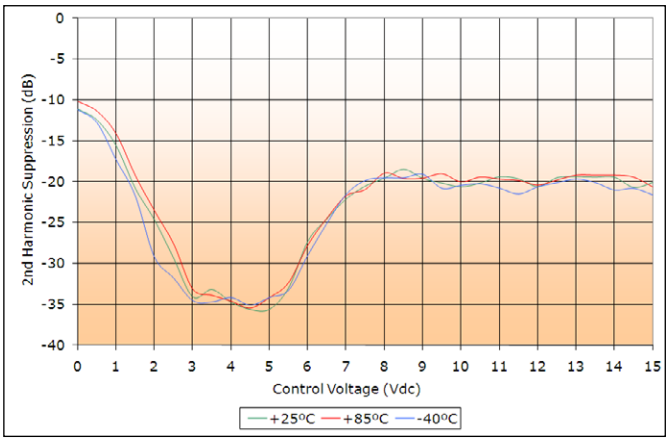

Fig. 10. This plot shows the measured second harmonics characteristics of the SWR VCO tunes from 4500 to 9000 MHz for coupling factor $\beta_{opt}\cong 1$.

These bandwidths support a wide variety of portable and fixed communications applications.

The new SWR VCOs can also be designed into compact housings with low phase noise and optimized bandwidths to challenge the performance of high-Q ceramic-resonator, surface-acoustic-wave (SAW) resonator, Dielectric resonator

and YIG resonator oscillators as well as low-Q resonators based on lumped circuit elements and printed transmission lines but at about one-third the size.

The investigation perform includes the study of the frequency reference sources for minimum jitter caused due to mechanical and thermal stress, thereby less prone to phase hits over the tuning range. The additional feature of this topology is user defined frequency band by adjusting the length/spacing and optimizing the phase velocity and group delay of the SWR networks.

III. Ultra Low Phase Noise SWR VCO

The scope of this paper is to design ultra low phase noise reference SWR VCO for PLL applications that supports the fast convergence by using dynamically tuned SWR network for maximum group delay, thereby, improved dynamic loaded Q, and hence low noise performance over the band.

Fig. 11 shows the block diagram of novel SWR oscillator topology, capable of operating over a wide tuning (6000-12000 MHz) and temperature range (–40°C to +85°C) with minimal frequency drift (less than 10 MHz) due to the temperature. As shown in Fig.11, multi-mode coupled-SWR network is connected across the base and collector of the three terminal active device (bipolar transistor), can be characterized as high Q mode coupling resonator that eventually improves the time average loaded Q over the multi-octave-band operation. As illustrated in Fig.11, the active impedance created by the 3-terminal active device has a negative real part with a real magnitude, and an imaginary part with an imaginary magnitude. The real magnitude is a function of the imaginary magnitude and the imaginary magnitude is selected such that the real magnitude compensates the loss of the SWR as well coincides with a maximum-slope inflection point of the phase characteristic curve for improved group delay. In addition to this, the mode coupling approach includes a methodology for optimum dynamic coupling to enhance the dynamic loaded Q, and to reduce or eliminate phase hits, while reducing the susceptibility to microphonics to an extremely low level, and retaining low phase noise and broadband tunability.

In addition to this, the noise feedback and DC bias circuit is coupled across the base and collector terminals of the active device. A multi-mode coupled resonator network as shown in Fig.11 is capacitively coupled across the base and collector terminals. A slow wave coupled resonator and a progressive wave-coupled resonator described in Fig.11 are coupled in distributed domain at the collector terminal. A phase compensating network is capacitively coupled between the base terminal and the slow-wave and progressive-wave coupled resonators. An RF output signal is coupled through a distributed coupled medium, which is coupled across the slow wave and progressive wave resonator networks.

As shown in the Fig. 12, the lay of the coupled SWR network is symmetrically structured to minimize the stray reactance that would otherwise limit or reduce the circuit tuning range or bandwidth.

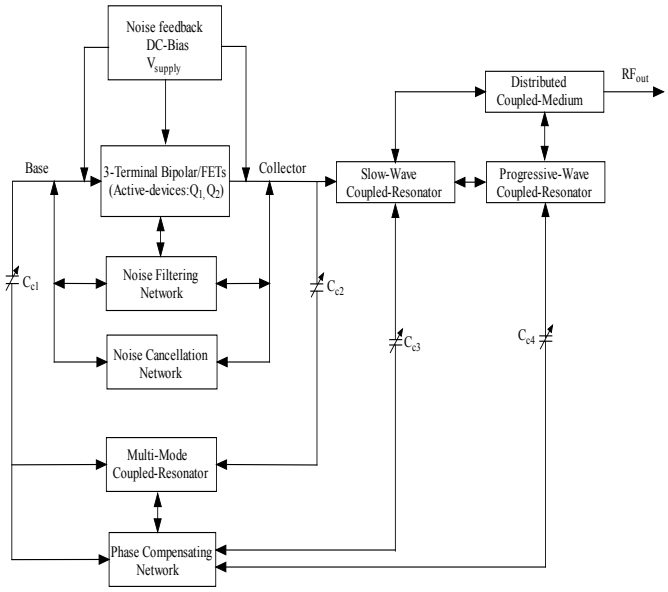

Fig. 11: Block diagram of configurable SWR VCO (6000 MHz-12000 MHz)

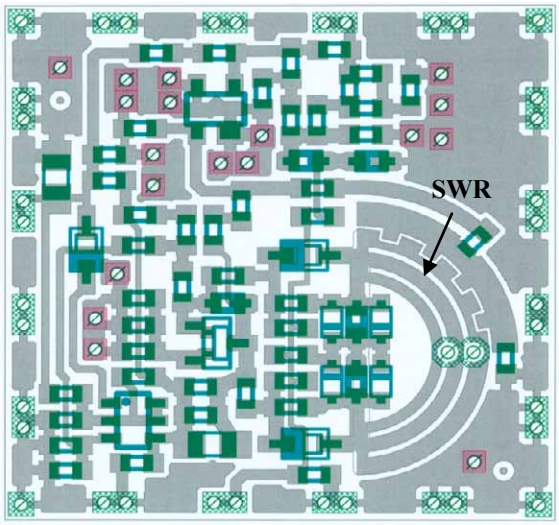

Fig. 12: Layout of the SWR VCO (6-12 GHz) with 5 Volt, 30 mA

An objective of this paper was to improve the Q value of the SWR by cascading a progressive wave coupled resonating network having multiple asymmetric coupled line to increase the phase derivative and group delay [$\delta\varphi/\delta\omega$] of the resonator in a given cycle. Therefore, VCO circuit is designed such that the phase condition occurs in the steepest part of the phase characteristics curve of the SWR network. In this way, coupled mode resonance may substantially coincide with a maximum-slope of the phase characteristic curve of the oscillator circuit, and the operation of the oscillator circuit about this point results in the circuit operating within the lowest phase noise domain of the phase characteristic curve, thereby improved effective dynamic loaded Q.

The layout shown in Fig. 12 is fabricated on 22 mil thick PCB of dielectric constant 3.38. The choice of substrate depends on size, higher-order modes, surface wave effects, implementations (couplings, line length, width, spacing, and spacing tolerances), dielectric loss, temperature stability, and power handling (dielectric strength and thermal conductivity). In many applications, keeping resonator structures to a minimum size and weight is very important. It would seem that planar resonator structures which can be fabricated using printed-circuit technologies would be preferred whenever they are available and are suitable because of smaller sizes and lighter weight. In this paper, we introduce a new class of planar resonators based on coupled slow-wave structure, depicted like saw-tooth/gear structure, which is not only compact size but also have a wider tuning range. Furthermore, SWR is loaded with variable capacitor for uniform loaded Q over the tuning range. As we know that if there were no dispersion, the phase velocity would be constant but this is true only for the unloaded line. However, for the periodically loaded line the phase velocity is frequency dependent, therefore, there is trade-off between constant phase velocity and dispersion.

Fig. 13 illustrates the measured Q of the uncoupled, coupled and MCSW resonator. The quality factor (Q) is given by

$$Q = \frac{\omega_0}{2}\left[\frac{\partial\varphi}{\partial\omega}\right]; \quad \omega_0 = 2\pi f_0 \tag{19}$$

where f_0 and φ are the resonant frequency and phase of the oscillator signal.

The dynamic time average Q factor of the resonator, as well as the tuning diode noise contribution, sets the noise performance of the VCO, and in general, the dynamic loaded Q is inversely proportional to the frequency range of the VCO. The phase noise can vary dramatically over the tuning range of a multi-octave-band VCOs; therefore it is a major challenge to explore and find ways to realize uniform loaded Q over the tuning range.

As shown in the Fig. 13, MCSWR (Multi-coupled slow wave resonator) network acts like a Q-multiplier over the 6-12 GHz, peaking at 9 GHz due to evanescent mode- coupling. The variable coupling capacitors C_c (C_{c1}, C_{c2}, C_{c3}, C_{c4}), as shown in Fig. 11 are designed for the optimum loading of the coupled resonator network across the active device, and dynamically tuned for optimum loaded Q ($m_{opt} \cong 0.5$) for minimum phase noise performance across the band. The values of the coupling capacitor C_c are derived from the input stability circle, and it should be within the input stability circle so that the circuit will oscillate at a particular frequency for the given lowest possible value of the C_c over the band.

The noise factor F of the oscillator is minimized by noise feedback circuit [2] and dynamically controlling the conduction angle of the active device by adjusting optimum drive level corresponding to the desire oscillation frequency. By doing so, the control parameters such as negative resistance, loop gain, and phase shift can be adjusted for improving the phase noise performance over the band.

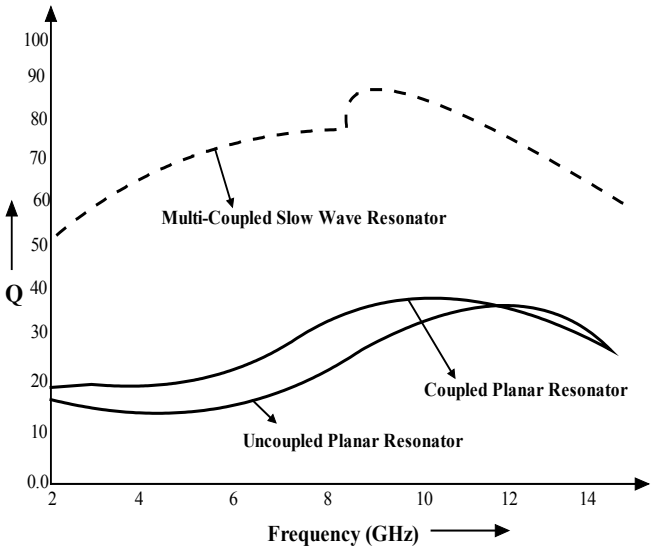

Fig. 13: Measured quality factor (Q) of the slow wave resonator

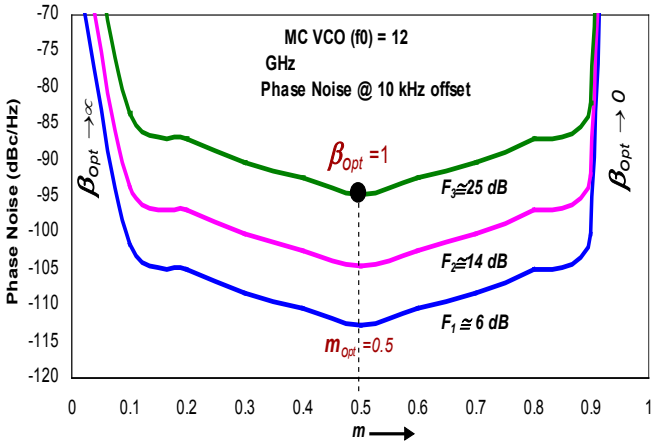

Fig. 14. Simulated phase noise plot of MCSWR VCO with respect to m_{opt},

Figure (14) shows the CAD simulated phase noise plot for a 12 GHz MCSWR VCO (Fig. 13) at offset 10 kHz from the carrier with respect to m_{opt} and β_{opt}.

Fig. 15 shows the typical measured phase noise plots at for 12 GHz carrier frequency. The typical measured phase noise @ 10 kHz offset from the 12 GHz carrier is -110 dBc/ Hz, which agrees within 3-4 dB of the CAD simulated results and to author's knowledge, the reported resonator topology shows first oscillator using slow wave dynamics in multi-mode regimes.

The theoretical treatment and experimental validation of a new class of slow wave resonator suggests the possibility of cost-effective alternative of high Q dielectric resonator based signal sources. Other features and advantages of the present technology include power efficiency, low phase noise, and amenability to integration in chip form.

IV. Synthesizer Using Multi-Band Tunable SWR VCO

Technologies for creating frequency synthesizers are diverse, from traditional analog methods using PLLs to direct digital synthesizers (DDS) that rely on high-speed digital–to-

analog converters (DACs) to transform digital input words into analog output signals. Frequency synthesizers can be categorized into mainly three groups: analogue, digital or mixed signal (hybrid). The frequency synthesizer described in this Figure (16) falls into the hybrid category [7]. As shown in Figure (16), the block diagram for a typical synthesizer includes a SWR VCO, phase-lock-loop (PLL) IC, charge pump, loop filter, amplifier, and voltage regulator. A typical unit tunes from 4000-8000 MHz in 1-MHz steps with settling time of less than 4 ms and typical phase noise of -104 dBc/Hz at 100 kHz offset from the carrier. Figure (17) shows the measured phase noise plot for miniaturized wideband VCO (0.2-1GHz/1-4GHz/4-8GHz/8-12 GHz) with limited power supply (3.1V, 10mA) that enables power-efficient frequency synthesizers (Figure 16) in a SMD package measuring just 0.6 x 0.6 inches.

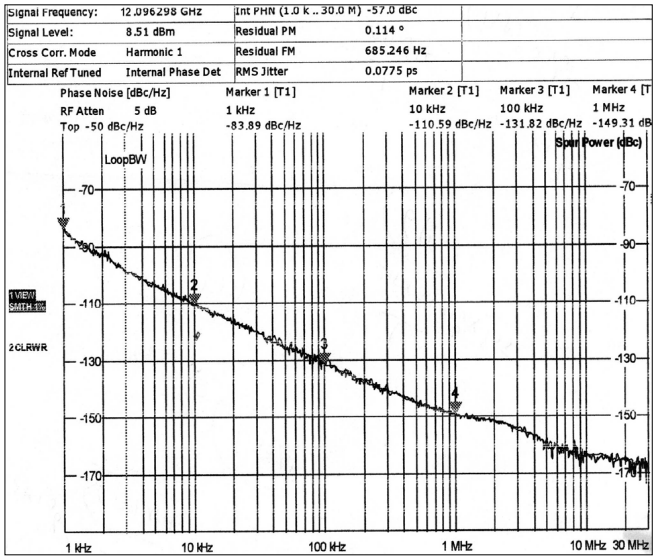

Fig.15 A typical measured phase noise plot of 12 GHz MCSWR VCO

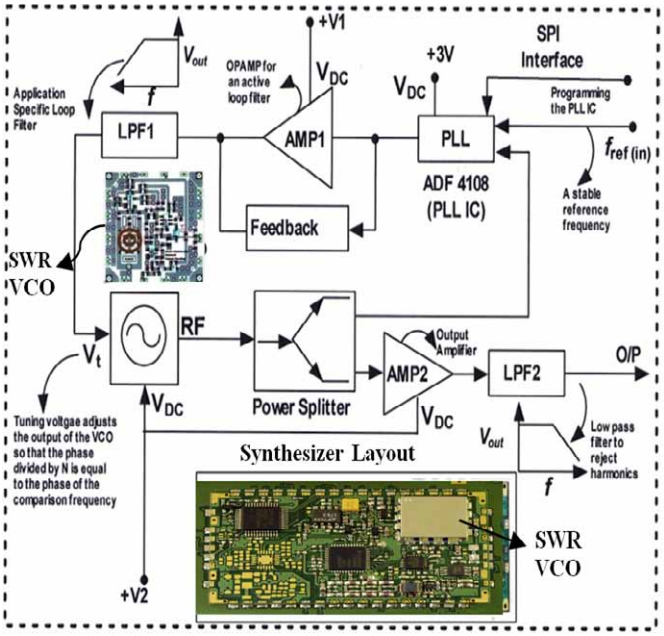

Fig.16. Block diagram of configurable synthesizer using Tunable SWR VCO

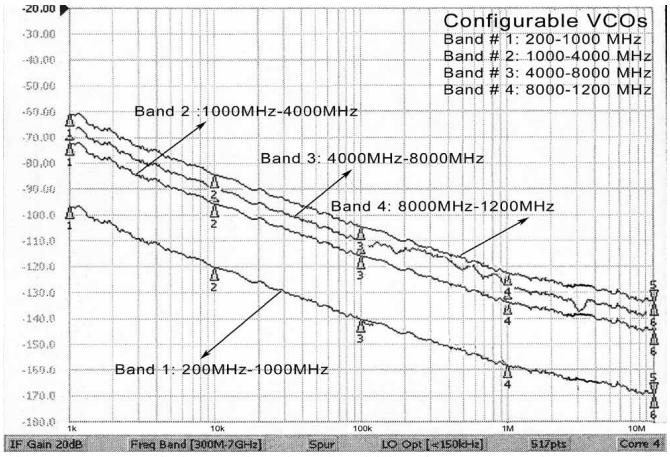

Fig. 17. Measured phase noise plot of multi-band SWR VCO for $m_{opt} \cong 0.50$

Figures (18) and (19) show the measured data of phase noise for 4000-8000 MHz configurable synthesizer. The synthesizer draws typically 30 mA current from a 5-V supply and can operate as low as 100 MHz and can be extended to 12 GHz using multi-band/multi-mode VCOs resulting low cost and power-efficient configurable synthesizer in 0.6x0.6 inches with excellent performances in terms of cost and phase noise.

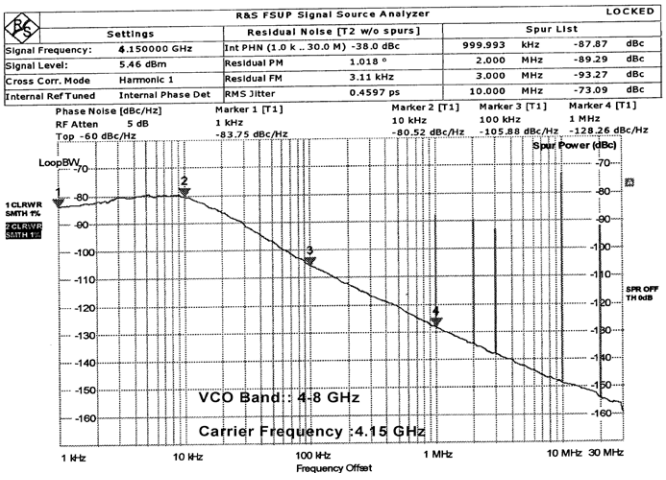

Fig.18. Measured phase noise plot at 4.15 GHz of synthesizer (4-8 GHz)

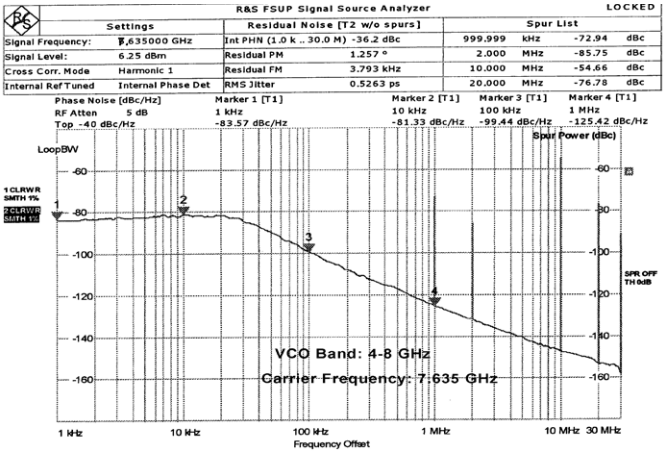

Fig.19. Measured phase noise plot at 7.635 GHz of synthesizer (4-8 GHz)

V. CONCLUSION

We have reported details of multi-band SWR VCO providing concurrent and seamless tuning over a wide tuning range for feeding tiny configurable synthesizer circuit. The freedom of selection of the frequency, low phase noise, low phase hits, low power consumption, compact size, and stable over temperature will make SWR VCO technology promising and attractive for next generation high frequency mobile communication systems and test and measuring instruments.

***Abstract*—A laser-cooled rubidium fountain clock is studied at Shanghai Institute of Optics and Fine Mechanics (SIOM). One important characteristic of the setup was, instead of six laser beams used in normal fountains, a fold optical path (FOP) was used to trap, cool, and launch atoms, which decreased laser power by 60% and the optical system was simplified greatly. This fountain clock had been operated with the center Ramsey fringe of line-width of 1Hz and the signal noise ratio (SNR) of 100. Recently, some evaluations of the fountain clock systematic uncertainty have been finished. By comparing with an H-maser (VCH-1003A), the evaluation of the frequency instability was obtained by $8\times10^{-13}\tau^{-1/2}$ and 6×10^{-15} in one day. The system errors (type-B uncertainty) had been evaluating, and some results, such as second-order Zeeman shift and blackbody radiation shift, had been achieved. Some experiments of ^{85}Rb fountain were also reported in this paper.**

I. INTRODUCTION

As a combination of the separated oscillatory field [1] method and the laser cooling techniques[2], the atomic fountain clock (AFC)s have been developed to be the most accurate running clocks in the world[3]. The combined standard fractional uncertainties of the AFCs[4,5,6,7] have reached to 10^{-16}. The first laser-cooled rubidium fountain clock at SIOM was constructed in 2005, and a center Ramsey fringe with the line-width of 1Hz and the signal noise ratio (SNR) of more than 100 were obtained. Since 2009, the evaluating works of the frequency stability and the fractional uncertainties were started and some improvements for the fountain were advanced.

II. FOUNTAIN SETUP

Schematic of the fountain device was illustrated in Fig. 1, detailed description can be found in [8]. Atoms were trapped and cooled by magneto-optical trap (MOT) and optical molasses (OM), and then were launched by optical moving molasses (OMM) in cooling zone, at the bottom of the device, with its pressure under 2×10^{-7} Pa. The cylindrical state-selection cavity was located above the cooling zone, with the mode of TE011 and its diameter and height of 6.92cm and 3.46cm respectively. The detection zone above state-selection cavity included two parts to detect atoms at state F=2 and F=1, respectively. The Ramsey cavity, the same with the state-selection cavity in cavity mode, diameter and height, was located 59.7cm above the cooling center and inside the magnetic shields made of miu-metal (three internal layers) and soft iron (the external layer), the quality factor was 18 000, the temperature of Ramsey interaction zone was kept at 52℃ to ensure the resonance frequency of the cavity.

The optical system of the fountain was shown in Fig. 2. A diode laser (TOPTICA TA100) was treated as a master, whose frequency was locked to the saturated absorption crossover optical resonance of F=2→F'=3 and F=2→F'=2 transitions, exported 150mW laser power to supply the whole fountain. The laser was divided into three parts known as detecting beams, cooling beams and repumping beams. The detecting beams and cooling beams were obtained by some of optical components (wave plates and polarization beam splitters) and four acousto-optic modulator (AOM)s to tune the frequency and power of the beams. The repumping beams were produced by a method of modulating a fiber electro-optic modulator (FEOM) with 6.7GHz modulating frequency. There

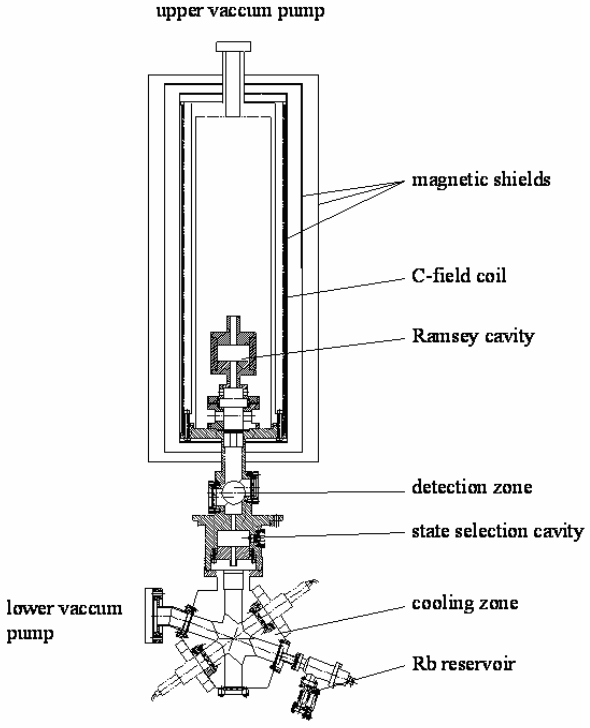

Figure 1. Schematic of the Rb fountain clock at SIOM

were two characteristics at our optical setup: the first one was a fold optical path (FOP) structure used to cool and launch atoms. As shown in Fig.3, two input beams were reflected six times by six mirrors to cool atoms instead of conventional six-beam launching structure in normal (1, 1, 1) fountains. As discussing in [9], FOP could work as a normal six-beam fountain and fit all requirements of fountain, and compared with a normal fountain, which reduced 2/3 of the laser power and decreased a lot of parts for optics and fiber, it was less power dissipation, more stable, compact, and easier to manipulate. The results demonstrated in the experiment showed that the trapping number (~10^8) and temperature (2.5μK) of cooling atoms in FOP were approximate with that in normal six-beam-fountain. The other characteristic was that repumpping beams created by an FEOM instead of a laser enhanced the stability of the optical system as FEOM was more compact, stable and reliable than a laser.

The microwave system of the fountain was consisted of a local oscillator and a microwave synthesis chain. The work shown below was base on a device synthesizer (Agilent E8257C) referring to H-maser or oscillator (OSA, 8607), whose phase noise affected the SNR of Ramsey fringe and the stability of fountain. And now, with the help of Giorgio Santarelli at SYRTE, a new synthesizer was researched, the residual phase noise of two synthesis chains was measured at frequency 7.034GHz and was shown in Fig.4. In the pulsed

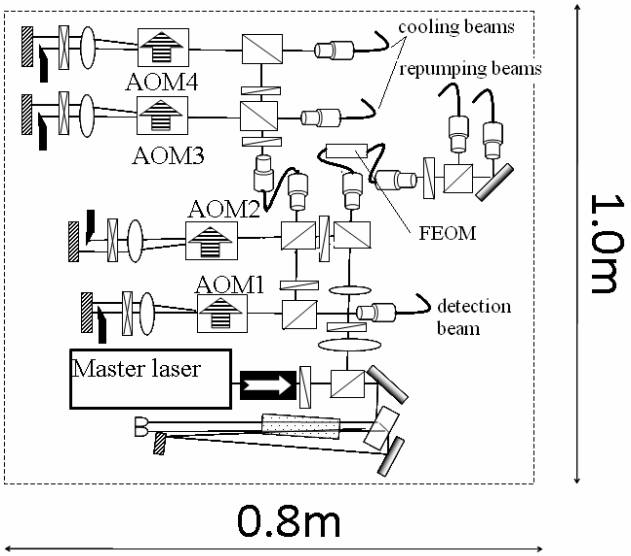

Figure 2. Schematic of the optical setup of the fountain.

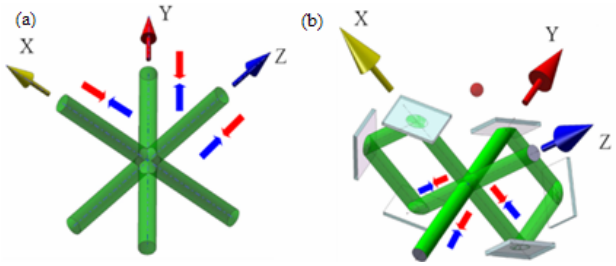

Figure 3. Schematic of input beams in cooling zone of the fountain device. The launching atoms way was (111) in the cooling zone. (a) Normal 6-beam-fountain; (b) FOP-based fountain

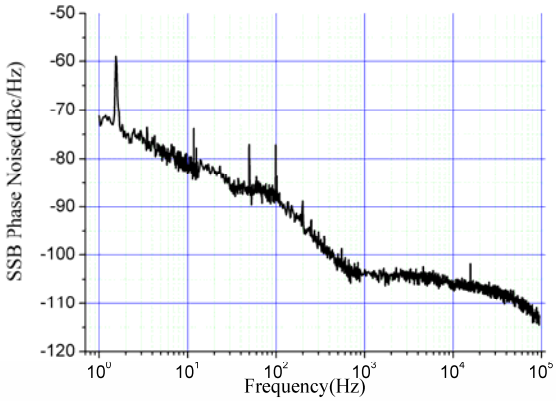

Figure 4. Residual phase noise of two chains at frequency 7.034 GHz.

operating fountain, the phase noise at Fourier frequencies, close to multiples of $1/T_C$, was down-converted, which leaded to degradation of frequency stability[10] named Dick effect[11], the data in Fig.4 means that the contribution of synthesizer to the short-term stability would be less than $1\times10^{-13}\tau^{-1/2}$.

III. PERFORMANCE OF THE FOUNTAIN

The device cycled with a normal fountain procedure, 'trapping and launching – state selecting – interacting - detecting', as description in [8], the falling atoms with launching velocity of 4.188m/s was measured by time of flight method at 10^6 level with the temperature at 2.5μK at detection zone, and the fountain cycle was 2s. The acquired Ramsey fringe was shown in Fig. 5, the interaction time between the atoms and microwave field was 10ms, the free evolution time was 0.5s, the line-width of the Ramsey central fringe was 1Hz, the SNR is more than 100, and the short-term stability was estimated to be $8\times10^{-13}\tau^{-1/2}$ based on SNR.

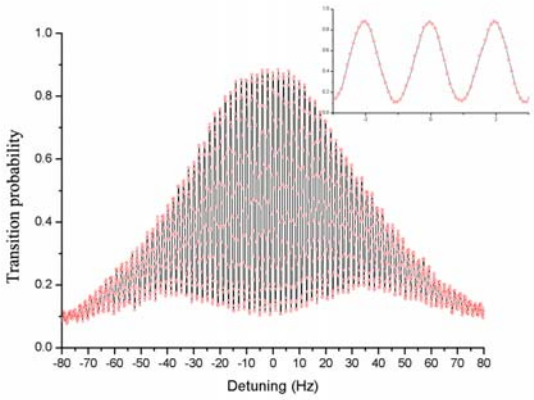

Figure 5. Ramsey interference fringe of ^{87}Rb fountain at SIOM.

The frequency instability (statistical error) of the fountain was measured by comparing the local oscillator (5MHz, BVA-8607) locked to the fountain with H-maser (VCH-1003A) using a commercial phase comparator, the Allan standard deviation was shown in Fig. 6. The short-term stability of the fountain was limited by the Dick effect from previous microwave synthesis chain. The compared result was believable after 10s as every feedback signal to local oscillator had a time delay about two fountain cycles (4s). Another comparing method was used by taking the H-maser as the reference of the commercial synthesis (Agilent E8257C) and the feedback signal was sent to the synthesis by using GPIB-488 card communication, the Allan standard deviation was obtained from the error signal shown in Fig. 7, the evaluation of the frequency instability was obtained by $9\times10^{-13}\tau^{-1/2}$ and 6×10^{-15} in one day. The comparing time was about 10 days.

A series of interested experiments correlative with laser-cooled ^{85}Rb atomic fountain were performed in our fountain device[12]. ^{85}Rb atoms were trapped and cooled by MOT and OM and were then launched by OMM when changing the lock-in peak of the saturated absorption of laser and adjusting the modulating frequencies of AOMs and FEOM, the cooling temperature was about 1.5μK and the detected atomic number in the detection zone was at 10^7 level. In our fountain device, the cavities were designed for ^{87}Rb with the resonance frequency of 6.835GHz which was far away from the clock frequency of ^{85}Rb at 3.036GHz, so the microwave field for ^{85}Rb was built by antenna-coupling, an antenna was located above the top window of the fountain, emitting two microwave pulses for Ramsey interaction. The Ramsey fringe, averaged by 7 times, was obtained and shown in Fig. 8 when the launching velocity was 4.188m/s, and the line-width was 2.1Hz. The frequency stability of ^{85}Rb atomic fountain was evaluated, and the Allan standard deviation was shown in Fig. 9 with stability of $4\times10^{-12}\tau^{-1/2}$ and 5×10^{-14} in 8000s. A +5.8Hz deviation from 3 035 732 439.0(60) Hz was measured in the experiments, however, as space microwave field brought many large uncertainties, the accuracy was bad. A special fountain device for ^{85}Rb is necessary for measuring the clock frequency of ^{85}Rb with uncertainty at 10^{-15} level, which has a potential application on measuring the variation of the fine structure constant[13,14].

IV. CORRECTED SYSTEMATIC FREQUENCY BIASES

The frequency biases and frequency uncertainties due to the systematic errors in the fountain were estimated in experiments, and the corrected biases included second-order Zeeman shift, blackbody radiation shift and gravitational redshift.

The clock transition of the rubidium fountain occurred in hyperfine ground state $|F=2,m_F=0\rangle$ to $|F=1,m_F=0\rangle$, and the first-order Zeeman shift was zero and the second-order Zeeman shift must be considered due to the presence of the C-field which afforded the quantized axis for the atoms. This field brought clock frequency shift by $\Delta\nu = 0.0575\text{Hz}/\mu\text{T}^2$. In our fountain, the magnetic map was carried out by measuring the Rabi transition envelope, two approaches were employed by microwave antenna coupling[15] and simulated Raman transition[16] respectively, and the data of the methods coincided well. The magnetic field from lower cut-off waveguide of the Ramsey cavity to the apogee of the atomic trajectory was illustrated in Fig.10 by using the simulated Raman transition approach. The second-order Zeeman relative shift was estimated as 143.6×10^{-15} in the case, the current of the C-field had been monitored for a long time (more than one day) and the fluctuation was less than 0.015%, the corresponding frequency uncertainty was less than 5×10^{-16}.

The blackbody radiation shift was a little big as the microwave cavity temperature was kept at 52.0℃ to adjust the resonance frequency of the cavity to 6.835GHz. Four PT100 thermal resistances were adhered to the vacuum tube of interaction zone to monitor the temperature of the zone, three of them were monitors and the other one was employed as a reference for the control system in the fountain. The temperature fluctuation in the fountain was shown in Fig.11, which indicated that the temperature gradient was about 2K and the fluctuation was ±0.1K, the blackbody shift was calculated to be -17.6×10^{-15} and the uncertainty was less than 5×10^{-17} by the quoting coefficient[17].

The clock frequency also changed with the gravitational potential. The gravitational redshift was measured to be 1.0×10^{-15} and the uncertainty was about 1×10^{-16} by measuring the altitude of the fountain from GPS.

V. UNCORRECTED SYSTEMATIC FREQUENCY BIASES

The cold atom collision shift for rubidium was very small compared with cesium. As the shift was estimated to be less than 0.8×10^{-16} according to the experimental result in BNM-SYRTE[18] and the uncertainty was less than 0.4×10^{-16}, the shift was not corrected. And direct measurement by method of high/low density is one of our following works.

The Majorana transition due to nonadiabatic change of the magnetic field encountered by the atoms resulted in frequency shift of the fountain[19,20]. To estimate the effect, the magnetic map in whole vacuum device was measured by the simulated Raman transition shown in Fig. 12 and the zero field was not found. The atomic numbers in state $m_F\neq0$ after the state-selection process were not found with in SNR at about 100, and the shift was conservatively evaluated to be less than 4×10^{-16}.

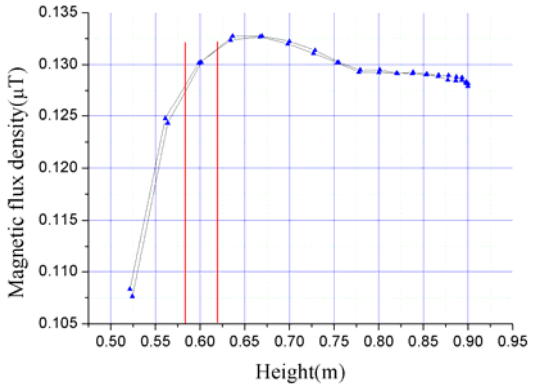

Figure 10. Magnetic map above the lower cut-off waveguide. The horizontal axis is height above cooling zone central, the area between the two red line is Ramsey cavity, the magnetic flux density in the different position is measured by the simulated Raman transition approach.

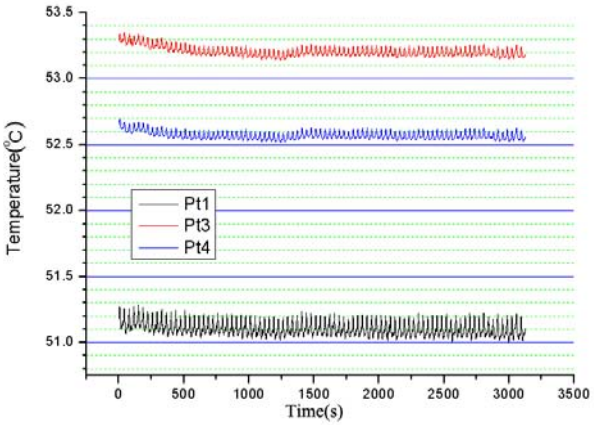

Figure 11. Temperature fluctuation of the Ramsey interaction in the fountain. The different color line represents the thermal resistor in the different position.

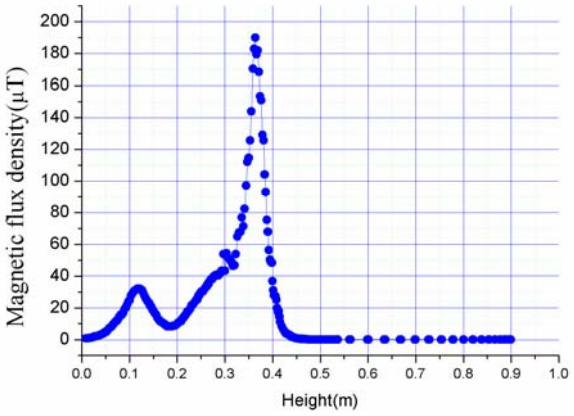

Figure 12. Magnetic map above cooling zone.

Other uncorrected frequency biases are to be measured, such as the correlative shift with microwave and cavity, light shift, Ramsey and Rabi pulling and so on.

VI. CONCLUSIONS

A rubidium fountain clock, continuously worked for more than 10 days, was developed in SIOM, the statistical error and the systematic error were estimated. The short-term frequency stability of the fountain, limited by the microwave synthesis chain, was $9\times10^{-13}\tau^{-1/2}$ and the long-term stability had reached 6×10^{-15} in one day.

To improve the performance of the fountain, a better simplified and stable optical system, with new microwave synthesis chain, effective prepared method of the atomic state and a set of the precise control system are in process. In the near future, a new microwave synthesis chain will be used, and the short-term stability is expected to be less than $3\times10^{-13}\tau^{-1/2}$.

ACKNOWLEDGEMENTS

The authors would like to thank Giorgio Santarelli and Hai-feng Jiang for their help on microwave synthesizer, and the work is supported by National Natural Science Foundation of China No. 10974215 and the Open Research Fund of State Key Laboratory of Precision Spectroscope.

***Abstract*—The 2nd harmonic signal has been recognized for some time as a "status-of-health" indicator for Rb clocks. Unfortunately, while the 2nd harmonic signal can provide *qualitative* assessments of clock-signal health, at present there is no analytic theory capable of connecting the 2nd harmonic to various parameters of interest. In large part, the difficulty lies in the fact that clocks operate in a regime where none of the standard approximations for solving field/matter interaction problems apply, in particular the Quasi-Static Approximation (QSA) which arguably has the greatest intuitive appeal. Here, we describe our first set of studies examining the validity of the QSA under conditions where the Rabi frequency, the field's modulation frequency, and the atom's dephasing rate are all nearly equal. Specifically, we examine the QSA's prediction of the 2nd harmonic signal amplitude as a function of microwave power. Our results suggest that the QSA can have utility for understanding the *relative* change in the 2nd harmonic signal with microwave power, and therefore potential *quantitative* utility for understanding a Rb clock's status-of-health.**

I. INTRODUCTION

In the standard frequency-feedback loop of atomic clocks, a field's frequency is modulated at f_m; the atomic dynamics are detected and demodulated at the modulation's fundamental frequency (i.e., the 1st harmonic signal), and this demodulated signal is then used to generate a correction voltage for a crystal oscillator. Typically, the intuitive understanding of this process is obtained by viewing the atomic dynamics in terms of the quantum system's static response to the resonant field:

1st harmonic dynamics ⇔ Static lineshape 1st derivative,

2nd harmonic dynamics ⇔ Static lineshape 2nd derivative.

Consequently, the Quasi-Static Approximation (QSA) to the atomic dynamics suggests that a 2nd harmonic signal can be employed as a measure of the atoms' frequency discrimination capability (i.e., the slope of the static lineshape's 1st derivative). In a phrase, the 2nd harmonic signal can be employed as a vapor-cell clock's status-of-health indicator.

However, in order to obtain large signal-to-noise ratios and narrow atomic linewidths in atomic clocks, it is typical to operate under conditions such that $f_m \sim \Omega \sim \gamma$, where Ω and γ are the Rabi frequency and dephasing rate, respectively. Unfortunately, this regime of operation is neither quasi-static (large γ), adiabatic (large Ω), nor sudden (large f_m). Consequently, none of the standard approximations of atomic dynamics legitimately apply, notably the QSA.

In order to develop a better intuitive understanding of atomic dynamics in the regime of clock operation, and in particular the nature of the atoms' 2nd harmonic response to a frequency modulated field, we have begun a series of experiments investigating 2nd harmonic signals under clock operating conditions (i.e., $f_m \sim \Omega \sim \gamma$). Here, we discuss our first set of experiments examining the amplitude of 2nd harmonic signals as a function of microwave power, and the comparison of our results to the predictions of a QSA model. In the next section, we outline the QSA model, and discuss the conditions of clock operation that would lead one to doubt its validity. Then in Section III we discuss our experimental system. Our results are presented in Section IV, where they are compared with the QSA model as well as a 2-level density matrix model of the 2nd harmonic signal. Our conclusions are presented in Section V.

II. THE QUASI-STATIC APPROXIMATION

A. Overview of the QSA Model

As is well known, the signal of a Rb atomic clock is obtained by passing the light from a lamp through an absorption cell contained within a microwave cavity as shown in Fig. 1 [1]. In the absence of microwaves, the light intensity transmitted by the vapor is high as a consequence of optical pumping [2], which removes atoms from the optically absorbing state. However, when resonant microwaves are applied to the vapor atoms return to the optically absorbing state, and the transmitted light intensity decreases. Thus, the light intensity transmitted by the vapor carries information on the atoms' response to the microwave field, which is the origin of the Rb atomic clock signal.

Under static conditions, the light intensity transmitted by a Rb vapor of length L, I(L), is given by the Beer-Lambert law of exponential attenuation [3]:

$$I(L) = I_o e^{-\eta N \sigma L}. \quad (1)$$

Here, I_o is the light intensity at the entrance to the vapor, N is the number density of Rb atoms in the vapor, σ is the optical absorption cross section, and η corresponds to the fraction of

This work was funded by U.S. Air Force Space and Missile Systems Center under Contract No. FA8802-04-C-0001.

atoms in the absorbing state. According to the Generalized Vanier Theory of the alkali atom's 0-0 hyperfine transition [4], η is given by

$$\eta = \frac{g_p \gamma_c}{g_u B + g\gamma_c}\left[\frac{\gamma^2 + \Delta^2 + \left(\gamma/\Gamma_\alpha\right)\Omega^2}{\gamma^2 + \Delta^2 + \left(\gamma/\Gamma_\beta\right)\Omega^2}\right], \qquad (2)$$

where Δ is the microwave field detuning,

g_p = degeneracy of the optically excited ground-state hyperfine level, $F = \widetilde{F}$,

g_u = degeneracy of the non-optically excited ground-state hyperfine level,

γ_c = dephasing rate due to "collisions," [a]

B = optical photon absorption rate,

$$g = g_p + g_u,$$

$$\gamma = \frac{B}{2} + \gamma_c,$$

$$\Gamma_\alpha = \frac{g_p \gamma_c (B + \gamma_c)}{g_p (B + \gamma_c) - \widetilde{F} B},$$

$$\Gamma_\beta = \frac{2\gamma_c (B + \gamma_c)(g_u B + g\gamma_c)}{(g_u - 1)B^2 + (g + 2g_u)B\gamma_c + 2g\gamma_c^2}.$$

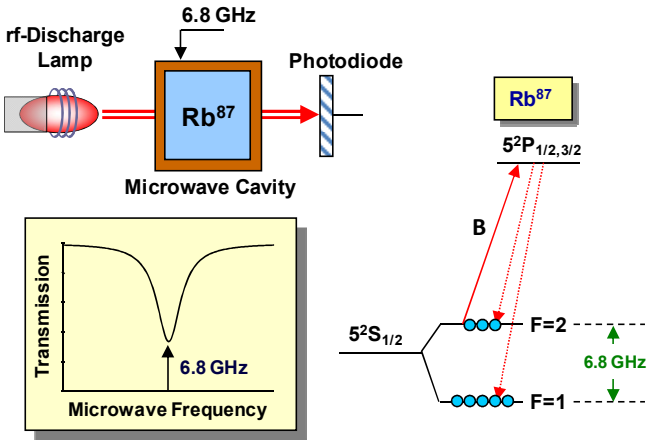

Figure 1: Generic diagram of a Rb atomic clock. In this figure, the lamplight excites Rb^{87} atoms out of the F = 2 ground-state hyperfine level, so that $\widetilde{F} = 2$, $g_p = 5$, and $g_u = 3$. The atoms are excited out of the F = 2 hyperfine manifold at the rate B.

As employed here, *the QSA model assumes that the dephasing rate of the atomic system is larger than all other parameters describing the atomic dynamics* [5]. In particular, if the field's frequency, ν, is modulated in some fashion:

$$\Delta(t) \equiv \nu(t) - \nu_o = (\bar{\nu} - \nu_o) + \delta_m g(t, f_m), \qquad (3)$$

where $\bar{\nu}$ is the field's average frequency, δ_m is the amplitude of the periodic frequency modulation, and $g(t,f_m)$ is an arbitrary periodic function of time with period $1/f_m$; then the QSA assumes that $\gamma >> f_m, \delta_m$, along with the assumption that the system is not in the regime of power broadening: $\gamma >> \Omega$.

We now expand I(L) in a Taylor series about $\Delta_o \equiv (\bar{\nu} - \nu_o)$:

$$I(t) = I(L, \Delta_o) + \delta_m g(t, f_m)\left.\frac{\partial I}{\partial \Delta}\right|_{\Delta_o} + \frac{\delta_m^2 g^2(t, f_m)}{2}\left.\frac{\partial^2 I}{\partial \Delta^2}\right|_{\Delta_o} + \ldots, \qquad (4a)$$

or, since the transmitted light intensity only depends on the microwave detuning through η,

$$I(t) = I(L, \Delta_o) + \delta_m g(t, f_m)\left(\frac{\partial I}{\partial \eta} + \frac{\delta_m g(t, f_m)}{2}\frac{\partial^2 I}{\partial \eta^2}\frac{\partial \eta}{\partial \Delta}\right)\left.\frac{\partial \eta}{\partial \Delta}\right|_{\Delta_o} + \frac{\delta_m^2 g^2(t, f_m)}{2}\frac{\partial I}{\partial \eta}\left.\frac{\partial^2 \eta}{\partial \Delta^2}\right|_{\Delta_o} + \ldots. \qquad (4b)$$

Since we're interested in on-resonance conditions (i.e., $\Delta_o = 0 \Rightarrow \eta = \eta_o$), the first derivative of η with respect to Δ is zero, and so we have to second-order in the Taylor-series expansion

$$\frac{\delta I(t)}{\langle I \rangle} \equiv \frac{I(t)}{I_o e^{-\eta_o N\sigma L}} - 1 = -N\sigma L \frac{\delta_m^2 g^2(t, f_m)}{2}\left.\frac{\partial^2 \eta}{\partial \Delta^2}\right|_{\Delta_o = 0}. \qquad (5)$$

Finally, computing the derivatives of Eq. (2) we obtain

$$\frac{\delta I(t)}{\langle I \rangle} = -\frac{N\sigma L g_p \gamma_c}{(g_u B + g\gamma_c)}\frac{\gamma(\Gamma_\alpha - \Gamma_\beta)}{\Gamma_\alpha \Gamma_\beta}\frac{\delta_m^2 g^2(t, f_m)\Omega^2}{\left(\gamma^2 + \left(\gamma/\Gamma_\beta\right)\Omega^2\right)^2}. \qquad (6)$$

B. The Atom's 2nd Harmonic Response

From the photodiode shown in Fig. 1, the signal will typically pass to a splitter, one branch of which will go to the RF port of the "fundamental-signal" mixer. The local oscillator of this mixer will be derived from $g(t,f_m)$ (e.g., $\sin(2\pi f_m t)$), and this mixer's output, S_1, will provide the correction signal that is used to lock the microwave field's frequency to the 0-0 hyperfine resonance frequency (i.e., $dS_1/d\Delta_o$).

The other branch of the split signal will also go to the RF port of a mixer. However, in this case the LO signal will be derived from $g^2(t,f_m)$ (e.g., $\cos(4\pi f_m t)$). The output of this mixer, S_2, yields the 2nd harmonic signal of interest for status-of-health monitoring, since it provides a measure of $d^2S_1/d\Delta_o^2$, and after passing through a low pass filter the amplitude of S_2 will be given by

$$S_2 = \frac{N\sigma L g_p \gamma_c}{(g_u B + g\gamma_c)}\frac{\gamma(\Gamma_\alpha - \Gamma_\beta)}{\Gamma_\alpha \Gamma_\beta}\frac{\delta_m^2 \Omega^2}{\left(\gamma^2 + \left(\gamma/\Gamma_\beta\right)\Omega^2\right)^2}. \qquad (7)$$

[a] By collisions, we mean all processes other than light absorption that lead to dephasing (e.g., diffusion out of the light field). Additionally, to simplify the equations, we have assumed that the longitudinal "collisional" relaxation rate equals the collisional dephasing rate.

There are at least two things worth noting about Eq. (7). First, independent of the form of the modulation (e.g., sinewave or squarewave), the QSA predicts a 2nd harmonic signal. This is somewhat surprising in the case of squarewave modulation, since the microwave field is never truly on resonance; it simply samples the field at two specific frequencies symmetrically placed about resonance. Nevertheless, the QSA recognizes that the nonlinear nature of the atom's response to the field is captured by the atomic dynamics, and that a 2nd harmonic signal is produced.

Additionally, the QSA indicates that S_2 will have a resonance-like response to the Rabi frequency. This is perhaps best illustrated by writing $\Omega^2 = \alpha P$, where P is the microwave power, and then transforming to a new variable $y \equiv \ln(\alpha P/\gamma\Gamma_\beta)$. In effect, the variable "y" is akin to the microwave power measured in dB. With this transformation, Eq. (7) becomes

$$S_2 = \left(\frac{N\sigma L g_p \gamma_c}{(g_u B + g\gamma_c)} \frac{(\Gamma_\alpha - \Gamma_\beta)}{4\Gamma_\alpha} \frac{\delta_m^2}{\gamma^2} \right) \operatorname{sech}^2\left(\frac{y}{2}\right), \quad (8)$$

where $\operatorname{sech}^2(y/2)$ has a well-known resonance-like shape: resonance occurs at $y = 0$ (i.e., $\alpha P = \gamma\Gamma_\beta$) and the symmetric lineshape has a FWHM of $\Delta y_{1/2} \cong 3.526 \Rightarrow 15.31$ dB (i.e., $\Omega^2_{high} = \alpha P_{high} \cong 5.83\gamma\Gamma_\beta$ and $\Omega^2_{low} = \alpha P_{low} \cong 0.17\gamma\Gamma_\beta$.)

C. *Fundamental Problems for the QSA*

There are at least three serious problems with the quasi-static approximation in terms of its ability to describe the atomic dynamics occurring in vapor cell clocks. First, and perhaps most serious, vapor-cell atomic clocks *do not* operate in a regime where $\gamma \gg f_m, \delta_m$, and Ω. In order to ensure a high signal-to-noise ratio without losing atomic line-Q via power broadening, vapor-cell atomic clocks operate with $\Omega \sim \gamma$ (i.e., clocks operate at the onset of saturation). Further, since the linewidth of the 0-0 hyperfine resonance is on the order of γ, S_1 can be made largest by choosing $\delta_m \sim \gamma$ [6]. Finally, the signal amplitude can be further enhanced through a process akin to adiabatic fast passage if $f_m\delta_m \sim \Omega^2$ (and as a consequence of $\Omega \sim \gamma$, $f_m\delta_m \sim \gamma^2$) [7]. Therefore, for reasons of maximum signal-to-noise ratio and atomic line-Q, vapor-cell atomic clocks typically operate under conditions where $\gamma \sim f_m \sim \delta_m \sim \Omega$.

In addition to the above considerations, squarewave frequency modulation posses an additional problem. When the frequency of a reasonably strong resonant field changes abruptly, a quantum system will undergo transient nutation [8]. In the atomic dynamics, this will appear as a damped oscillation: the oscillation frequency will be given by $\sqrt{\Omega^2 + \Delta_o^2}$, and the decay time will be $\sim \gamma^{-1}$. Of course, none of this is captured by the quasi-static approximation, and we are left to wonder how the transient nutation would influence a 2nd harmonic signal.

Finally, though not as serious as the previous issues but nonetheless problematic, the QSA truncates the Taylor series expansion at 2nd order. While this yields a relatively simple expression for the 2nd harmonic signal, it is not necessarily true that the higher-order terms are negligible. In particular, as noted above $\delta_m \sim \gamma$, suggesting that terms containing $(\delta_m/\gamma)^\kappa$ will not be negligible for $\kappa > 2$.

For all the reasons cited in the preceding paragraphs, we must expect the QSA to fail in predicting the behavior of the 2nd harmonic signal. The question we want to (partially) address in the following sections concerns the relative magnitude of this failure. Said differently, to what extent can the QSA provide us with *any* insight into S_2?

III. EXPERIMENT

Figure 2 shows a block diagram of our experimental arrangement. We stabilize our VCSEL diode laser wavelength using the ^{87}Rb resonance cell on the left of the figure (cell A); this cell contains 10 torr of N_2 as a buffer gas, and is maintained at a temperature of 37 ^{o}C. Though the Rb atomic clocks employed in GNSS and satellite communication systems use an rf-discharge lamp [9] rather than a diode laser as their light source [10-12], we use a laser to give us better control of the light field. With the laser, we not only have the ability to vary the intensity of the light and see its effect on the 2nd harmonic signal, we can also easily vary the laser frequency. Varying the laser center frequency gives us an opportunity to mimic spectral shifts in an rf-discharge lamp's output [13], and to thereby study the effect of such variations on the 2nd harmonic signal, which might arise as a consequence of the light shift [14].

The light intensity passing through cell A is kept very low, so that optical pumping does not occur. The laser light also passes through a second ^{87}Rb resonance cell (cell B), which again contains 10 torr of N_2 as a buffer gas. The laser light optically pumps the rubidium atoms in cell B, which is our atomic-clock signal cell, and creates a population imbalance between the atom's ground state hyperfine levels. Since the optical pumping process essentially removes atoms from the optically-absorbing hyperfine level, the laser light passing through this second cell is relatively high when the optical pumping process completes. (The optical pumping process is relatively fast, taking roughly a millisecond to complete.) If microwaves of the appropriate frequency impinge on the vapor of atoms, however, atoms are forced to return to the optically absorbing hyperfine level with a concomitant decrease in the transmitted light intensity. Consequently, as illustrated in the top graph on the right, plotting the vapor's absorption as a function of microwave frequency yields a Lorentzian absorption profile. In addition, we modulate the frequency of the microwaves in our experiment at $f_m \sim 100$ Hz. We can then monitor the atoms' first harmonic response to the microwaves or the atoms' second harmonic response to the microwaves using a lock-in amplifier and the appropriate reference frequency for the lock-in. This is shown in the lower graph on the right in Fig. 2. In this work, we are primarily concerned with the amplitude of the 2nd harmonic signal when the microwaves are on resonance, corresponding to locked vapor-cell clock conditions.

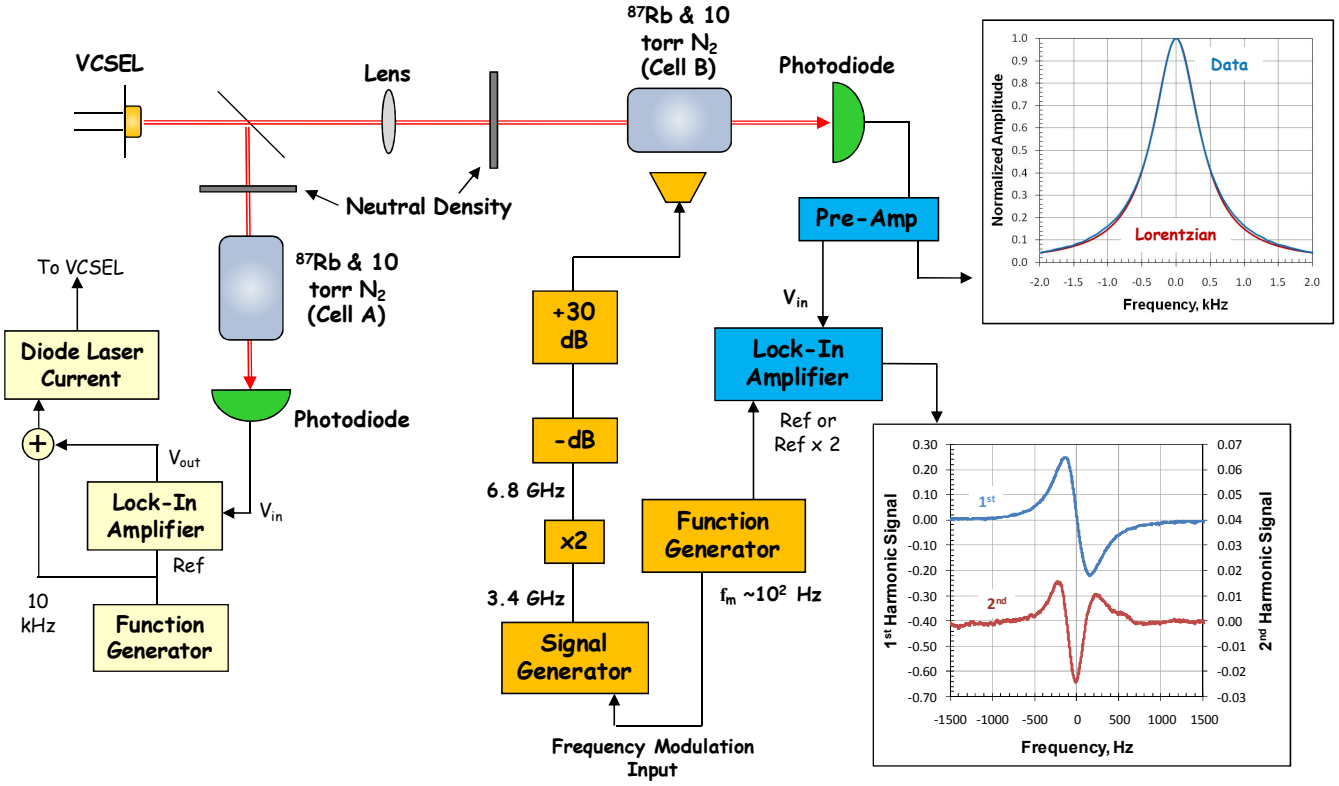

Figure 2: Block diagram of our experimental arrangement.

IV. Results

A. Experiment vs. Theory

The curve of the 2nd harmonic amplitude as a function of Rabi frequency is known as a "Rabi resonance" [15], and this is shown for our experiment in Fig. 3: $\gamma = 136$ Hz, $f_m = 118$ Hz, and $\delta_m = 120$ Hz. In the figure, the blue curve (rightmost) corresponds to a 2-level density matrix calculation, and the reddish curve (leftmost) to the predictions of the QSA. Note that the density matrix calculations and the experimental results agree reasonably well, indicating that the overall nature of the atomic dynamics (at least with regard to S_2's dependence on Ω) is not overly influenced by the multi-level nature of the Rb system. At present, we believe that the slight disagreement between the density matrix theory and experiment may be due to inhomogeneous broadening [16],[a] and in future work we plan to examine this possibility more carefully.

If we don't concern ourselves with the center position of the Rabi resonance, then Fig. 4 shows S_2 as a function of microwave power in dB, where the normalizing power is set equal to that corresponding to the peak of the Rabi resonance in the three separate cases. Again the reddish curve (now the wider curve) corresponds to the QSA, and the blue curve (i.e., the narrower curve) corresponds to the 2-level density matrix calculation. In the case of Fig. 4, the QSA does very well in predicting the shape of the Rabi resonance, to some extent better than that of the 2-level density matrix calculations. However, we should not infer too much from the QSA's better agreement with the experimental data, since this is very likely coincidental, and due to the nature of our (hypothesized) inhomogeneously-broadened transition lineshape.

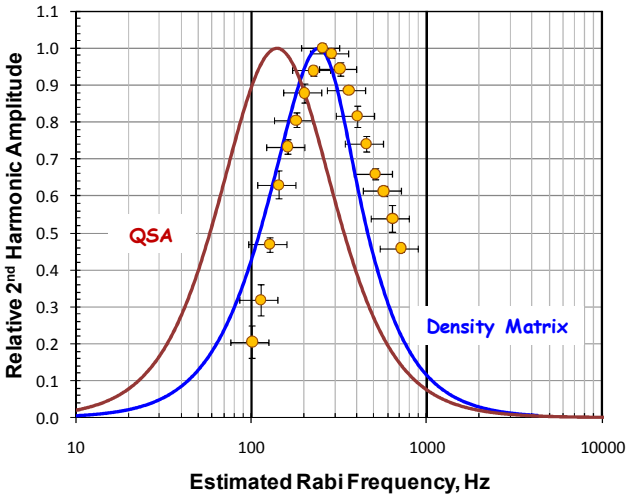

Figure 3: The Rabi resonance: S_2 vs. Ω. For these results, the resonance cell temperature was 33 °C, corresponding to an optical attenuation coefficient, $N\sigma L$, of 0.8.

[a] Nevertheless, it seems strange that inhomogeneous broadening should play a significant role in our experiments. As illustrated in Fig. 2, the 87Rb 0-0 transition lineshape is very well described by a Lorentzian. Typically, inhomogeneous broadening leads to clear non-Lorentzian character in a transition lineshape.

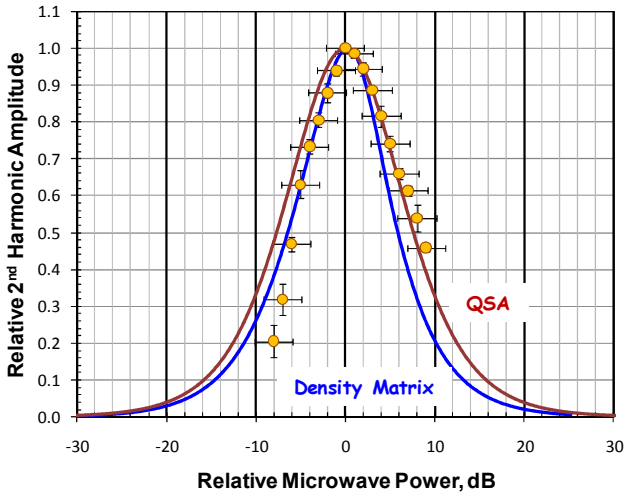

Figure 4: The Rabi resonance: S_2 vs. $20\text{Log}_{10}[\Omega/\Omega_{peak}]$. Here, Ω_{peak} is the microwave Rabi frequency that maximizes the Rabi resonance. The data is the same as that of Fig. 3.

The results of Figs. 3 and 4 suggest that the QSA is likely fairly good in predicting the *shape* of the Rabi resonance, but not so much its peak position. However, from a practical standpoint, it is the shape of the Rabi resonance that has the greatest value in the 2nd harmonic signal's employment as a status-of-health indicator: given a change in the 2nd harmonic signal, we want to know the relative microwave power change that could have occurred. Therefore, given the agreement between the 2-level density matrix calculations and experiment, we decided to more fully examine the QSA's utility for status-of-health monitoring by comparing the predictions of the QSA to those of the 2-level density matrix under a wide variety of modulation conditions.

B. QSA vs. 2-Level Density Matrix

From Eq. (7), it is straightforward to show that $\Omega_{peak} = (\gamma\Gamma_\beta)^{1/2}$ for the QSA. Note, however, that in the limit of large ground-state degeneracy g,

$$\frac{\Gamma_\beta}{\gamma} \cong \frac{4\left(1+B/\gamma_c\right)}{\left(2+B/\gamma_c\right)^2}. \qquad (9)$$

Thus, under the conditions of most interest for vapor phase clocks (i.e., $B \le 3\gamma_c$), we have $0.8 \le (\Gamma_\beta/\gamma)^{1/2} \le 1$; so that for vapor-phase clocks the QSA yields $\Omega_{peak} \cong \gamma$.

Of course based on Fig. 3, we know that this prediction of the QSA is in error when the modulation parameters are not small. However, we also know from previous work on Rabi resonances that when the modulation parameters are large we expect $\Omega_{peak} \cong 2f_m$ [15]. Thus, a reasonable empirical expression to hypothesize for the Rabi frequency that maximizes S_2 is

$$\Omega_{peak} = \sqrt{\gamma^2 + 4f_m^2}. \qquad (10)$$

Figure 5 shows the peak of the Rabi resonance, Ω_{peak}, (relative to the expression given by Eq. (10)) as a function of the normalized modulation frequency: circles and diamonds correspond to two different values of the modulation depth, while the dashed line is the prediction of the QSA. The first thing to note from the figure is that in the limit of small modulation frequency and small modulation depth the 2-level density matrix calculations appear to asymptote to the QSA. More importantly, however, under conditions of vapor cell clock operation: $f_m \sim \gamma$ and $\delta_m \sim \gamma$, the empirical expression of Eq. (10) appears to be a reasonably good estimator of the Rabi frequency that yields the maximum 2nd harmonic signal.

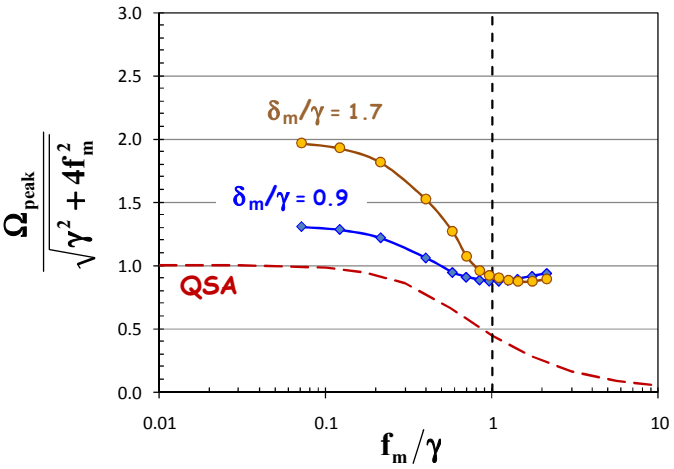

Figure 5: This figure shows the Rabi frequency that maximizes S_2, Ω_{peak}, as a function of the relative modulation frequency. Note that Ω_{peak} is plotted relative to the empirical expression of Eq. (10). In the figure, circles and triangles correspond to two different values of the frequency modulation amplitude, δ_m, with the results obtained from the 2-level density matrix calculations. The dashed line is Ω_{peak} as obtained from the QSA: $\Omega_{peak} = \gamma$.

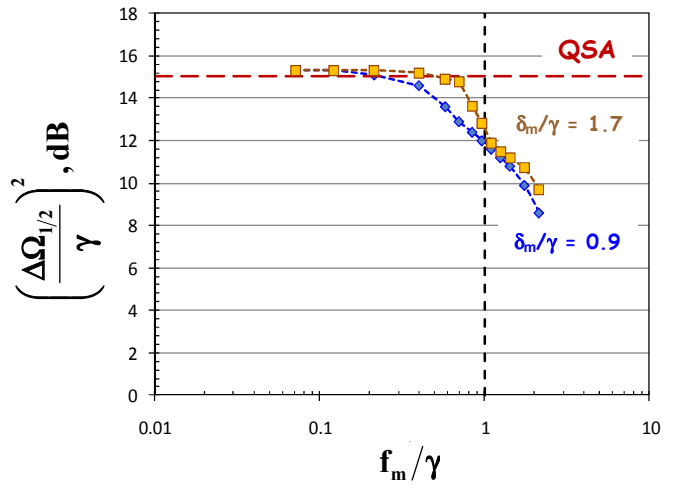

Figure 6: This figure shows the FWHM of the Rabi resonance, $\Delta\Omega_{1/2}$, as a function of the relative modulation frequency; the circles and triangles correspond to two different values of the frequency modulation amplitude, δ_m, with the results obtained from the 2-level density matrix calculations. The dashed line is $\Delta\Omega_{1/2}$ as obtained from the QSA.

Figure 6 shows the FWHM of the Rabi resonance in dB (i.e., Fig. 4 and Eq. (8)), as a function of the relative modulation frequency. Again, the 2-level density matrix calculations agree with the prediction of the QSA in the limit

of small modulation frequency. However, even under conditions of typical clock operation (i.e., $f_m \sim \gamma$), the agreement between the QSA and the 2-level density matrix calculations is not too bad: the QSA only overestimates the FWHM by about 20%, and for engineering status-of-health purposes this is likely a tolerable error.

V. CONCLUSIONS

In this work, we have examined the quasi-static approximation (QSA) and its ability to predict the magnitude of the 2nd harmonic signal in vapor-cell atomic clocks as a function of microwave power. More specifically, we examined the QSA when the microwaves are resonant with the 0-0 hyperfine transition frequency, since this is the only condition of relevance for the 2nd harmonic signal's use as a status-of-health indicator. In general, the QSA *does not* predict the position of the Rabi resonance very well. However, this short-coming of the QSA is easily overcome through the use of the empirical formula given by Eq. (10): $\Omega_{peak} = \sqrt{\gamma^2 + 4f_m^2}$.

Under vapor-cell clock operating conditions, the QSA *does* appear to do an adequate job in predicting the FWHM of the Rabi resonance (in dB), though it overestimates the width by about 20%. For the engineering application of status-of-health monitoring, this is likely not too large an error. Specifically, if a change in microwave power produces a significant change in the 2nd harmonic signal, we should be able to use the QSA to estimate approximately how large a microwave power change occurred.

***Abstract*—In this paper we consider the theory of coherent population trapping resonance formation in cell with anti-relaxation wall coating illuminated by the narrow laser beam. We study the dependence of resonance amplitude and width on radiation intensity and illuminated zone diameter.**

I. INTRODUCTION

In Ramsey spectroscopy method [1] the ansamble of quantum systems (atoms or molecules) is interrogated by series (at least by two) of coherent field applications separated in time. The Ramsey interrogation can be realized either with an atomic (or molecular) beam passing through two spatially separated fields, or with a pulsed electromagnetic field (see [2] and references therein). The effect of atomic-motion induced Ramsey narrowing of Coherent Copulation Trapping (CPT) resonance has been studied both experimentally and theoretically in buffered and coated cells, see [3-8] and references therein. The signature of this effect is the spectral narrowing of the dark resonance due to motion of oriented atomic spin in-and-out of the optical interaction region, see Figure 1 (a). In [4] the authors identify the main feature of the phenomenon in buffer gas cell while in [5] they extensively explain the model developed for the interpretation. In [6, 8] the atomic-motion narrowing effect was studied experimentally. It was found [6] that in weak fields the light shift and light broadening increase linearly with the square of illuminated zone, i.e. it behaves only on the total power of laser beam. More detailed theory of the CPT resonance formation in partially illuminated wall coated cell without buffer gas was developed in [7]. In [8] the similar theory was developed independently and demonstrates good quantitative agreement with experiment. At the same time, divergences between theory and experiment in [8] increases with the laser intensity and beam diameter.

In present work we consider the theory [7] and the limit case of this theory in weak laser fields. In present work we consider a model based on a simplified three-level atom, see Fig.1.a. We suppose all the main parameters of atom (such as energies of levels, atomic mass, et.c.) close to the parameters of D1-transition in ^{87}Rb atom, where the transition between levels *1* and *2* is microwave and to level *3* is optical.

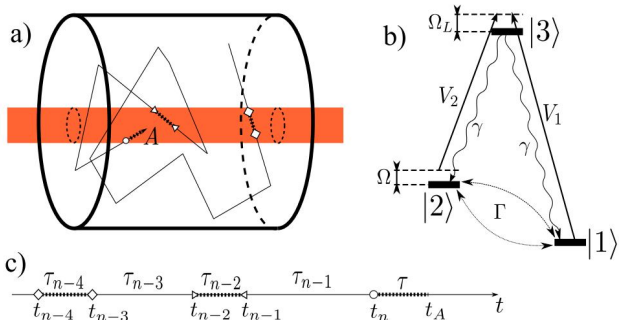

Figure 1. (a): Example of indiviual atom trajectory. Segments of trajectory are shown by fringed lines inside and by solid lines outside the beam (red). (b) Λ system describing the spin state of atom V_1 and V_2 are the laser Rabi frequencies of resonance laser field components, Γ and 2γ are the ground and exited state relaxation rates respectively, Ω_L and Ω_R are the optical and two-photon (Raman) detunings. (c): time axis illustrating the individual "history" of atom.b)

II. THEORETICAL MODEL

A. *Density matrix equations*

The density matrix evolution for this system can be inscribed in common form as:

$$\dot{\rho}_{ij} = -\frac{i}{\hbar}\sum_k \left[H_{ik}\,\rho_{kj} - \rho_{ik}\,H_{kj} \right] + \sum_{k,l} \Gamma_{ij,kl}\,\rho_{kl}\,, \qquad (1)$$

where H_{ik} is the matrix element of the atomic Hamiltonian, $\hat{H}$. Following the standard theory is $\hat{H} = \hat{H}_0 + \hbar\hat{V}(v_z,t)$ where $\hat{H}_0$ is the Hamiltonian of the unperturbed atom including static perturbation and $\hbar\hat{V}(v_z,t)$ represents the atom-laser interaction which depends on the time, *t*, and on the atomic velocity components along the quantization axis, v_z; $\Gamma_{ij,kl}$ is the relaxation matrix element describing the relaxation processess. In the case of atomic system contained in evacuated wall coated cell the relaxation processes are: the collisions between the atom and the coating material, the spin-exchange collisions and the reservoir losses. Also we suppose

that the cell length is small in comparison with wavelength λ_{21} of microwave $|1\rangle \leftrightarrow |2\rangle$ transition. In such a case we can neglect the Doppler broadening of this transition (Dicke narrowing, see [9]).

Let us firstly consider the density matrix equations for atoms inside the laser beam. After goto the rotating frame, adiabatic elimnation of exited state $|3\rangle$, and using the normalization condition $\rho_{11} + \rho_{22} = 1$, one can obtain the equation for spin state density matrix in the beam zone as:

$$\begin{aligned} \dot{f} &= G\frac{V_2^2 - V_1^2}{\gamma'} - (W+\Gamma) f - 4F\frac{V_1 V_2}{\gamma'} J, \\ \dot{R} &= -G\frac{V_1 V_2}{\gamma'} - (W+\Gamma) R - (\Omega - \Delta) J, \\ \dot{J} &= F\frac{V_1 V_2}{\gamma'} f + (\Omega - \Delta) R - (W+\Gamma) J, \end{aligned} \tag{2}$$

where $f = \rho_{11} - \rho_{22}$, $R = \mathrm{Re}(\rho_{12})$, $J = \mathrm{Im}(\rho_{12})$, $\gamma' \simeq \gamma + \Gamma_L / 2$ is the optical coherence relaxation rate, $2\gamma \simeq 3.6 \cdot 10^7$ s^{-1} is the spontaneous decay rate of excited state $|3\rangle$, Γ_L is a laser spectrum line width, $\Delta = F(V_1^2 - V_2^2)/\gamma'$ is a light shift, $W = G(V_1^2 + V_2^2)/\gamma'$ is an optical pumping rate. $F = F(v_z)$ and $G = G(v_z)$ are the real and imaginary parts of $\gamma'/(\gamma' - i(\Omega_L - k v_z))$ respectively, $k = \omega / c$ is the wave number of optical radiation. The variation of the transmitted light is proportional to the exited state population $\rho_{exc} \equiv \rho_{33}$ which can be expressed via ground state density matrix $\hat{\rho} = (f, R, J)$ as

$$\rho_{33} = \frac{W}{2\gamma} + \frac{G}{2\gamma\gamma'}\left(\left[V_1^2 - V_2^2\right] \cdot f + 4 V_1 V_2 \cdot R\right). \tag{3}$$

The set of equations (2) can be symbolically inscribed as

$$\dot{\hat{\rho}}(v_z, t) = \hat{\hat{A}}(v_z)\hat{\rho}(v_z, t) + \hat{B}(v_z), \tag{4}$$

and (4) as

$$\rho_{33}(v_z, t) = \hat{U}^T(v_z)\hat{\rho}(v_z, t) + D(v_z). \tag{5}$$

When atom is outside the laser beam, $\rho_{33} = 0$ and its ground state density matrix $\hat{\rho}$ evolves according to the set of equation similar to (4) but with zero values of V_1, V_2 and Δ:

$$\dot{\hat{\rho}}(v_z, t) = \hat{\hat{A}}'\hat{\rho}(v_z, t). \tag{6}$$

B. Motion of atom inside the cell

In this work we consider the cylindrical cell illuminated by the co-axial cylindrical laser beam. We suppose that the laser intensity is distributed homogeneously over the cross-section of the beam. So we can subdivide all the cell volume by "beam zone" inside the beam and "dark zone" outside the beam. In beam zone the density matrix describing the internal state of certain atom is governed by the equation (4) whereas in dark zone it is governed by equation (6). Let us consider an atom moving by the trajectory showed at Figure 1 (b). Suppose that at observation time t_A atom is in the point A in the beam. During time T between t_n and t_A the density matrix of this atom is governed by equation (4). The solution is:

$$\hat{\rho}(t_A) = \left(e^{\hat{\hat{A}} \cdot T} - 1\right)\hat{\hat{A}}^{-1}\hat{B} + e^{\hat{\hat{A}} \cdot T}\,\hat{\rho}(t_n). \tag{7}$$

In one's turn, during time τ'_{n-1} between t_{n-1} and t_n (see Figure 1(c)) the density matrix evolution is governed by (6).

$$\hat{\rho}(t_n) = e^{\hat{\hat{A}}' \cdot \tau'_{n-1}}\,\hat{\rho}(t_{n-1}), \tag{8}$$

et.c. Therefore we obtain an infinite sequence. After averaging over atomic velocities and times spent in beam and dark zones and summation one obtain [7]:

$$\begin{aligned} \rho_{33} = \overline{D} + \overline{\hat{U}^T (e^{\hat{\hat{A}} \cdot T} - 1)\hat{\hat{A}}^{-1}\hat{B}} + \overline{\hat{U}^T e^{\hat{\hat{A}} \cdot T}} \times \\ \overline{e^{\hat{\hat{A}}' \cdot \tau'}}\left(1 - \overline{e^{\hat{\hat{A}} \cdot \tau}}\,\overline{e^{\hat{\hat{A}}' \cdot \tau'}}\right)^{-1} \overline{\left(e^{\hat{\hat{A}} \cdot \tau} - 1\right)\hat{\hat{A}}^{-1}\hat{B}}. \end{aligned} \tag{9}$$

The averaging procedure will be given below.

If the characteristic velocity of the density matrix evolution is small in comparison with transition rate between illuminated and dark zone, i.e., if

$$\overline{\tau} \cdot (W + \Gamma) << 1, \quad \overline{\tau}' \cdot \Gamma << 1, \tag{10}$$

where $\overline{\tau}$ and $\overline{\tau}'$ are the average times what atom spent in beam and dark zones continuously, we can expand the exponents in (9) linearly. Keeping the zero power term of $\tau \cdot \hat{\hat{A}}$, $\tau' \cdot \hat{\hat{A}}'$ we obtain:

$$\rho_{33} = \overline{D} - \overline{\hat{U}^T} \cdot \left(\overline{\hat{\hat{A}}'\tau'} + \overline{\hat{\hat{A}}\tau}\right)^{-1} \cdot \overline{\hat{B}\tau}. \tag{11}$$

This is an expression for ρ_{33} in the beam zone whereas $\rho_{33} = 0$ in the dark zone. Averaging ρ_{33} over the atomic trajectory or, the same, over the cell volume (this averaging is denoted by brackets), we obtain:

$$\langle \rho_{33} \rangle = \frac{\overline{\tau}}{\overline{\tau} + \overline{\tau}'} \left(\overline{D} - \overline{\hat{U}^T} \left(\overline{\hat{\hat{A}}} + \frac{\overline{\tau}'}{\overline{\tau}} \overline{\hat{\hat{A}}'} \right)^{-1} \overline{\hat{B}} \right). \quad (12)$$

Let us consider an expression (15) more detailed. It is easy to see from (2) — (5) that $\overline{D}$, $\overline{\hat{U}}$ and $\overline{\hat{B}}$ are proportional to the squares of Rabi frequencies V_1 and V_2 and therefore $\overline{D}$, $\overline{\hat{U}}$ and $\overline{\hat{B}}$ linear over the radiation intensity. The matrix $\hat{\hat{A}}$ can be written as $\hat{\hat{A}} = \hat{\hat{A}}' + \hat{\hat{A}}''$, where $\hat{\hat{A}}'$ is independent, and $\hat{\hat{A}}''$ is linear on the radiation intensity. It allows us to rewrite (12) as:

$$\langle \rho_{33} \rangle = \langle \overline{D} \rangle - \left\langle \overline{\hat{U}^T} \right\rangle \left\langle \overline{\hat{\hat{A}}} \right\rangle^{-1} \langle \overline{B} \rangle. \quad (13)$$

Therefore if (11) is fulfilled, the CPT resonance parameters are determined by the total power by the whole cross-section of the cell independently on the laser beam diameter.

It should be noted that the calculation method is applicable to the homogeneously illuminated wall-coated cell with presence of buffer gas. In this case we should put $\overline{\tau}' = 0$ in (11) and threat $\overline{\tau}$ as average time between collisions of active and buffer atoms. It is easy to see that increasing of the buffer gas pressure leads to decreasing of $\overline{\tau}$. It leads to meet the condition (11) of applicability of expression (13).

C. Averaging

Here we describe the details of numerical calculation of (9). Let us denote the eigenvectors and eigenvalues of $\hat{\hat{A}}$ as $\hat{X}^{(i)}$ and λ_i respectively:

$$\hat{\hat{A}} \hat{X}^{(i)} = \lambda_i \hat{X}^{(i)}. \quad (14)$$

Let us introduce the matrixes $\hat{\hat{X}}$ and $\hat{\hat{\Lambda}}$:

$$\hat{\hat{X}} = \left(\hat{X}^{(1)}, \hat{X}^{(2)}, \hat{X}^{(3)} \right), \quad (15)$$

$$\hat{\hat{\Lambda}} = \hat{\hat{X}}^{-1} \hat{\hat{A}} \hat{\hat{X}} = \begin{pmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{pmatrix}. \quad (16)$$

Similarly we build the matrixes $\hat{\hat{X}}'$ and $\hat{\hat{\Lambda}}'$ by the eigenvectors and eigenvalues of $\hat{\hat{A}}'$. Vector $\hat{B}$ can be easily decomposed by $\hat{X}^{(i)}$:

$$\hat{B} = \sum_i \hat{X}^{(i)} b_i = \hat{\hat{X}} \hat{b}, \text{ where } \hat{b} = \hat{\hat{X}}^{-1} \hat{B}. \quad (17)$$

Expressions like $e^{\hat{\hat{A}} \cdot t}$ in (11) can be written as

$$e^{\hat{\hat{A}} \cdot t} = \hat{\hat{X}} e^{\hat{\hat{\Lambda}} \cdot t} \hat{\hat{X}}^{-1} = \hat{\hat{X}} \begin{pmatrix} e^{\lambda_1 t} & 0 & 0 \\ 0 & e^{\lambda_2 t} & 0 \\ 0 & 0 & e^{\lambda_3 t} \end{pmatrix} \hat{\hat{X}}^{-1}. \quad (18)$$

Using (14) — (18) we can express (9) as

$$\begin{aligned} \rho_{33} = \overline{D} + \overline{\hat{U}^T \hat{\hat{X}} (e^{\hat{\hat{\Lambda}} \cdot T} - 1) \hat{\hat{\Lambda}}^{-1} \hat{b}} + \overline{\hat{U}^T \hat{\hat{X}} e^{\hat{\hat{\Lambda}} \cdot T} \hat{\hat{X}}^{-1}} \\ \times \overline{\hat{\hat{X}}' e^{\hat{\hat{\Lambda}}' \cdot \tau'} \hat{\hat{X}}'^{-1}} \left(1 - \overline{\hat{\hat{X}} e^{\hat{\hat{\Lambda}} \cdot \tau} \hat{\hat{X}}^{-1}} \; \overline{\hat{\hat{X}}' e^{\hat{\hat{\Lambda}}' \cdot \tau'} \hat{\hat{X}}^{-1}} \right)^{-1} \\ \times \overline{\hat{\hat{X}} \left(e^{\hat{\hat{\Lambda}} \cdot \tau} - 1 \right) \hat{\hat{\Lambda}}^{-1} \hat{b}}. \end{aligned} \quad (19)$$

Here the overline denotes the averaging over v_z, T, τ and τ'. As an example, let us consider an expression

$$\begin{aligned} \overline{\hat{\hat{X}} e^{\hat{\hat{\Lambda}} \cdot \tau} \hat{\hat{X}}^{-1}} = \int_{-\infty}^{+\infty} M_1(v_z) \times \\ \int_0^{+\infty} \hat{\hat{X}}(v_z) e^{\hat{\hat{\Lambda}}(v_z) \cdot \tau} \hat{\hat{X}}^{-1}(v_z) f(\tau) \, d\tau \, dv_z. \end{aligned} \quad (20)$$

Here $f(\tau)$ is the probability density function of random value τ, $M_1(v_z) = (\pi v_T)^{-1/2} \exp\left(-v_z^2 / v_T^2\right)$ is the one-dimensional Maxwell distribution function for v_z, $v_T = \sqrt{2 k_B T / m}$ is the most probable velocity, k_B — is a Boltzmann constant, T is a temperature, m is atomic mass. It is easy to see that the dependence on τ is appeared only in arguments of $e^{\hat{\hat{\Lambda}}(v_z) \cdot \tau}$ and is reduced to the form of $e^{\lambda' \tau'}$. Therefore it is convinient to introduce the function

$$g(\lambda) = \int_0^{\infty} \exp(\lambda \tau) f(\tau) d\tau \quad (21)$$

and to write down the *il*-th matrix element of (20) as

$$\begin{aligned} \left(\overline{\hat{\hat{X}}' e^{\hat{\hat{\Lambda}}' \cdot \tau'} \hat{\hat{X}}'^{-1}} \right)_{il} = \sum_k \int_{-\infty}^{+\infty} M_1(v_z) \times \\ X'_{ik}(v_z) \cdot g'\left(\lambda'_k(v_z) \right) \cdot \hat{\hat{X}}^{-1}_{kl}(v_z) dv_z. \end{aligned} \quad (22)$$

This expression contains only one integral over v_z.

Now let us find the probability distribution functions $f(\tau)$, $f'(\tau')$ and $f_T(T)$. The time τ what atom spent in the beam is

$$\tau = \frac{2\sqrt{r^2 - R^2 \sin^2 \varphi}}{v_\perp}, \tag{23}$$

where φ is an angle between the atomic velocity projection $\vec{v}_\perp$ on the plane orthogonal to the cell axis and the vector normal to the cell vall, R and r are the cell and beam radius respectively, $v_\perp = |\vec{v}_\perp|$. The probability density function of $v_\perp$ is a two-dimensional Maxwell distribution function $M_2(v_\perp) = 2\exp\left(-v_\perp^2 / v_T^2\right) v_\perp / v_T^2$. The probability density function $\Phi(\varphi)$ of random value φ is proportional to $\cos\varphi$ [8]. Note that the value of φ varies from 0 to $\arcsin(r/R)$ if atom passes the beam. Therefore $\Phi(\varphi) = R\cos\varphi / r$. It gives us the cumulative distribution function $F_\tau(\tau)$ of random value τ as

$$\begin{aligned} F_\tau(\tau) &= \int_0^{\arcsin(r/R)} \Phi(\varphi) \int_{\frac{2\sqrt{r^2 - R^2\sin^2\varphi}}{\tau}}^{\infty} M_2(v_\perp) dv_\perp d\varphi \\ &= \frac{\tau v_T \sqrt{\pi}}{4ir} e^{-\frac{4r^2}{\tau^2 v_T^2}} \operatorname{erf}\left(\frac{2ir}{\tau v_T}\right), \end{aligned} \tag{24}$$

what gives us $f(\tau)$ as

$$f_\tau(\tau) = \frac{dF_\tau(\tau)}{d\tau} = -\frac{1}{\tau} + \frac{v_T\sqrt{\pi}}{4ir} e^{-\frac{4r^2}{\tau^2 v_T^2}} \operatorname{erf}\left(\frac{2ir}{\tau v_T}\right)\left[1 + \frac{8r^2}{\tau^2 v_T^2}\right]. \tag{25}$$

The average time $\overline{\tau}$ what atom spend in the beam continuously is

$$\overline{\tau} = \int_0^\infty f(\tau)\,\tau\, d\tau = \int_0^\infty \left(1 - F(\tau)\right) d\tau = \frac{\pi^{3/2}}{2}\frac{r}{v_T}. \tag{26}$$

Now let us find the probability density function f_t of time t what atom continuously spent in the beam before the observation time t_A. Let dn/dt is a number of atoms coming into the beam per unit of time. Total number of atoms in the beam is:

$$N_{tot} = \int_0^\infty \left(1 - F_\tau(t')\right)\frac{dn}{dt'} dt', \tag{27}$$

(because $1 - F_\tau(t')$ is the probability for atom to survive in the beam during time t'). Therefore the number of atoms what already spent time t or more is

$$N_{t+} = \int_t^\infty \left(1 - F_\tau(t')\right)\frac{dn}{dt'} dt'. \tag{28}$$

It gives us the cumulative distribution function $F_t(t)$:

$$F_t(t) = 1 - \frac{\int_t^\infty \left(1 - F_\tau(t')\right)\frac{dn}{dt'} dt'}{\int_0^\infty \left(1 - F_\tau(t')\right)\frac{dn}{dt'} dt'}, \tag{29}$$

and the probability density function f_t:

$$f_t(t) = \frac{1 - F_\tau(t)}{\int_0^\infty \left(1 - F_\tau(t')\right) dt'} = \frac{1 - F_\tau(t)}{\overline{\tau}}. \tag{30}$$

It gives:

$$g_\tau(\lambda) = 1 + \lambda\,\overline{\tau}\, g_t(\lambda). \tag{31}$$

We should note that the function $g_t(\lambda) = \int_0^\infty e^{\lambda x} \cdot f_t(t)\, dt$ can not be expressed via elementary functions. So we approximated the exact expression (30) by

$$\begin{aligned} f_t(t) &\to \frac{v_T}{r}\tilde{f}_t\left(t\frac{v_T}{r}\right), \\ \tilde{f}_t(x) &= \frac{2}{\pi^{3/2}} e^{-bx} + \frac{16\left(1 - e^{-ax}\right)^3}{3\pi^{3/2} x^2} + A x e^{-cx}. \end{aligned} \tag{32}$$

The coefficients $A = 0.70839$, $a = 0.49$, $b = 2.286$ and $c = 1.272$ were chosen so as to functions $f_t(t)$ and $\tilde{f}_t\left(t\, v_T / r\right) v_T / r$ have the same asymptotes at infinity coincides near zero to a second-order terms by t inclusive, and that the function $\tilde{f}_t(x)$ has the correct norm $\int_0^\infty \tilde{f}_t(x)\, dx = 1$. It gives us

$$\begin{aligned} g_t(\lambda) &= \tilde{g}_t(\lambda r / v_T), \\ \tilde{g}_t(\Lambda) &= \frac{2}{\pi^{3/2}}\frac{1}{b - \lambda} + \frac{A}{(c - \lambda)^2} + \frac{16}{3\pi^{3/2}}\big(p(-\Lambda) \\ &\quad - 3p(a - \Lambda) + 3p(2a - \Lambda) - p(3a - \Lambda)\big), \end{aligned} \tag{33}$$

where $p(\beta) = \beta \ln \beta$. It is easy to find $g_\tau(\lambda)$ using (33) and (31).

At last we must found the probability density function $f'(\tau')$ for time τ' what atom spent in dark zone before go to beam. There are two different possibilities for atom when it is collide with the cell wall: it can collide elastically, or stick to the wall and after fly out in arbitrary direction. If atom is sticking to the wall after collision, we should note that the probability for atom to reach the highlighted zone between some pair of consecutive wall collisions is much less than to move through the cell in dark zone. In any wall collision act atom obtain some random value of velocity, and the probability to reach the highlighted zone is not depend on the number of collisions what atom experienced being in dark zone continuously. Therefore the probability density function $f'(\tau')$ can be approximated by the exponential distribution:

$$f'(\tau') = \frac{1}{\overline{\tau}'} \exp\left[-\frac{\tau'}{\overline{\tau}'}\right], \tag{34}$$

what gives

$$g'(\lambda') = \frac{1}{1-\lambda'\overline{\tau}'}. \tag{35}$$

Average time $\overline{\tau}'$ what atom spent in dark zone continuously can be calculated as

$$\overline{\tau}' = \overline{\tau}\frac{R^2 - r^2}{r^2}. \tag{36}$$

III. Results and Discussion

We made the simulations of the CPT resonance line shape and dark resonance parameters in Λ-atomic vapors in cylindrical cell with $R = 0.5$ cm. Atomic mass Macca атомов m was taken to be equal of ^{87}Rb mass, $T = 20$ °C, ground state relaxation rate $\Gamma = 300$ s^{-1}, optical coherence relaxation rate $\gamma' = 1{,}8 \cdot 10^7$ s^{-1}, $V_1 = V_2 = V$, $\Omega_L = 0$. Beam radius r was a variable parameter. We took the optical pumping rate $\overline{W}$ averaged over v_z as a main characteristic of laser intensity:

$$\overline{W} = \frac{2V^2}{\gamma'}\overline{G}, \quad \overline{G} = \int_{-\infty}^{+\infty} M_1(v_z)\, G(v_z)\, dv_z. \tag{37}$$

In our case $\overline{G} \approx 0{,}0168$, and $V = 2{,}3 \cdot 10^4 \sqrt{\overline{W}}$, where both V and $\overline{W}$ are measured in inverse seconds ($2\pi \cdot 1$ s^{-1} = 1 Hz).

It is convenient to introduce the value of

$$\left\langle \overline{W} \right\rangle = \frac{\overline{W} \cdot r^2}{R^2} = \frac{\overline{W} \cdot \overline{\tau}}{\overline{\tau}' + \overline{\tau}}. \tag{38}$$

i.e. the optical pumping rate averaged both over v_z and the cell volume. The value of $\left\langle \overline{W} \right\rangle$ is determined by the ratio of the laser power to the cell cross-section square.

It should be noted that the main contribution into the CPT resonance formation comes from the slow atoms whose velocity projection v_z is less or of order of $\gamma' \cdot \omega / c$. Therefore it is useful to introduce the characteristic optical pumping rate for slow atoms:

$$W_{slow} = V^2 / \gamma' = \overline{W} / (2\overline{G}). \tag{39}$$

Typical dark resonance line shape calculated according eq. (9) is presented on Figure 3. The resonance has characteristic "dual" structure: it consists on the broad "pedestal" with several tenth of kHz width, and a narrow central peak whose width is about 100 Hz. The broad peak is formed by atoms whose passed the beam once whereas the narrow peak is formed by multiply passage. This result is in agreement with experimental data presented in [3,5,6,8].

We studied the dependence of the central peak parameters on the laser power and beam diameter and verified the applicability of eq. (13). The $\left\langle \overline{W} \right\rangle$- dependences of central peak amplitude and FWHM are presented on Figure 3 and Figure 4 respectively. These dependences were calculated according (13) (solid line) and according (9) for various values of r. It should be outlined that $\left\langle \overline{W} \right\rangle$ is proportional to the laser intensity what is inverse proportional to r^2 at fixed laser power. Therefore the narrowing of the beam (at fixed power) leads to the narrowing and decreasing of amplitude of the CPT resonance.

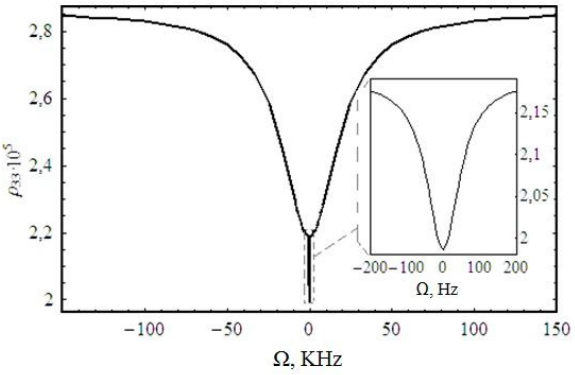

Figure 2. Dual structure of the dark resonance for $\overline{W} = 10^3$ s^{-1} and $r = 1$ mm.

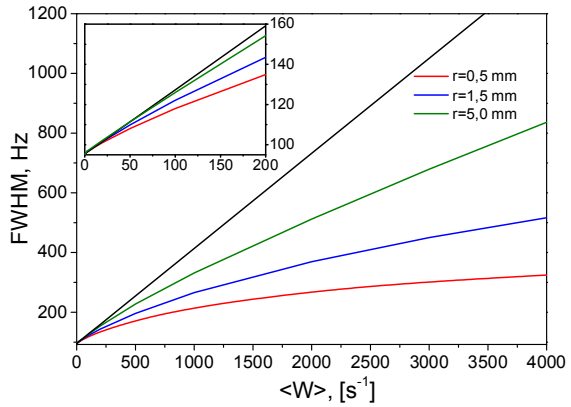

Figure 3. Dependence of the CPT resonance line width on $\langle \overline{W} \rangle$. The resonance line shape was calculated according (13) (solid line), and (9) (short dash, dot and dash) for various values of r.

Let us consider now the applicability of eq. (13). Characteristic values of $\overline{\tau}$ are: $\overline{\tau} = 5.9 \cdot 10^{-6}$ s for $r = 0.5$ mm, $\overline{\tau} = 1.75 \cdot 10^{-5}$ s for $r = 1.5$ mm, and $\overline{\tau} = 5.03 \cdot 10^{-5}$ s for $r = 5$ mm (in the last case the time $\overline{\tau}$ is not the time what atom spent in the beam continuously but the time between velocity-changing collisions). Consider the conditions (10) of applicability of eq. (13). In our case $\Gamma = 300$ s^{-1}, and even at $r = 0.5$ mm the value of $\overline{\tau}' = 5,8 \cdot 10^{-4}$ s, the second condition of (10) is fulfilled. The first condition of (13) reads as $\overline{\tau} \cdot W_{slow} << 1$ for slow atoms. It gives the following bounds for $\langle \overline{W} \rangle$: $\langle \overline{W} \rangle << 56$ s^{-1} for $r = 0,5$ mm, $\langle \overline{W} \rangle << 170$ s^{-1} for $r = 1,5$ mm, and $\langle \overline{W} \rangle << 660$ s^{-1} for $r = 5$ mm. Figure 4 shows that the resonance linewidth calculated according (13) and (16) are noticeably differs from these values of $\langle \overline{W} \rangle$.

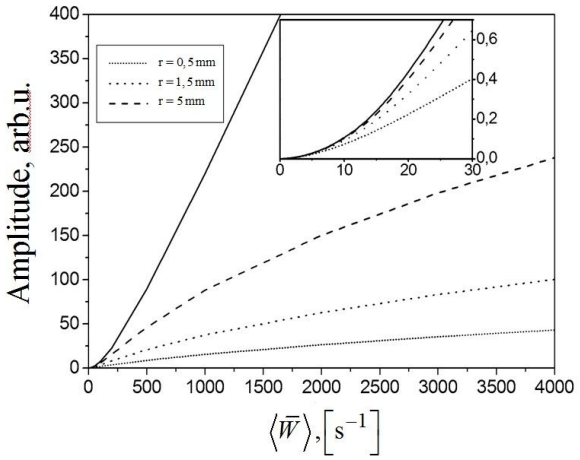

Figure 4. Dependence of the CPT resonance amplitude on $\langle \overline{W} \rangle$. The resonance line shape was calculated according (13) (solid line), and (9) (short dash, dot and dash) for various values of r.

The dependence of central peak amplitude on $\langle \overline{W} \rangle$ is presented on Figure 5. As for FWHM, the formula (13) is applicable if conditions (10) are fulfilled. But now these conditions reads strongly, i.e., $W_{slow} \cdot \overline{\tau} < 0.1$. It should be noted that even if the laser beam illuminate the whole cell volume, the CPT resonance amplitude doesn't reach the values predicted by formula (13). To increase the amplitude it is necessary to increase the velocity-changing collisions rate. It can be attained by adding some amount of buffer gas into wall-coated cell.

IV. Conclusion

In present work we present the theory of CPT resonance formation in partially illuminated wall-coated cell without buffer gas. This method is applicable also to the wall-coated cell with buffer gas below the diffusion approximation density limit, if these cells are illuminated by the laser light homogeneously. We obtain a simple calculation formula (13) what can be used if conditions (10) are fulfilled. It is found that if conditions (10) are broken, both amplitude and linewidth decreases with decreasing of the laser beam diameter, but amplitude decreases more significantly.

Abstract: This paper introduces a digital servo using single frequency modulation for passive hydrogen maser. The main parts of this system include ADC, FPGA and DAC which sample error signal, process the signal and output two channels controlling voltage.

The algorithm is used to separate two errors by single frequency modulation principle. Then response curves of two channels are gotten to calculate proper PID controller parameters. In the end, two incremental PID controllers are used to get two channels control voltage to control the resonant cavity and OCXO respectively. The influence caused by the speed and precision of DAC to frequency stability has been analyzed. The experiments prove that the precision of DAC had a little influence on the short and medium term frequency stability at high control speed

The frequency stability of passive hydrogen maser with this system has been tested. It has achieved at $\sigma_y(1000)<3\times10^{-14}$.

I. INTRODUCTION

Shanghai Astronomical Observatory has devoted to development of hydrogen maser for a long period, since 2002 study on passive hydrogen maser had been carried out [1]. Since 2008, the electrical system digitization of signal-frequency passive hydrogen maser has been studying. The research of digital servo is a part of it, which Simplifies parameter regulation. And it has been achieved at $\sigma_y(1000)<3\times10^{-14}$.

II. DESIGN

In the physics package, magnetron cavity is used. The bulb is located in the center of cylindrical radiofrequency cavity. The magnetic shielding of the physics package has 4 layers and its shielding factor is about 50000.The passive Hydrogen maser is subdivided into two principal functional packages, the physics package which provides the actual atomic oscillator, and the electronic package which provides the atomic signal processing circuits and parameter control functions. The gain of physics package maser is about 3.2dB at -80dBm microwave signal input, and the H line-width is about 5Hz, as shown in fig1.

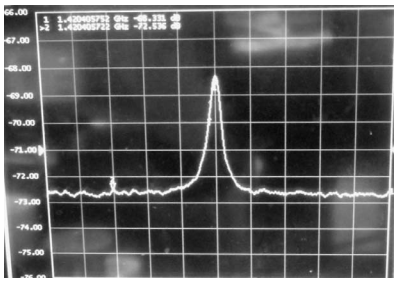

Figure 1. The parameters of the passive maser.

The main units of electronic package are detailed in fig2.These units are in charge of frequency locking of an OCXO (Oven Controlled Crystal Oscillator) and ACT (Automatic Cavity Turning) varactor diodes which compensates the frequency variation of the cavity.

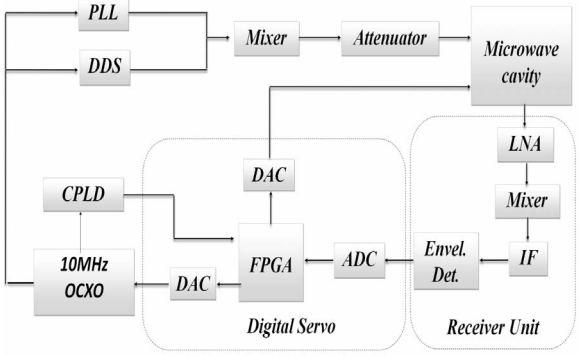

Figure 2. The functional block diagram of the passive H maser

Supported by:
National Natural Science Foundation of China, No. 110910778704

The 10MHz of the OCXO is directly multiplied by 140 to 1.4GHz, at the same time, it is multiplied to provide the clock of DDS to generate 20.405157Hz FSK modulated signal. The modulating signal is square wave frequency at 12.5 KHz provided by CPLD. The 1.4GHz and the modulated signal are mixed to allow double servo system for both the OCXO and ACT. After the interaction with the hydrogen atoms in microwave cavity, the output signal are first amplified by Low Noise Amplifier (LNA), then frequency mix with a free running oscillator to 20 MHz, and AM converted by envelope detector after Intermediate Frequency (IF) amplifier to generate the error signal at 12.5KHz. Finally the error signal is processed by the servo system together with Phase shifter signal from CPLD to get proper control voltage for OCXO and ACT varactor diodes.

FPGA maximizes the flexibility of the controller because it can be varied through programming means, without modification of the controller hardware. This paper introduces a digital servo system based on FPGA.

The main hardware structures of this system include ADC, FPGA and DAC. The block diagram of the digital servo system is shown in Fig. 3.

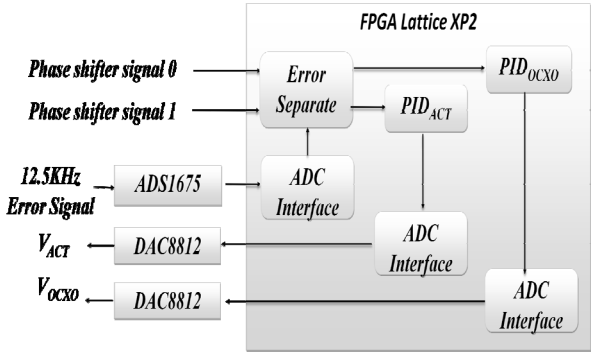

Figure 3. Block diagram of digital servo system

The ADS1675 samples the error signal form receiver unit at high sampling rate 1.28MHz. The ADC interface generates control signals in the FPGA that control the ADS1675 and transfer the 24 bit data to error separate module.

The error separate module separates two errors by single frequency modulation principle [2].

The two increment PID control systems take the errors and computes the correct signal based on the equation respectively [3].

$$\begin{aligned}\Delta u(k) &= u(k) - u(k-1) \\ &= P(\mathrm{e}(k) - \mathrm{e}(k-1)) \\ &+ I\mathrm{e}(k) + D(e(k) - 2e(k-1) + e(k-2))\end{aligned} \tag{1}$$

Δu is correction signal for OCXO and ACT varactor diodes; e is error; P, I and D are the proportional, derivative and integral parameters. PID parameters can be gotten from the response curves of two channels scanning process, which calculate proper PID controller parameters.

The two ADC interfaces generate necessary control signal in FPGA that control the DAC8812s and transfer the 16 bit data from the PIDs to DACs respectively. DAC8812s output DC voltage to control OCXO and ACT varactor diodes.

The state machine of the FPGA coding has 6 states, as shown in fig.4.

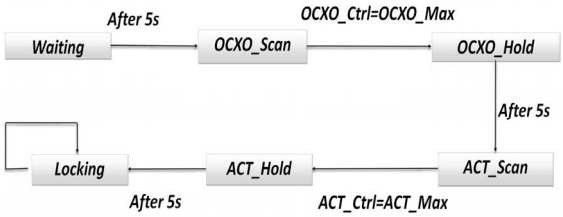

Figure 4. The state machine of the FPGA coding

At first waiting for 5s, In this state, the OCXO_Ctrl (The control variable of OCXO) set as the minimum, the ACT_Ctrl (The control variable of ACT varactor diodes) set as initial value. After 5s, get into OCXO_Scan state, in this state the OCXO_Ctrl increases to maximum.by degrees At the same time the maximum, minimum and square minimum error of the OCXO is ongoing record (fig. 5). In the COXO_Hold state, The Kp, Kd and Ki of PIDOCXO is calculated by response curve of OCXO_Scan , and set the OCXO_Ctrl at error square minimum point. The ACT_Ctrl has been also set as minimum. After 5s, get into ACT_Scan state, in this state, similar with OCXO_Scan to get response curve of ACT varactor diodes (fig. 6). In ACT_Hold state, The Kp, Kd and Ki of PIDACT is calculated by the results of ACT_Scan, and set the ACT_Ctrl at error square minimum point. The system will be in locking state after 5s. In Locking state, two channel of PID control the OCXO and ACT varactor diodes at its own speed.

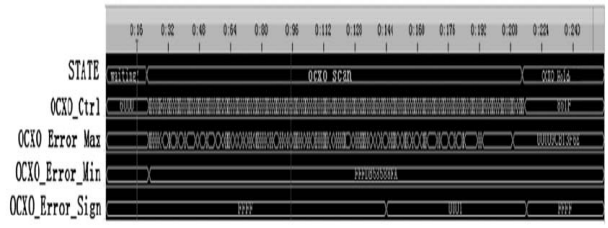

Figure 5. The OCXO_Scan state

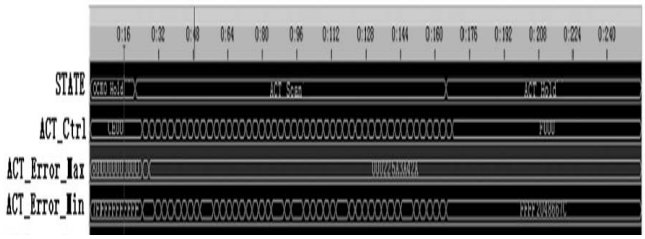

Figure 6. The ACT_Scan state

Form these two figure, we can see that the response curve of OCXO and ACT are linear within the scope of the scanning. The scope of the scanning is gotten from the experiment, and they will lock in this liner scope too.

III. VERIFICATION

Based on the above software and hardware, digital servo circuit is completed. In order to validate digital servo circuit, the frequency stability of the passive H maser with this digital servo is tested by PicoTime (from SpectraTime of Switzerland). The active H maser VCH-1003 provides the reference frequency. Tested results shown that frequency stability of the passive H-maser has been achieved at $\sigma_y(1000)<3\times10^{-14}$.

The experiments in the influence caused by the speed and precision of DA on frequency stability have been done for component selection.

The FPGA controls the DAC to imitate 14 bit, 13bit, 12bit DAC. The frequency stability has been tested with these different DAC at 7ms control speed. The experiments prove that DA had a little influence on the Short and medium term frequency stability at high control speed.

IV. CONCLUSION

This paper details the software and hardware design of a digital servo using single frequency modulation for passive hydrogen maser. Based on this servo system, good short-term stability is achieved. In order to further validate the effectiveness of the designed system, long-term stability will be tested with parameter regulation in future.

The Orientation Dependence of the SHF Radio-Optical Resonance Frequency Light Shift in Rubidium Vapors

***Abstract*— The results of the theoretical and experimental research of the light and orientation frequency shift effects in laboratory scheme of the ^{87}Rb cell frequency standard are provided. The real orientation frequency shift importance is shown.**

I. INTRODUCTION

The information on dynamics of behavior of so-called light shift has principal significance for utilization of a radio-optical resonance effect. With reference to vapors of the alkaline metals light shift as it is known contains two components [1]:

- Scalar shift $\Delta\nu_0$ which has similar values for all magnetic sublevels of the hyperfine structure F or F^*
- Tensor shift $\Delta\nu_T$ which is connected to the atom polarization dependence on the quantum magnetic number m_F

Light shift effect is a major destabilizing factor in the optical pumped quantum discriminators used in the rubidium vapor cell frequency standards [2]. In the classical scheme which suggests usage of isotopic filtering of the pumping light, the errors in these devices are largely determined by the scalar component of the light shift.

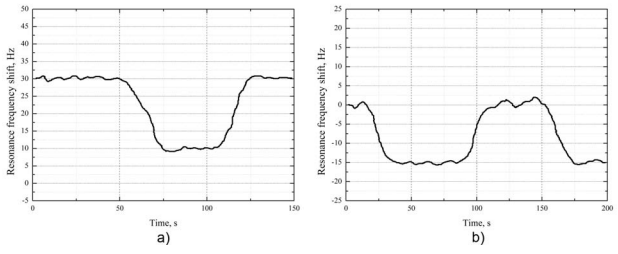

Figure 1. An example of the light(a) and orientation(b) shifts recording

In the case of optical pumping of ^{87}Rb vapor by nonresonant light of the second isotope contribution of the tensor component in the resulting light shift of the *0-0* transition does not exceed *15* and *2%* respectively for the pumping lines D_1 and D_2 [3]. As shown in [4], the situation changes radically if the optical pumping of ^{87}Rb vapor is provided by the spectral lamp with isotopic filtering of resonant light in a ^{85}Rb vapor cell. So, when pumping is provided by only D_1 spectral line $\Delta\nu_T$ values of magnetic-independent microwave transition can be significantly (several times) greater than the scalar frequency shift $\Delta\nu_0$. In this case, a characteristic feature of the light shift tensor component is its proportionality to the factor $1\text{-}3\cos^2\theta$, where θ is an angle between the direction of the working magnetic field and the pumping light beam [5].

The consequence of this dependence is ability to control the light shift in order to minimize it in the rubidium quantum discriminators used in the technique of frequency model measures [2]. This paper presents experimental results that confirm analytical studies [4] for various modes of spectrally selective optical pumping of ^{87}Rb vapors.

II. EXPERIMENT

The experiment was provided on a laboratory prototype of a quantum discriminator, which functional diagram contains the well-known set of composite components used in the gas cell frequency standards.

The discriminator was placed to the center of Helmholtz coils that create magnetic field in the working area of the absorption chamber with a working substance inside. To reduce external magnetic disturbances and irregularities of the laboratory magnetic field the entire system was placed in a dual-layer magnetic shield with a shielding factor about 10^3. Resonant microwave field that induces transitions in the hyperfine structure of rubidium atoms was produced by the ordinary scheme of frequency multiplication of the reference oscillator, followed by amplification. In the detection of the radio-optical resonance signal the standard synchronous detection technique and frequency servo-control of the reference oscillator to the resonance value were used.

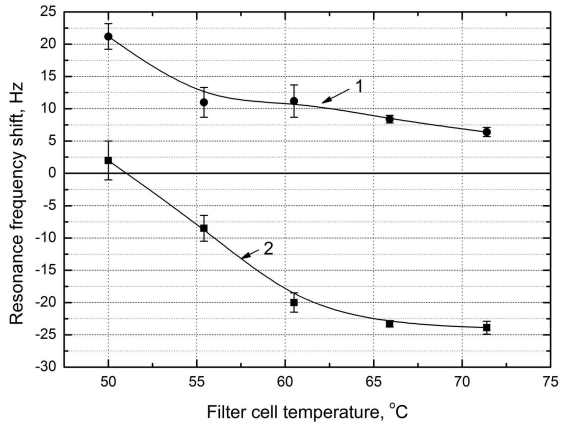

Figure 2. Experimental dependences of experimental dependences of the orientation (1) and light (2) shifts on the filter cell temperature for $I_{D1}=1,5I_{D2}$

Light-shift behavior was observed on the PC monitor at a fixed change in the pumping light intensity by a neutral and interference filters while changing the magnetic field direction angle θ from *0* to *90°* Fig. 1. The corresponding experimental dependences of the light and orientation shifts on the filter cell temperature in the case of optical pumping by the lamp source with spectral components intensity ratio D_1 and D_2 as 2 to 3 are shown on the Fig. 2.

The figure shows that there is no such filter cell temperature that provides a zero orientation shift for noticed above pump regime. This conclusion sorts well with the findings of the analytical studies [4] and illustrates the importance of the tensor component of the D_1 pumping line even in the form of a significant weakening of the D_2 line. To determine their optimum ratio at which the orientation shift of *0-0* transition frequency is minimized, we calculated the corresponding dependence, similar to how it is done in [4].

III. THEORY

The calculation was performed for the pump spectrum approximated by the sum of the Doppler contours with different weight contribution of the components D_1 and D_2 (Fig. 3 (a,b)) at a constant integrated intensity of the source (100μW/cm2). It is clear that requirements for the spectral component composition of the lamp source are not identical for minimization both light and orientation frequency shifts in the resonance transition. This situation causes to meet compromise requirements to maintain a high stability of the quantum discriminator's operating frequency.

In the case of laser pumping of one of the D_2 transition lines, orientation frequency shift is much higher than the value observed at the same integrated intensity of the spectral lamp source Fig. 4. In this case, attention is drawn to the fact that orientation shift takes place even at a zero light frequency shift that corresponds to the laser source tuned on the resonant frequency of the atomic transition.

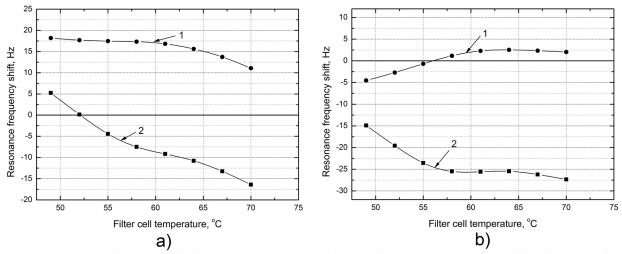

Figure 3. Calculated dependences of the orientation (1) and light (2) shifts on the filter cell temperature for different pumping modes: a) $I_{D1}=1,5I_{D2}$ b) $I_{D1}=10I_{D2}$

IV. CONCLUSION

Our experiments and calculations confirm an essential role of the tensor component for the orientation frequency shift of the *0-0* transition for both spectral lamp and laser pumping. In the experiment with lamp source interference filters usage can only reduce but not eliminate the influence of this component. However, it can significantly reduce the orientation shift of the *0-0* transition. For instance, ratio of intensities of the D_1 and D_2 lines as 1 to 20 leads to a tenfold weakening of the orientation shift in the filter cell temperature range 60-70 °C.

The results of these studies suggest that despite the relatively weak dependence of the frequency of the *0-0* transition on the absolute value of the external magnetic field, the requirement to ensure the constancy of the angle between the pumping light direction and the magnetic field vector is absolutely essential in quantum discriminators for moving and rotating applications.

Abstract—Adequate coherent pulsed microwave input into microwave cavity of atomic clock can induce Ramsey fringes of the atomic transition, by which the line width of atomic clock can be greatly reduced and the performance might be improved. This method has been applied to the pulsed optically pumped （POP） rubidium clock.

Shanghai Astronomical Observatory has studied the application of this method in passive hydrogen maser. Electrical circuit for pulsed microwave frequency sweeping has been designed, and the Ramsey fringes of hydrogen atom have been observed, which means that this method for passive hydrogen maser is feasible. We plan to optimize the parameters of the system and microwave pulse to further reduce the line width and design full-scale servo circuit to realize the pulsed microwave hydrogen maser. Finally system performance will be measured and optimized. This work is original in China.

I. Introduction

For the property of high stability and narrow width, transition spectrum of specific atom can be utilized as reference signal to control crystal oscillator. This is the basic principle of atomic clock. Line width of the atomic transition spectrum is one of the most critical factors of the atomic clock [1]. All kinds of technologies are taken to ensure the narrow line width. In the passive rubidium clocks, glass cell filled with buffer gas is adopted to keep rubidium atoms in a rather limited space so as to reduce the Doppler broadening; in the hydrogen clocks, the atomic storage bulb technology is introduced, which greatly extends the atoms' storage time and their life time; in the caesium beam clocks, method of separated interaction regions works: caesium atoms pass two separated in-phase microwave fields when flying in the physical package which induces Ramsey interference whose line width at central fringe is greatly reduced.

Recently, a new method to induce Ramsey interference emerges. Successively importing two coherent pulsed microwave signals into the microwave cavity could simulate two coherent microwave fields which are separated in space. Ramsey interference could also be induced in this way. This method has been applied to the pulsed optically pumped (POP) rubidium clock successfully. Ramsey interference fringes have been observed and the POP rubidium clock has been locked on the central Ramsey interference fringe.

Principle of passive hydrogen maser is similar to rubidium clock. Atoms interact with detecting signal. Stimulated transition is induced and error signal is provided, by which voltage-controlled crystal oscillator is locked. And atomic signal gain of the passive hydrogen maser is about 3dB. So the method inducing Ramsey interference with pulsed microwave could also be applied to passive hydrogen maser. Time & frequency research center in Shanghai Astronomical Observatory has carried out research on pulsed microwave atomic clock based on conventional passive hydrogen maser.

II. Theory

When two coherent microwave pulses are imported into the passive hydrogen maser, the transition probability $P(\tau)$ of atom system is [2]

This research is supported by National Natural Science Foundation of China, No.11003037
Also supported by the Knowledge Innovation Program of the Chinese Academy of Sciences

$$P(\tau)=\frac{4b^2}{\Omega^2}\sin^2\frac{1}{2}\Omega\tau \left(\cos\frac{1}{2}\Omega\tau\cos\frac{1}{2}\Omega_0 T-\frac{\Omega_0}{\Omega}\sin\frac{1}{2}\Omega\tau\sin\frac{1}{2}\Omega_0 T\right)^2, \quad (1)$$

where b represents the Rabi angular frequency, Ω_0 is the angular frequency offset of imported microwave signal from atomic resonance frequency, T is the interval between two coherent pulses and Ω is defined as

$$\Omega^2=b^2+\Omega_0^2. \quad (2)$$

When the frequency of inducing microwave fits the atomic resonance frequency, which means $\Omega_0=0$, (1) and (2) give

$$P(\tau)=\sin^2 b\tau. \quad (3)$$

Equation (3) shows that, when $b\times\tau=\pi/2$, the transition probability $P(\tau)$ attains maximum. So if $\tau=10\times10^{-3}s$, we should set $b=157rad/s$. In the microwave cavity of hydrogen clock, b is determined by (4):

$$b=\mu_B\langle B_z\rangle_b/\hbar, \quad (4)$$

where μ_B is Bohr magneton, $\langle B_Z\rangle_b$ is the mean value, over the bulb volume, of the amplitude of the projection of the microwave magnetic induction on the direction z of the static magnetic field. And the microwave power P in the cavity is:

$$P=\varpi_0 V_b\langle B_z\rangle_b^2/2\mu_0 Q_C\eta', \quad (5)$$

where ϖ_0 is the hydrogen atom transition frequency, V_b is the volume of the atomic storage bulb, μ_0 is the permeability of vacuum, Q_C is the cavity quality factor and η' is the filling factor of the microwave cavity. From (4) and (5), the microwave power P in the cavity is given by

$$P=\varpi_0 V_b b^2\hbar^2/2\mu_0\mu_B^2 Q_C\eta'. \quad (6)$$

Assuming $b=157rad/s$, from (6) we have $P=0.91\times10^{-9}W$, about-$59.6dBm$. That is to say, if the width of microwave pulse is $10\times10^{-3}s$, the microwave power in the storage bulb of hydrogen clock should be $-59.6dBm$. Considering that the microwave cavity has energy attenuation of about $-13dB$, imported power of the microwave pulse should be about $-47dBm$.

III. Experimental Setup

To verify the applicability of inducing Ramsey interference with microwave pulse in passive hydrogen maser, we construct a set of test system to detect the Ramsey interference fringes of hydrogen atoms. Fig. 1 shows the schematic of the test system.

The physics package of microwave pulsed hydrogen clock is based on conventional passive hydrogen maser. The physics package contains electrode microwave cavity, whose loaded quality factor is about 10000, energy attenuation is about -13dB and filling factor is about 0.5. The atomic storage bulb has a diameter of 60×

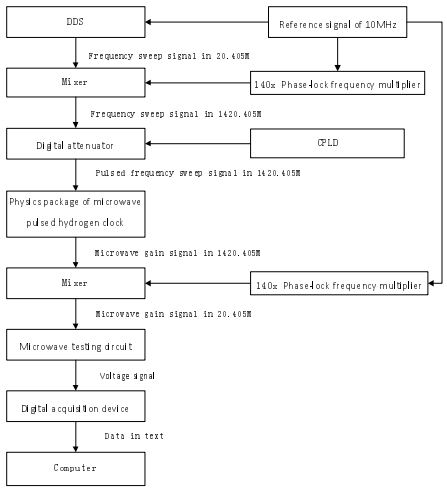

Fig. 1. Schematic setup of the test system for Ramsey fringes of hydrogen maser.

10^{-3}m, a length of 150×10^{-3}m and a volume of 420×10^{-3}L. Storage time of atoms is about 0.8s. The working current of 3×10^{3}V ion pump is 300×10^{-6}A. Relaxation time T1 and T2 of hydrogen atoms are about 200×10^{-3}s. There are 4 layers of magnetic shielding, whose shielding factor is about 50000.

In the test system, a reference signal of 10×10^{6}Hz is multiplied to 1.4×10^{9}Hz by a phase-lock frequency multiplier, then mixed with intermediate frequency signal of 20.405×10^{6}Hz generated by Direct Digital Synthesizer(DDS) to output microwave signal at 1.420405×10^{9}Hz. Pattern control signal generated by Complex Programmable Logic Device (CPLD) has a pulse duration $t_1=10\times10^{-3}$s, a typical pulse interval $t_p=100\times10^{-3}$s and a Ramsey time $T=t_1+t_p=110\times10^{-3}$s, which are shown in Fig. 2. It controls the digital attenuator which attenuates the 1.420405×10^{9}Hz microwave signal to obtain pulsed microwave signal. We should adjust the power of the microwave signal to ensure $b\times t_1=\pi/2$. The pulsed microwave signal is imported into the microwave cavity and interacts with hydrogen atoms, and then Ramsey interference could be induced. Frequency of the intermediate frequency signal is adjusted linearly to implement frequency sweep whose center frequency is $1.420405xxx\times10^{9}$Hz and width is 100Hz. Microwave signal in cavity is exported, mixed to about 20×10^{6}Hz and transformed to voltage signal by a microwave testing circuit composed of AD8307. The voltage signal is collected and stored by the digital acquisition device. Accumulating a period of the data, we can get the Ramsey fringes.

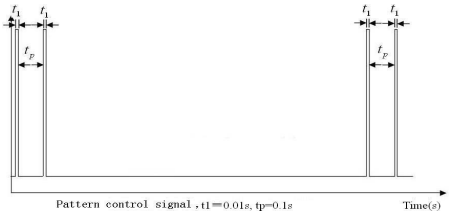

Fig. 2. Pattern control signal generated by CPLD.

IV.Most Recent Result

At present, we have gotten the decay signal of hydrogen atoms induced by the microwave pulses, shown in Fig. 3. Ramsey fringes could be obtained by collecting and processing the data in effective region, shown in Fig. 4. The central fringe with line width of about 1.5Hz and the side fringes are clear in Fig. 4.

The S curve could be acquired by differentiating the data of the Ramsey fringes and be used to lock the hydrogen clock in future, shown in Fig. 5. Changing the power of the pulsed microwave to make $b\times t_1$ deviate from $\pi/2$ will broaden the Ramsey fringes, shown in Fig. 6. This fit the result of the relevant experiments[3].

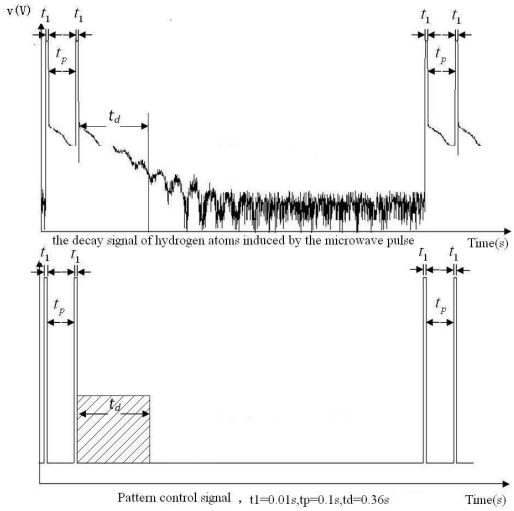

Fig. 3. Relaxation signal of hydrogen atoms stimulated by pulsed microwave signal.

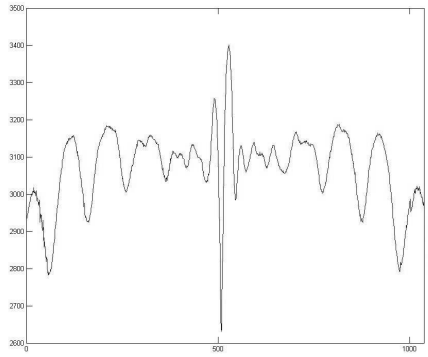

Fig. 4. Ramsey fringes of hydrogen maser.

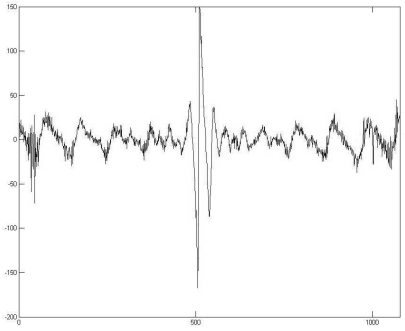

Fig. 5. S curve of pulsed microwave hydrogen maser.

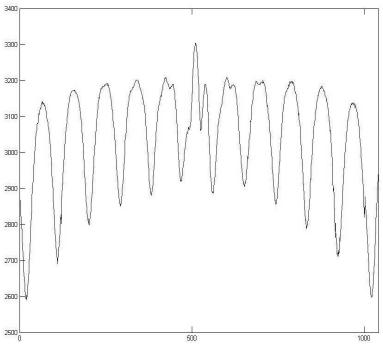

Fig. 6. The Ramsey fringes of hydrogen maser at deflected microwave pulse parameters.

Increasing the pulse interval t_p could compress the line width of the Ramsey fringes. Fig. 7 shows the contrast of the line widths of the Ramsey fringes in different intervals. And when $t_p=160\times10^{-3}$s, the line width is down to about 1.2Hz.

V. Discussion

Time & frequency research center in Shanghai Astronomical Observatory has carried out theoretical analysis and relative researches on pulsed microwave atomic clock based on conventional passive hydrogen maser and has constructed a set of test system. The Ramsey fringe was observed and its line width is about 1.2Hz, smaller than conventional passive hydrogen maser obviously. At present, we are optimizing the pulse parameters to compress the line width of the Ramsey fringes and to improve the Signal Noise Ratio (SNR) of the fringes as far as possible.

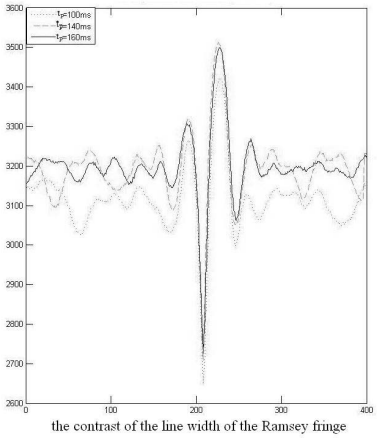

Fig. 7. The contrast of the widths of central wave crests of Ramsey fringes

In future we would deploy digital serving circuit and high stability voltage-controlled crystal oscillator to form a closed control loop based on the existing test system. Assisting with the auxiliary circuit such as temperature control system, C field system and dissociator, a whole pulsed microwave hydrogen clock would be built up. We will optimize the system parameters to obtain good electricity performance including frequency stability and frequency drift.

***Abstract*—A compact, portable rubidium atomic beam clock based on lamp pumped and fluorescence detection scheme is proposed. The expected short-term frequency stability can be more than two orders of magnitude better than previous experimental results. The usages of lamp pumping, fluorescence detection and microwave slow-wave resonance structures make this design robust and compact. The shortcomings will be discussed too.**

I. INTRODUCTION

With the development of optical frequency standards based on cold atoms or ions, improved accuracy and stabilities have been achieved during the last few years. However, most of them are still running in scientific laboratories and require professional scientific researchers for day-to-day maintenance. The traditional microwave frequency standards, such as rubidium gas cell clock, cesium beam clock and hydrogen maser are still the most popular commercial frequency standards. Especially the most accurate cesium beam clock, like Agilent 5071A, is widely used in time keeping, satellite navigation and deep space exploration.

Here we propose a rubidium beam clock scheme similar as cesium beam clock to improve the performance. The initial idea and preliminary experimental results of an optically pumped rubidium beam clock was reported by Arditi *et al.* around thirty years ago [1]. Later, a detailed theoretical analysis of the operation was developed [2]. From the analysis, it was concluded that the performance limitation of this kind of beam clock was dominated by the poor signal to noise ratio of the optical detection signal.

With the development of the diode lasers, a few groups in the world started working on the laser-pumped cesium and rubidium beam clocks [3-7]. The main advantages are the higher utilization rates of the atoms and the more compact design. Experimental results also demonstrated the improved results. However, due to the frequency drift of the diode lasers, the long-term performance is not so great. This limits the further improvements and the marketing of the products. Up to now, as far as we know, there are still no commercial laser-pumped cesium or rubidium beam clocks available.

This work is supported by "the Fundamental Research Funds for the Central Universities".

II. OPERATION AS AN ATOMIC CLOCK

In ref. [8], we proposed the scheme based on lamp-pumping and fluorescence-detection. Here we briefly summarize the main changes in comparison with Arditi *et al.* design.

A. Lamp-pumping

In our scheme, we use ^{87}Rb lamp with ^{85}Rb filter cell to produce pumping light, which can improve the pumping rate of rubidium atoms by a factor of 2.

B. Fluorescence-detection

The fluorescence detection instead of transmission detection can provide higher signal to noise ratio. The improvement is around two orders, whose calculation can be seen in ref. [8].

C. Multiple photo- detectors

Since the time constant of the servo-loop can be in the range of second, multiple photo-detectors can be used to detect the fluorescence signal, and the photo-detectors' output can be combined to further improve the signal to ratio. Taking into account the actual available vacuum space, we estimate that a reasonable number for the detectors is around 10, which means the signal to noise ratio is improved by a factor of 3.

D. Microwave slow-wave structure

The microwave slow-wave structure is a widely used helical type, where the microwave field propagates along the wire of the helix. The other end of the helix is grounded. The microwave is completely reflected and a standing wave field forms inside the structure. For the Ramsey type beam clock the linewidth is inversely proportional to the distance between the two microwave interaction regions. For the microwave slow-wave structure the linewidth depends on the total effective length of the wire. This design has been widely used in traditional rubidium gas cell clocks, and is much more compact.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

E. Multi-reflecting mirrors design

Since the light intensity of rubidium lamp is quite low, the interaction length of light and atoms can be extended by multi-reflected to increase the fluorescence signal in the optical detection region, which is similar as the design of Arditi *et al.* The structure is shown is Fig. 1.

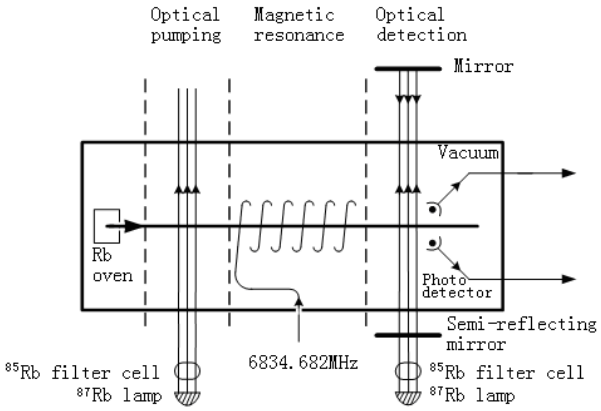

Fig.1. Structure of lamp pumping and fluorescence detection rubidium beam clock

III. DISCUSSION

The proposed scheme of a lamp-pumping fluorescence detection rubidium beam clock has the advantage of a high pumping efficiency, compact structure, light weight, and easy magnet field shielding in comparison with magnetic field selected type cesium beam clocks. It is also more practical than laser pumping beam clocks. The theoretical performance level potentially can be more than two orders of magnitude higher than the former design, and is comparable with commercial cesium beam clocks. However, consider the same temperature of oven (110℃) of rubidium and cesium, on one hand, the velocity of ^{133}Cs and ^{87}Rb are 247m/s and 305m/s, respectively. On the other hand, the saturated vapor pressure of rubidium is only one-third of cesium. In order to get the similar linewidth, we have to extend the length of microwave slow-wave structure, which should be around half meter and larger than that of cesium beam clock.

***Abstract*— The integrating sphere is used to generate the diffuse light for cooling atoms. The microwave field is produced in a cylindrical cavity on a TE011 mode. We have realized the microwave interrogation with the pulsed optically pumped (POP) scheme. The Ramsey fringe is demonstrated and some factors to affect the signal to noise ratio (SNR) and the contrast of the fringe are discussed. Optimization of the experimental parameters is still in progress.**

I. Introduction

In 1989, Chu's group built the first cold sodium atomic fountain frequency standard [1]. And then, many other groups built their own atomic fountain clocks. The cold atomic fountain clock has an outstanding performance, but its size is usually larger than 1 m^3, which restricts its applications in some aspects, such as for space application. In making a well performed compact cold atom clock, the integrating sphere has its special features. It uses the diffuse light cooling technique, which does not need any light beam collimation and power balance, and the atoms can be cooled, prepared, and microwave interrogated at the same place [2], [3]. This technique was first realized by Ketterle in 1992 [4]. Cooling cesium atoms directly from the background vapor with the diffuse light was realized in 2001 [5] and Rubidium in 2009 [6]. Recently, Esnault *et al.* have developed the HORACE Cesium clock [7], whose microwave cavity is spherical, and the short term frequency stability has reached to 2.2×10^{-13}, and the long term performance is around 3×10^{-15} in 10^4 s of integration.

Here we develop an integrating sphere rubidium cold atom clock with the POP scheme, which has characters of all optical cooling, simple structure with small volume, and low power consumption, and has potential features in space application. Different from the HORACE clock, we apply the cylindrical microwave cavity, which is easy to be fabricated and sophisticated. The cylindrical cavity has better structure of magnetic field, and we expect that the integrating sphere atom clock with cylindrical cavity will have a better performance.

In this paper, firstly, we will describe the experimental setup and the experimental procedure. Then we will demonstrate the Ramsey fringe and discuss some factors to affect its SNR and contrast.

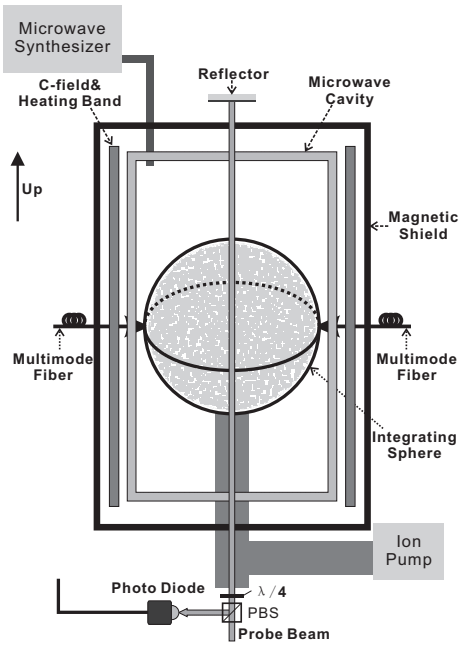

Fig. 1. The schematic of the experimental setup

II. Experimental setup

In our experiment, the integrating sphere is used to generate the diffuse light [6], and the diffuse reflection coefficient at the inner surface is about 98 % at 780 nm. The experimental setup is shown in Fig. 1. A glass cell that is used to contain the ^{87}Rb vapor atoms is located inside the sphere. A cylindrical microwave cavity on the TE011 mode, is tuned to be resonant at 6.835 GHz, and the quality factor of the cavity is about 10, 000. Outside of the cavity, the temperature control system is applied for the cavity to stabilize the resonant frequency. The μ - metal is used to shield the geomagnetic field. C - magnetic field is generated by a solenoid with a pair of compensating coils, and it is around 20 mG in our experiment. The vacuum is about 10^{-6} Pa, which is maintained by a 8 l/s ion pump. Quartz oscillator is the local oscillator (LO) and the 6.835 GHz signal is produced by the microwave synthesizer.

Here, an external cavity diode laser is divided into three

978-1-61284-110-6/11/$26.00 ©2011 IEEE

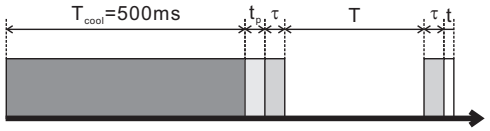

Fig. 2. The time sequence of experiment. T_{cool} - time of cooling light, t_p - time of pumping light, τ - time of the microwave pulse, T - separated time of the two microwave pulses, t - detecting time.

beams (cooling, pumping, and probe laser beams) whose frequency are shifted by three different acousto - optic modulators (AOM). The cooling, pumping, and repumping laser beams (repumping laser is generated by another external cavity diode laser) are combined and injected into the integrating sphere through two multimode fibers.

As shown in Fig. 1, the probe laser beam crosses the cold atomic cloud vertically, and it is retroreflected by a mirror to avoid heating the cold atoms. Finally, we use a photodiode to detect the absorption signal at the bottom. And the power of the probe beam is 0.7 μW, the radius is about 1 mm.

III. Cooling and Interrogation

In order to capture more cold atoms, the loading time of cold atoms in the integrating sphere is about 1 s [8]. In fact, the cycle frequency is another important factor affecting the instability of the clock. We can utilize the pulsed diffuse laser cooling method [9] to shorten the cooling time to 500 ms, and the dead time is 13.5 ms. Making further efforts to reduce the cycle time is necessary in the next work.

Figure 2 is the experimental sequence. Firstly, we turn on the cooling and repumping laser lights to cool the atoms. The cooling laser is detuned -3Γ (natural linewidth) of the transition of $5^2S_{1/2}$, $F = 2 \rightarrow 5^2P_{3/2}$, $F' = 3$. The total power of the cooling laser is about 100 mW, the repumping laser is 6 mW. 500 milliseconds later, about 10^9 atoms are captured successfully, and all of the cold atoms are populated in $F = 2$ states. Secondly, we apply a pumping laser light for $t_p = 1$ ms, whose frequency is a little red shift from the resonant frequency of $F = 2 \longrightarrow F' = 2$. Nearly all of the atoms can be pumped into the ground states of $F = 1$. Then, two $\pi/2$ microwave pulses are applied to make the atoms accomplish the clock transition of $F = 1, m_F = 0 \longrightarrow F = 2, m_F = 0$. The time of each microwave pulse duration is 1 ms, i. e. $\tau = 1$ ms, the separated time between the two interactions is $T = 10$ ms. Finally, after the clock transition, we turn on the probe beam for 0.5 ms to detect the atoms which are populated at the states of $F = 2$, $m_F = 0$, i. e. $t = 0.5$ ms. Using this sequence, there is about 30 % cold atoms experience the clock transition.

IV. Results and Discussion

With the above sequence, the Ramsey fringe can be determined when we sweep the microwave frequency around the resonance frequency, as shown in Fig. 3. The linewidth of the central fringe is about 45 Hz, which is determined by $T + \tau$ [10].

We average the experimental data over five measurements. The contrast is more than 70 %, and the SNR is about

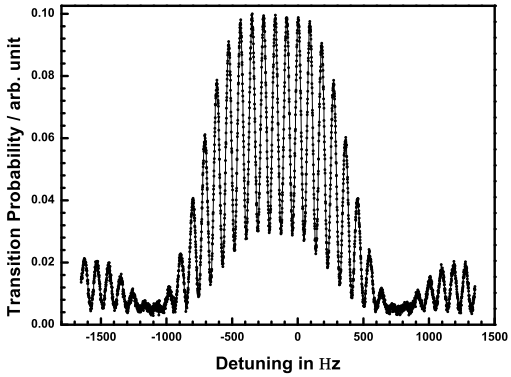

Fig. 3. The observed Ramsey fringe

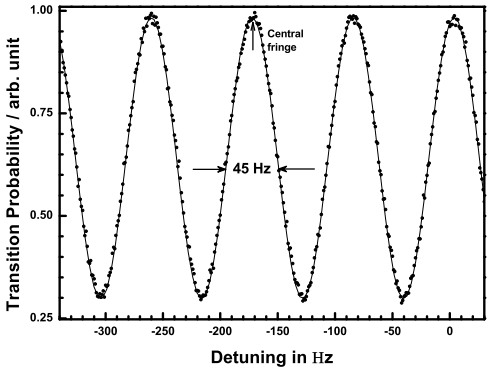

Fig. 4. In the vicinity of the resonance frequency for 10 ms Ramsey pulse separation time

100. Here there are some factors to affect the contrast. First, collisions from the background gas will break the coherence of the cold atoms. This effect can be reduced by improving the vacuum of the system. Second, a relaxation caused by the inhomogeneity of the magnetic field inside the magnetic shield is another factor in breaking the coherence. This is mainly caused by the imperfect of the magnetic shield, the C - field and even the stray magnetic field caused by the temperature control system. So we should put the temperature control system outside the magnetic shield in the future work. Third, the unbalance of the microwave pulses will also reduce the contrast of Ramsey fringe, which may be caused by the nonuniform of the microwave cavity along the probe beam direction and the power shift of the microwave synthesizer. In our system, the above three factors may be the main reasons for the losing contrast. SNR is mainly determined by the noise from the intensity and frequency of probe laser, and the noise from the electrical system. In addition, variation of the atomic population in $F = 2$ will also decrease the SNR.

Figure 4 is the Ramsey fringe in the vicinity of the resonance frequency, from which we can see that there is about

170 Hz shift from the resonance frequency. It may be caused by two main factors. First, the frequency deviation of the LO generates an obvious frequency shift. In the future work, we will use H - maser clock as the LO. Second, the residual magnetic field inside the magnetic shield, as mentioned above, will generate a second order Zeeman shift.

Now, we have locked the cold atom clock, but optimizing the performance of the stability is still under progressing.

V. Conclusion

We demonstrate the Ramsey fringe of the cold ^{87}Rb atoms in the integrating sphere with the cylindrical microwave cavity, and have discussed the factors to affect its contrast and SNR. Now, we are improving the vacuum of the system and performance of the magnetic shield and the homogeneity of the C - field.

Our aim is to make a compact cold atom clock for space application. In the micro - gravity environment, the loss of the cold atoms is only determined by the thermal diffusion [11] and the collisions from the background, so the lifetime of the cold atoms in space is much longer than on the earth, and the linewidth of the central fringe will be extremely narrowed. Besides that, we can also recapture the cold atoms much quicker in the micro - gravity environment, so the cooling time can be shortened. The integrating sphere cold atom clock will have better performance in space.

***Abstract*— We demonstrate that the microwave resonant frequencies of ground-state ^{87}Rb and ^{133}Cs atoms have a nonlinear dependence on the pressure of the buffer gas Xe. Surprisingly, though the frequency shifts of Rb and Cs in the heavy noble gases Ar, Kr, and Xe are all negative, the nonlinearity in Xe is of the opposite sign to the nonlinearities in Ar and Kr. This discrepancy suggests that the frequency shifts due to alkali-noble van der Waals molecules in Xe are opposite in sign to the those in Ar and Kr. The nonlinearity in Xe shows a reproducible deviation from a simple model used to describe the shifts in Ar and Kr, which suggests that the spin-rotation interaction plays a significant role in the frequency shifts due to molecules. No nonlinearities were observed with the gases He and N_2, as expected, and also Ne to within experimental error, which suggests that molecules do not form in Ne. Additionally, we present improved measurements of the shifts of Rb in Ar and Kr and of Rb and Cs in He and N_2.**

I. Introduction

Compact, portable atomic frequency standards are based on the microwave resonance frequencies of alkali-metal atoms in inert buffer gas. The frequency shift of these resonances due to the buffer gas is known as the pressure shift. The size of the shift depends on the temperature and is remarkably linear with the buffer gas pressure p. Previous work has uncovered a nonlinear dependence of the pressure shifts of ^{87}Rb and ^{133}Cs in Ar and Kr, but not He and N_2, which is thought to be due to the loosely-bound van der Waals molecules that are known to form between alkali-metal and buffer-gas atoms in Ar, Kr, and Xe, but not He and N_2 [1], [2]. The precise measurement of nonlinear pressure shifts is a means to study van der Waals molecules and poorly-known interatomic potentials, and is important for determining optimal buffer gas mixtures. Here we present the first measurements of the nonlinear pressure shifts of ^{87}Rb and ^{133}Cs in natural abundance Xe.

II. Experimental Setup

We measured the resonant frequencies ν of ^{87}Rb and ^{133}Cs as a function of the pressure p of a pure buffer gas for the 0–0 hyperfine (or clock) transition between the higher- and lower-energy ground-state hyperfine sublevels $|\alpha\rangle$ and $|\beta\rangle$ with azimuthal angular momentum quantum numbers $m = 0$. Fig. 1 is a sketch of the experimental setup for both the Rb and Cs measurements, which is a laser-pumped, vapor-cell atomic clock that closely follows the description in Ref. [1]. To isolate the pressure shift, we suppress the frequency shift due to the laser, known as the light shift, by using feedback to lock the laser to a (pressure-dependent) zero-shift optical frequency that produces no light shift.

The Rb and Cs vapor cells are cylindrical Pyrex cells, 17 mm in diameter and 25 mm or 13 mm long, respectively, filled with a small amount of ^{87}Rb or ^{133}Cs metal. Both cells have an external buffer-gas reservoir, pressure gauge, and vacuum port, which permit convenient changes of the buffer-gas species and pressure. Section VI discusses the uncertainty in pressure measurement.

An air-heated, non-magnetic oven (O) holds the cell at a constant temperature of 40.0°C for Rb and 35.0°C for Cs. For this work, we extended our measurements to higher pressures than in Ref. [1]. We found that stabilization of the temperature gradient along the section of the vapor cell that exits the oven was necessary to reduce the additional clock noise and drift at higher pressures that are due to temperature-induced changes in the cell volume. Using the Rb cell and setup, we were unable to detect any pressure difference between the heated and unheated portions of the vapor cells due to thermal transpiration.

Helmholtz coils (HC) cancel ambient magnetic fields and provide a static longitudinal field B_0 of 1.0 G for Rb and 0.2 G for Cs. A Toptica DL100 diode laser (DL) provides 795 nm D1 optical pumping light for Rb and 895 nm D1 light

for Cs. A Faraday rotator (FR) isolates the laser from back-reflected light. A pellicle (PE) skims off light for analysis with a wavemeter and a Fabry-Perot interferometer (not shown). Polarizers (PO) ensure that the pumping light is linearly polarized. A liquid crystal wave plate (LCW) driven by a function generator (FG) provides about 30% intensity modulation of the pumping light at a rate of 2 Hz. A beam shaper (BS), a beam expander (BE), and an iris (I) ensure that the pumping light fills the cell uniformly. A rotatable neutral density filter (NDF) adjusts the pumping light intensity. A lens (L) collects the transmitted pumping light onto a photodetector (PD).

Microwaves from a frequency synthesizer (FS) are transmitted towards the cell by a horn (H) roughly 10 cm away to drive magnetic resonances. A frequency counter (FC) referenced to a rubidium frequency standard (not shown) measures the microwave frequency to a precision of 1 Hz. To estimate the uncertainty in frequency measurement, we use the sample standard deviation, not the standard deviation of the mean. For Rb, the microwaves are frequency modulated internally by the FS at a rate between 0.2-9.0 kHz, depending on the buffer gas and pressure, and a modulation index of about 1. For Cs, the microwaves are frequency modulated at a rate of roughly 255 Hz by modulating an external 10 MHz quartz oscillator (Stanford Research Systems SC10) used as an external reference for the FS. This method lead to a restricted range of usable modulation parameters and to increased carrier noise for the Cs measurements.

A lock-in amplifier (LA1) with a 10-300 ms time constant provides an error signal for a proportional-integral-derivative (PID) controller (PID1) to lock the microwave carrier frequency to the clock transition. A second lock-in amplifier (LA2) with a time constant of roughly 1-3 s provides an error signal for another PID controller (PID2) to lock the laser to a zero-shift optical frequency using a piezoactuator. As a quick test for light-shift suppression, we use the NDF filter to temporarily adjust the laser intensity by a factor of 2–4 to verify the intensity independence of the clock output.

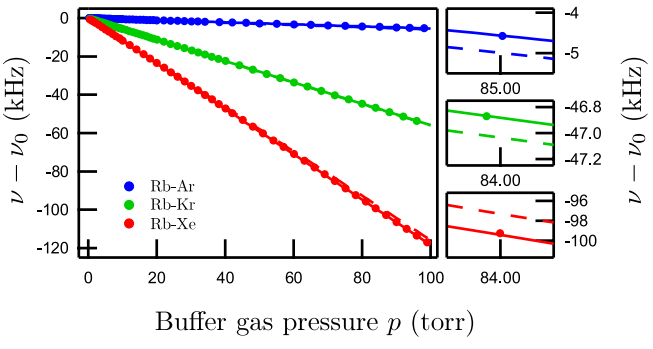

Fig. 2. Resonant frequency ν of ^{87}Rb in pure Ar, Kr, or Xe at a temperature of 40.0°C and magnetic field B_0 of 1 G, with zero-pressure frequency $\nu_0 \approx 6.834683$ GHz removed. Error bars are too small to display. Solid dots are the data, solid lines are the linear-limiting shifts $\nu_0 + sp$, and dashed lines are the binary shifts $\nu_0 + s_b p$, where $s_b = s - s_m$. Insets show that the linear-limiting shift is above the binary shift for Ar and Kr but below for Xe.

III. Nonlinear Pressure Shift of ^{87}Rb in Xe

The linear pressure shifts $\Delta^1\nu = \nu - \nu_0$ of alkali-metal atoms in the heavy noble gases Ar, Kr, and Xe are all negative [3], as measurements show for ^{87}Rb in Fig. 2. Previous work has shown that, after subtraction of the linear, limiting shift sp at high pressures, there is a residual nonlinear pressure shift $\Delta^2\nu = \Delta^1\nu - sp$ for Ar and Kr due to van der Waals molecules [1].

Fig. 3 shows data for ^{87}Rb in natural abundance Xe. Subtraction of the linear, limiting shift reveals a nonlinear pressure shift that is significantly larger than, and of opposite sign to, the nonlinear shifts observed in Ar and Kr. While the shift is described well by the model $\Delta_0^2\nu$ of Ref. [1] (Eq. (3), with parameters in Table I), developed for Ar and Kr, the fit residuals $\Delta^3\nu = \Delta^2\nu - \Delta_0^2\nu$ show a reproducible, nonlinear dependence on pressure not accounted for by that model.

As shown in Fig. 3(c), a new model $\Delta_1^2\nu$ (Eq. (7), with parameters in Table I), described in Section V, is an improved fit to the data. This model includes the effects of the spin-

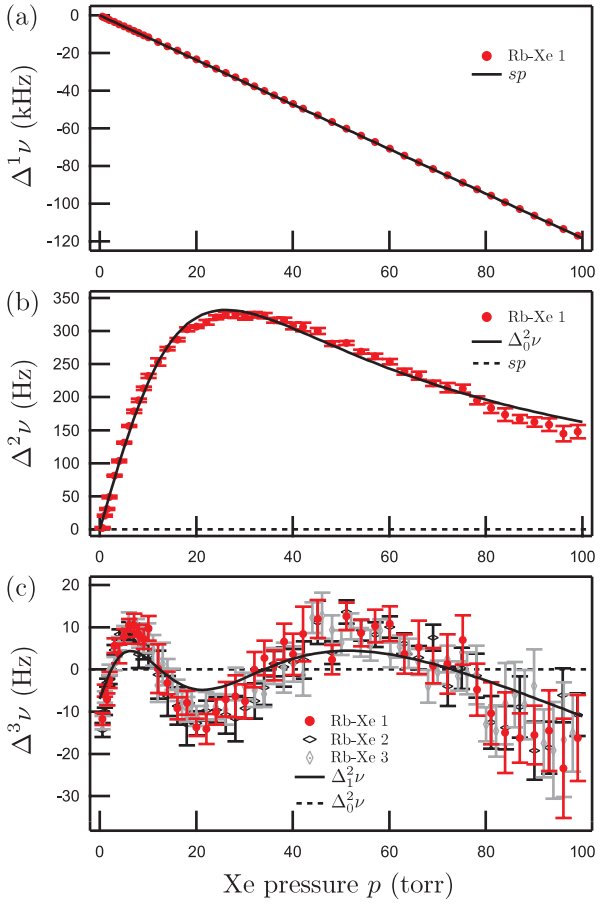

Fig. 3. Resonant frequency ν of ^{87}Rb in Xe at a temperature of 40.0°C and magnetic field B_0 of 1 G. The top panel (a) shows the shift $\Delta^1\nu = \nu - \nu_0$ from the zero-pressure frequency $\nu_0 \approx 6.834683$ GHz. The solid line is the linear, limiting shift sp at high pressures. The middle panel (b) shows the nonlinear shift $\Delta^2\nu = \Delta^1\nu - sp$. The solid curve is from Eq. (3) and Table I. The bottom panel (c) shows fit residuals $\Delta^3\nu = \Delta^2\nu - \Delta_0^2\nu$ for three separate data sets. The solid curve is from Eq. (7) and Table I.

rotation interaction, which were previously ignored. As a result, the data suggest that the spin-rotation interaction plays a significant role in the frequency shifts due to van der Waals molecules.

IV. Physics of Van der Waals Molecular Shifts

Short-lived van der Waals molecules are formed by three-body collisions and destroyed by two-body collisions. During the lifetime τ of a molecule, the alkali-metal atom is perturbed by the hyperfine-shift interaction

$$V_{\text{hfs}} = \delta A\, \mathbf{I} \cdot \mathbf{S}, \tag{1}$$

where δA is a perturbation to the hyperfine coupling of the nuclear spin $\mathbf{I}$ to the electron spin $\mathbf{S}$ for the alkali-metal atom, and by the spin-rotation interaction

$$V_{\text{sr}} = \gamma\, \mathbf{N} \cdot \mathbf{S}, \tag{2}$$

where γ is the coupling coefficient of the electron spin to the rotational angular momentum $\mathbf{N}$ of the colliding alkali-metal atom and buffer-gas atom or molecule [1], [2], [4], [5].

For a hypothetical van der Waals molecule with a single vibration-rotation state and negligible spin-rotation interaction ($\langle \gamma N \rangle = 0$), density matrix modeling predicts the nonlinear shift [1]

$$\Delta_0^2 \nu = -\left(\frac{1}{2\pi T}\right) \frac{\phi^3}{1+\phi^2}. \tag{3}$$

Here, the three-body molecular formation rate is $1/T$ and the effective hyperfine phase shift per molecule is

$$\phi = \langle \delta A \rangle [I] \tau / (2\hbar), \tag{4}$$

where $[I] = 2I+1$ and I is the nuclear spin quantum number of the alkali-metal atom. The molecules also contribute a slope

$$s_{\text{m}} = \phi/(2\pi T p) \tag{5}$$

to the slope s of the linear, limiting shift sp at high pressures.

V. Effects of the Spin-Rotation Interaction

For most alkali-noble molecules, the spin-rotation interaction is a large perturbation which introduces an effective molecular magnetic field

$$B_1 = \frac{\langle \gamma N \rangle}{g_S \mu_B} \tag{6}$$

oriented along $\mathbf{N}$, whose direction is distributed isotropically. Here, $g_S = 2.0023$ is the electronic g factor and μ_B is the Bohr magneton. For Rb and Cs in Xe, B_1 is much larger than the externally applied field B_0 in our measurements, so the total magnetic field seen by an alkali-metal atom in a molecule is approximately equal to B_1.

In this case, for hypothetical van der Waals molecules with a single vibration-rotation state, density matrix modeling predicts the nonlinear shift

$$\Delta_1^2 \nu = -\left(\frac{1}{2\pi T}\right) \sum_{\sigma=-2I}^{2I} \frac{W_\sigma (1+r_1\sigma)^3 \phi^3}{1+(1+r_1\sigma)^2\phi^2}, \tag{7}$$

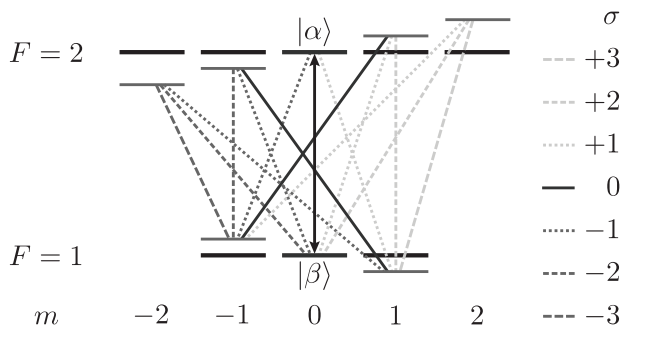

Fig. 4. Sketch of the different, effective hyperfine transitions indexed by σ in Eq. (7), which contribute to the 0-0 hyperfine coherence $\rho_{\alpha\beta}$ for ^{87}Rb. The transitions have different frequencies because of the first-order Zeeman shifts from the molecular field B_1.

where the dimensionless parameter

$$r_1 = \frac{2 g_s \mu_B B_1}{\langle \delta A \rangle [I]^2} = \frac{2\langle \gamma N \rangle}{\langle \delta A \rangle [I]^2} \tag{8}$$

characterizes the relative strengths of the spin-rotation and hyperfine-shift interactions, and the weight coefficients W_σ for the 0–0 hyperfine transition are

$$^{87}\text{Rb: } [W_3, \ldots, W_{-3}] = [9, 9, 23, 23, 23, 9, 9]/105 \tag{9}$$

$$^{133}\text{Cs: } [W_7, \ldots, W_{-7}] = [245, 245, 425, 425, 659, 659, 1231, 1231, 1231, 659, 659, 425, 425, 245, 245]/9009. \tag{10}$$

The weight coefficients W_σ depend on the choice of hyperfine transition, and as a result, so too does the nonlinear shift $\Delta_1^2 \nu$ of Eq. (7). The analysis that leads to Eq. (7) also predicts the molecular contribution s_{m} of Eq. (5) to the linear, limiting slope s at high pressures.

As sketched in Fig. 4 for ^{87}Rb, the summation index σ corresponds to the different, effective hyperfine transitions that contribute to the 0–0 hyperfine coherence $\rho_{\alpha\beta}$ after averaging over all orientations for B_1. The terms in the sum over σ in Eq. (7) are similar to $\Delta_0^2 \nu$, but have different effective phase shifts ϕ due to the first-order Zeeman shifts from B_1. The additional nonlinearity $\Delta^3 \nu = \Delta^2 \nu - \Delta_0^2 \nu$ observed in Fig. 3(c) is due to the interference of these terms as the molecular lifetime τ varies with the pressure p.

For $r_1 = 0$, the nonlinear shift Δ_1^2 of Eq. (7) simplifies to the previous model $\Delta_0^2 \nu$ of Eq. (3). In the limit of a large external field B_0, the analysis that leads to Eq. (7) also simplifies to Eq. (3).

VI. Pressure Gauge Nonlinearity

We measured the buffer gas pressure p with capacitance manometer gauges (MKS Instruments Baratron) to a precision of roughly ± 0.002 Torr and an accuracy of about $\pm 0.25\%$. We have found that these gauges typically have a significant quadratic nonlinearity. This pressure gauge nonlinearity can be mistaken for a nonlinear pressure shift, as Fig. 5 demonstrates for the case of ^{87}Rb in Ne.

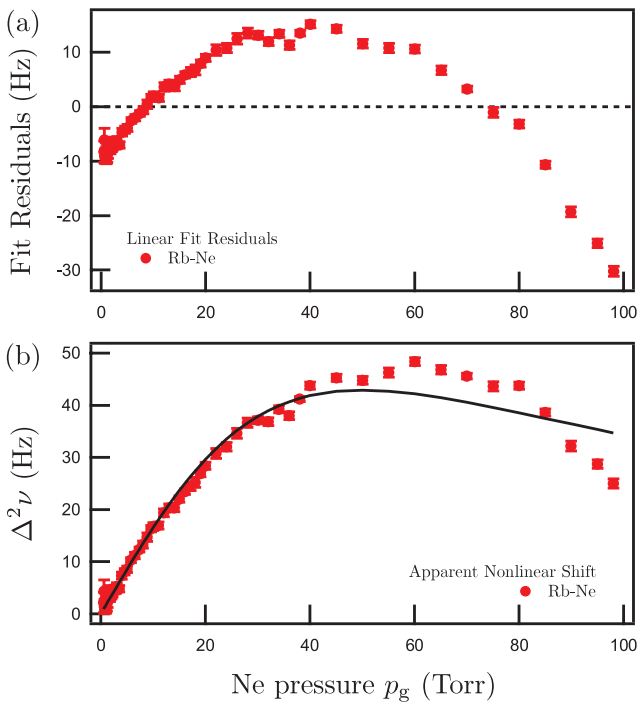

Fig. 5. Demonstration of a quadratic pressure gauge nonlinearity with measurements of the resonant frequency ν of ^{87}Rb in Ne at 40.0°C and $B_0 = 1$ G. The top panel (a) shows the residuals after fitting ν versus the gauge pressure p_g with a line, which have a quadratic dependence on the pressure p_g. The bottom panel (b) shows the apparent nonlinear shift $\Delta^2\nu$ after fitting ν versus p_g with the model $\Delta_0^2\nu$ of Eq. (3), which is due to the pressure gauge nonlinearity. For comparison, Fig. 6(b) shows the residuals after fitting ν versus the estimated pressure p from Eq. (11) with a line.

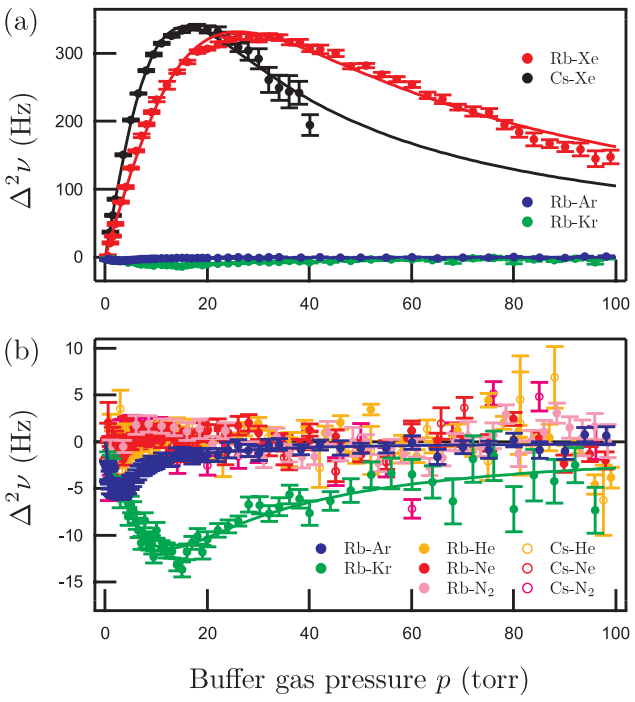

Fig. 6. Measured nonlinear shifts $\Delta^2\nu$ for ^{87}Rb at 40°C and $B_0 = 1$ G and for ^{133}Cs at 35°C and $B_0 = 0.2$ G. The top panel (a) shows the nonlinear shifts of Rb and Cs in Xe. The bottom panel (b) shows the nonlinear shifts of Rb in Ar and Kr and of Rb and Cs in He, Ne, and N_2. The curves shown are the model $\Delta_0^2\nu$ of Eq. (3). Fit parameters are listed in Table I.

We correct for this systematic error by estimating the actual pressure p from the measured pressure p_g as

$$p = r(\alpha)(p_g + \alpha p_g^2), \tag{11}$$

where the curvature α is determined for each pressure gauge through measurements of the shifts of the buffer gases He, Ne, and N_2. The coefficient

$$r(\alpha) = (1 + 75\alpha)/(1 + 150\alpha + 6000\alpha^2) \tag{12}$$

minimizes the least-squares linear bias of this correction, $\int (p - p_g)^2 dp_g$, over a 0-100 Torr pressure range. From our measurements, we determined the curvatures to be:

$$^{87}\text{Rb cell: } \alpha = (-3.40 \pm 0.22) \times 10^{-5} \text{ Torr}^{-1} \tag{13}$$

$$^{133}\text{Cs cell: } \alpha = (-1.71 \pm 0.46) \times 10^{-5} \text{ Torr}^{-1}. \tag{14}$$

Though the curvature for a pressure gauge may vary over time and with environmental conditions, these measured curvatures appear stable over the duration of our measurements.

After applying the correction of Eq. (11), we find that the pressure shifts of ^{87}Rb and ^{133}Cs in Ne are linear to within our experimental error, as shown in Fig. 6. However, the analysis for Ne is complicated by the observation of frequency shifts in some measurements at very low pressures, below about 1 Torr, which we think are systematic shifts of as yet undetermined origin. These low-pressure shifts were most noticeable with the Cs setup, where they were negative and could be as large as roughly -20 Hz at 0.7 Torr for Cs in He, Ne, or N_2. For the Rb setup, the low-pressure shifts were less reproducible and smaller, typically < 4 Hz at 0.5 Torr in Ar, Kr, Ne, and N_2, and were not observed in He. These shifts for Rb were usually negative, but could be of either sign for Rb in Ar. Detailed understanding of these low-pressure shifts requires further investigation.

VII. Nonlinear Pressure Shift Parameters

Table I lists the pressure-independent fit parameters for the nonlinear pressure shift data shown in Fig. 6. For Xe, the table includes results for both of the nonlinear pressure shift models, Eqs. (3) and (7). For Rb in Xe, the pressure-independent, spin-rotation parameter

$$r_1\phi p = \frac{\langle \gamma N \rangle \tau p}{[I]\hbar} \tag{15}$$

was set to an estimate calculated with the H_1^* and τp of Ref. [2]. For Cs in Xe, we were unable to estimate $r_1\phi p$ due to a lack of experimental data for τp, and so results are given for a fit to the data with $r_1\phi p$ as a free parameter. For the other gases, the table includes improved results over the previous work of Ref. [1], which are corrected for the pressure gauge nonlinearity.

As the data show, the effective ϕ due to molecules with Xe are negative, in contrast to the molecules with Ar and Kr.

TABLE I

FIT PARAMETERS FOR THE PRESSURE SHIFTS OF ^{87}RB AT 40°C AND $B_0 = 1$ G, AND OF ^{133}CS AT 35°C AND $B_0 = 0.2$ G.

Metal	Gas	$r_1\phi p$ rad Torr	Tp^2 sec Torr^2	ϕp rad Torr	s Hz Torr^{-1}
^{87}Rb	Xe	7.97	0.082 ± 0.010	-14.8 ± 1.5	-1184.0
		–	0.164 ± 0.013	-26.2 ± 1.2	-1183.7
	Ar	–	0.070 ± 0.012	2.21 ± 0.16	-53.71
	Kr	–	1.08 ± 0.31	12.5 ± 1.9	-558.1
	He				714.2
	Ne				387.3
	N_2				518.0
^{133}Cs	Xe	2.79	0.0185	-5.96	-2243.9
		–	0.059 ± 0.006	-15.8 ± 1.3	-2242.4
	He				1141.9
	Ne				579.9
	N_2				828.7

The linear shift coefficients s are in agreement with previous measurements [3], [6], [7]. The effective molecule formation rates $1/T$ are slower than those of Ref. [2], which could be a result of cancellation due to a variation of the phase shifts ϕ_v, and their sign, with different molecular vibration-rotation states v [1]. Table I also shows that the fit estimates for ϕp and Tp^2 are significantly affected by the choice of model, which highlights the importance of the spin-rotation interaction.

VIII. CONCLUSION

We report the first measurements of the nonlinear pressure shifts of ^{87}Rb and ^{133}Cs in Xe, and the first evidence that the spin-rotation interaction plays an important role in the hyperfine frequency shifts due to van der Waals molecules. We present a new model for nonlinear pressure shifts that includes the spin-rotation interaction in the limit of a weak external magnetic field, and which is a better fit to the Xe data. This model implies a dependence of the molecular shifts on the choice of the hyperfine transition and on the external magnetic field. No nonlinearity was observed for Rb and Cs in Ne, to within experimental error, suggesting that van der Waals molecules do not form in vapor cells with Ne buffer gas. We correct for a previously unknown pressure gauge nonlinearity with improved measurements of Rb in Ar and Kr and of Rb and Cs in He and N_2. Future work will explore the isotope dependence of the shifts due to van der Waals molecules with measurements of the nonlinear pressure shifts of ^{85}Rb in Ar, Kr, Xe, He, Ne, and N_2.

ACKNOWLEDGMENT

The authors are grateful to M. J. Souza for making cells, to F. Gong and S. W. Morgan for contributions to the original apparatus, and to J. H. Hendricks at NIST and D. Jacobs at MKS Instruments for helpful discussions about capacitance manometers. National Institute of Standards and Technology
Boulder, CO USA
tparker@boulder.nist.gov

***Abstract*—An update to a previous long term frequency comparison of cesium fountain primary frequency standards [1] has been made. This update covers the approximate three year interval from March 2008 to March 2011 and also includes two new standards. Also, simulated data have been used to estimate the biases and standard deviation of the Birge ratio as a function of the degrees of freedom.**

I. INTRODUCTION

In January 2010 the results of a long-term frequency comparison of cesium fountain primary frequency standards were reported in Metrologia covering the interval from August 2000 to June 2009 [1]. The new study presented here gives an update covering ten fountains from seven laboratories over the time frame from approximately March 2008 to March 2011. Included are two new fountains, NPL-CsF2 (at the National Physical Laboratory in the United Kingdom) and PTB-CsF2 (at the Physikalisch Technische Bundesanstalt in Germany), that were not present for the study in [1]. The methodology followed here is substantially the same as that in [1], but with one difference. Rather than using either NIST-F1 (at the National Institute of Standards and Technology in the USA) or SYRTE-FO2 (at the Laboratoire National de Métrologie et d'Essais, Systèmes de Référence Temps Espace in France) as references, only SYRTE-FO2 was used as the main reference. This change was made only because SYRTE-FO2 is almost always present for comparison. In the few instances when NIST-F1 was used as the reference, an adjustment based on the average frequency difference between NIST-F1 and SYRTE-FO2 was applied. Details of the comparison methodology are given in [1]. Also new in this paper are estimates from simulated data for biases and the standard deviation of the Birge ratio as a function of degrees of freedom. This information provides confidence levels for the Birge ratios.

II. FOUNTAIN COMPARISON METHOD

The comparisons were made using fountain data available in the BIPM (Bureau International des Poids et Measures) publication Circular T (www.bipm.org/jsp/en/TimeFtp.jsp?TypePub=publication). Pairs of data points that occurred close in time were used and in most cases there was some overlap. Both TAI (International Atomic Time) and AT1E (a post-processed maser ensemble at NIST) [1] were used as flywheel frequency references, and the average of the two independent results was calculated in order to gain a small reduction in the dead-time uncertainty. In all, 128 comparisons were made.

For a pair of runs all type A uncertainties, u_A, from both standards were combined in quadrature. Also the type B (systematic) uncertainties, u_B, from both standards were combined in quadrature. Over multiple runs the combined u_A averages down, while for multiple runs the weighted mean of the combined u_B was used. Consequently, u_B does not average down over time. u_A and u_B are added in quadrature to get the total uncertainty. It has been assumed that the u_B between standards are uncorrelated and that the u_B for the same standard is highly correlated over time. Neither assumption is strictly true, but the approach is a reasonable compromise.

Table 1 shows an example of a fountain comparison from a data pair. In the table MJD is the Modified Julian Date and y is the fractional frequency difference in units of 10^{-15}. u_{dead} is the uncertainty introduced by the noise in the flywheel due to misalignment of the run times shown in column one. $u_{dead} = 0$ if the start and stop times are identical. u_{TAI} is the transfer noise into TAI [2]. u_l includes dead time internal to the laboratory. u_A, u_l, u_{TAI}, u_{dead} are all type A uncertainties. u_C, u_{CA} and u_{CB} are the combined uncertainties of the comparison. All fountain uncertainties are 1 standard uncertainty (1 sigma).

The top left section in Table 1 shows the frequency of TAI with respect to NIST-F1 over the specified MJDs along with the associated uncertainties. The lower left section shows the same for SYRTE-FO2. The middle right section shows the comparison results, where u_{dead} comes from the lack of perfect overlap. AT1E was also used as a reference fly wheel in a manner similar to that in Table 1, and the two results were averaged to gain a small reduction in the dead-time

TABLE 1. Example of a fountain comparison data pair and the difference calculation for NIST-F1 and SYRTE-FO2. Fractional frequencies are in units of 10^{-15}.

NIST-F1

MJD	MJD	Duration	y(TAI-F1)	u_A	u_B	u_I	u_{TAI}
54314-54339	54326.5	25d	-3.4	0.3	0.3	0.1	0.4

u_{dead}	y(FO2-F1)	u_C	u_{CA}	u_{CB}	overlap
0.7	0.3	1.2	1.05	0.58	15d

SYRTE-FO2

MJD	MJD	Duration	y(TAI-FO2)	u_A	u_B	u_I	u_{TAI}
54309-54329	54319	20d	-3.7	0.3	0.5	0.1	0.5

uncertainty. The same procedure was used for all of the fountain comparisons.

III. BIRGE RATIO

The Birge ratio, R_B, is a consistency test and should be close to unity if stated uncertainties are correct. It is a test to see if the scatter in the data is consistent with the stated uncertainties. The definition of the Birge ratio is shown in equations (1) and (2) below, where χ_r^2 is the reduced chi-square. R_B can be calculated either for the same pair of standards over time or for the average frequency differences in a group of standards.

$$R_B = \sqrt{\chi_r^2} \tag{1}$$

$$R_B = \sqrt{\frac{\sum_{i=1}^{n} \frac{(y_i - \bar{y})^2}{u_i^2}}{(n-1)}} \tag{2}$$

The standard chi-square calculator (for example www.fourmilab.ch/rpkp/experiments/analysis/chiCalc.html) is stated to be not accurate when the degrees of freedom, DOF, are less than about ten. Therefore simulated data made up of 81,920 samples were used to confirm the standard deviation and bias of R_B as a function of DOF. The simulated data were generated using a common spread sheet random-number generator and the Box-Muller transformation to provide a Gaussian distribution. The results are shown in Figs. 1 and 2. The standard deviation (for a +/-34 % interval) as a function of DOF provides a confidence interval for the Birge ratio and is essentially the same for the simulated data as from the calculator as shown in Fig. 1. This is also true for the median as seen Fig. 2. The mean and median however are not the same because the distribution is asymmetric. Here the DOF is one less than the number of data points.

IV. FOUNTAIN COMPARISON RESULTS

Table 2 shows the results of the nine fountain comparisons for the interval of approximately March 2008 to March 2011.

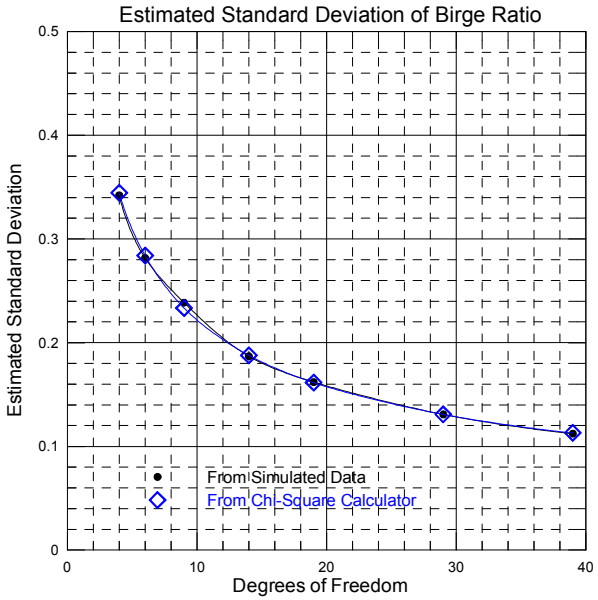

Figure 1. Estimated standard deviation of the Birge ratio from simulated data and from a chi-square calculator.

Each fountain is compared to SYRTE-FO2, and the average frequency difference, y_{avg}, is shown. The type A and type B uncertainties of the comparisons are U_{CA} and U_{CB}, and the combined total comparison uncertainty is U_C. The last column on the right gives the number of data pairs for each comparison. R_{BA} is the Birge ratio using only the type A uncertainties, and R_{BC} is the Birge ratio using the combined uncertainty. Here the Birge ratio is based on the scatter over time. In general one would expect R_{BC} to be less than 1 and R_{BA} to be larger than 1 [1]. There is cause for concern if R_{BA} is smaller than one in a statistically significantly fashion or if R_{BC} is larger than one in a statistically significantly fashion. This would indicate that the uncertainties are either overstated or understated respectively. Only SYRTE-FOM and IT-F1 (operated by the Istituto Nazionale di Ricerca Metrologica, (INRIM) in Italy) exhibit such behavior, with SYRTE-FOM having a small Birge ratio and IT-CSF1 having a large ratio. In both cases the deviation from 1 is more than two standard

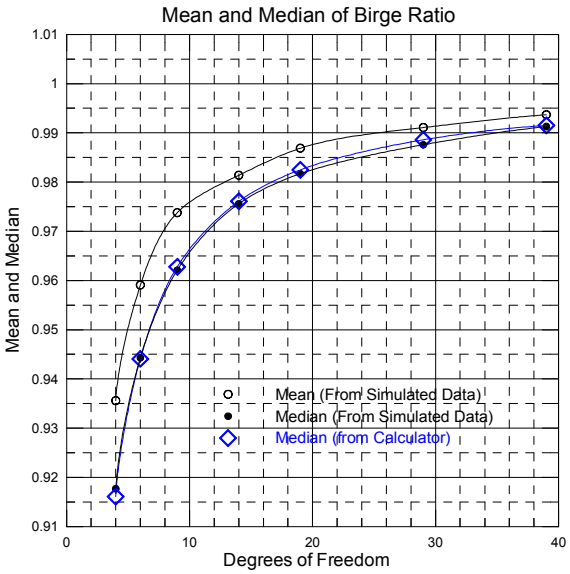

Figure 2. Biases in the Birge ratio at low degrees of freedom.

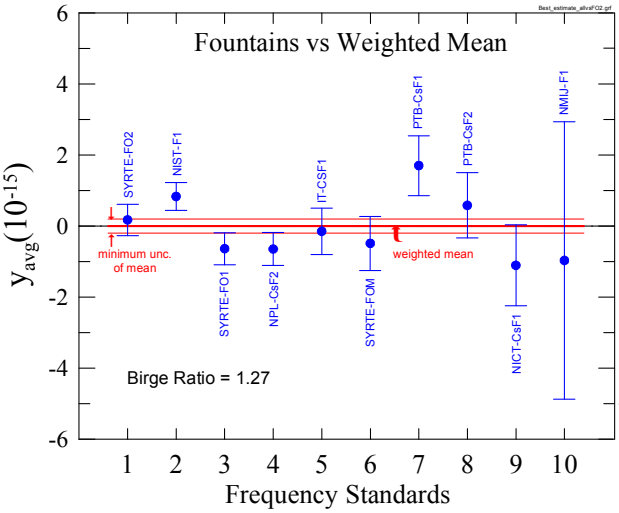

Figure 3. Average fountain frequencies vs the weighted mean.

TABLE 2. Fountain comparisons relative to SYRTE-FO2. All frequencies are in units of 10^{-15}. In this type of comparison an offset of 1.4 sigma or less is considered entirely normal.

Fountains	y_{avg}	U_C	U_{CA}	U_{CB}	R_{BA}	R_{BC}	# pairs
PTB-CsF1 vs SYRTE-FO2	+1.53	0.95	0.27	0.91	1.97	1.09	10
NIST-F1 vs SYRTE-FO2	+0.66	0.59	0.25	0.54	1.16	1.02	18
PTB-CsF2 vs SYRTE-FO2	+0.41	1.02	0.43	0.92	1.22	0.99	8
ITCS-F1 vs SYRTE-FO2	-0.32	0.79	0.31	0.73	1.89	1.56	15
SYRTE-FOM vs SYRTE-FO2	-0.66	0.88	0.24	0.85	0.56	0.43	14
SYRTE-FO1 vs SYRTE-FO2	-0.81	0.63	0.14	0.62	0.83	0.61	21
NPL-CsF2 vs SYRTE-FO2	-0.82	0.64	0.27	0.58	1.08	0.93	15
NMIJ-F1 vs SYRTE-FO2	-1.14	3.93	0.28	3.92	1.68	0.55	21
NICT-CsF1 vs SYRTE-FO2	-1.28	1.22	0.60	1.06	0.71	0.59	6

deviations. Significant errors in total uncertainties may come from sources other than the fountains themselves because substantial uncertainty is introduced by frequency transfer and dead time.

Three fountains in Table 2 show a positive average frequency offset relative to SYRTE-FO2, and six have a negative offset. In five cases the average frequency difference is larger than the total combined uncertainty, but no comparisons with SYRTE-FO2 exceed 2 sigma. In this type of comparison an offset of 1.4 sigma or less is considered entirely normal [1]. NMIJ-F1 is operated by the National Metrology Institute of Japan (NMIJ) and NICT-CsF1 is operated by the National Institute of Information and Communication Technology (NICT) in Japan.

A weighted mean of the offsets from SYRTE-FO2 can be calculated using the data in Table 2, and the average offsets from the mean for all ten fountains are shown in Fig. 3. The Birge ratio for the group of fountains shown in Fig. 3 is calculated using the combined uncertainties from each fountain. At 1.27 it is just over one standard deviation for nine DOF which is about 1.20 (see Figs. 1 and 2). The uncertainty of the weighted mean is about 2×10^{-16} if one assumes that all of the individual fountain uncertainties are uncorrelated. This is probably not true, but accurately quantifying the degree of correlation would be nearly impossible. Six of the ten standards in Fig. 3 are within 1 sigma of the mean and all are within 2 sigma. However, several standards are more than 2 sigma separated from each other. Specifically, NIST-F1 and PTB-CsF1 on the positive side of the mean versus SYRTE-FO1 and NPL-CsF2 on the negative side are separated by nearly 2.5 sigma.

V. CONCLUSIONS

Overall, the fountains are in fairly good agreement, although some deviate from the mean by nearly 2 sigma and from each other by nearly 2.5 sigma. The Birge ratio at 1.27 is just over one standard deviation and therefore does not indicate any serious problems. In the earlier study [1] the Birge ratio was 0.77, indicating less scatter relative to the stated uncertainties, which were generally larger than in the current study. In the current study, the scatter among the fountains is a little larger than one would expect from the stated uncertainties, but not enough to cause serious concerns. The Birge ratio indicates that there is a 90 % probability that, averaged over all the fountains, the uncertainties (including dead time and frequency transfer) have been understated by perhaps 20 %.

***Abstract*—In this paper, we propose a new method to reduce the temperature sensitivity of Chip Scale Atomic Clocks. We studied the relationship between RF power and the light shift as well as the relationship between the temperature and the collision shift, and the results are given. It is shown that the frequency shift caused by the change of the temperature can be compensated by the variation of light shift through the adjustment of RF power, in order to reduce the total output frequency shift.**

I. INTRODUCTION

Recently, chip scale atomic clocks (CSACs) [1, 2] have been recognized to be significant in the future portable electronic devices and other frequency standard fields [3-5]. Generally, CSACs are based on Coherent Population Trapping (CPT) [6-8] phenomenon which will occur in a Λ transition if the frequency difference of the two laser fields is close to the hyperfine splitting of the two ground states [9-11].

In CSACs, the atomic ground state hyperfine splitting frequency may be shifted as a result of collision between buffer gas atoms and alkali atoms. This frequency shift is sensitive to cell temperature. Because of the harsh application environment of CSACs, it is difficult to improve the temperature stability of the cell, which will limit the CSACs to achieve a good long-term stability. Many methods have been studied to reduce the temperature sensitivity of CSACs [12-14]. In our previous experiments, the rate of frequency shift with cell temperature is about 0.4Hz/K after optimizing the two buffer gases' ratio and pressure.

In order to reduce the dependence of the output frequency of CSACs on cell temperature, we propose that the frequency shift rate which is related to temperature can be compensated by adjusting the RF power level. The remarkable advantage of this approach is that we can relax the requirement on ambient temperature control. In the experiment, we measure the rates of frequency shift with temperature and RF power respectively. Then in the operation of CSACs, the cell temperature drift is detected and RF power level is adjusted exactly through the microprocessor in the control circuit to compensate the frequency shift coming from temperature drift.

Generally, the long-term instability of the temperature is around 1K. In this case, a frequency shift rate of 0.6Hz/K will lead to the clock frequency instability of 2×10^{-10}. After adjusting the RF power, the clock frequency instability is supposed to be improved to 10^{-11} region, which will broaden CSACs' application fields.

II. LIGHT SHIFT AND COLLISION SHIFT

Figure 1 shows the Λ type structure from simplifying the energy levels of the real atoms [15]. |1> and |2> are the two hyperfine splitting levels of ground state of alkali atoms, while |3> is the excited state. Γ* stands for the relaxation rate of the spontaneous emission of the upper level. γ_2 represents the rate of the coherence in the ground state tending to zero. Δ is the lasers detuning from optical resonance, while ω_1 and ω_2 are the laser angular frequencies.

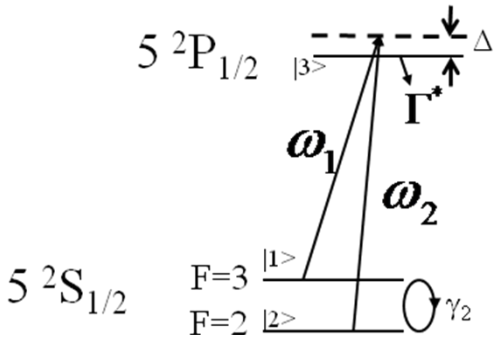

FIG. 1.Energy level of ^{85}Rb. Γ* is the decay rate from the excited state to the ground-state levels; Δ is the detuning; γ_2 is the ground-state relaxation rate of the coherence.

The total shift of the CPT resonance frequency can be expressed as

$$\nu_{total} = \nu_B + \nu_c + \nu_{ls} \quad . \tag{1}$$

Here ν_B is the magnetic field shift which is independent on the cell temperature. ν_c is the collision shift, and it is caused by the collisions between the buffer gases and the rubidium atoms and mainly influenced by the temperature as

$$\nu_c = P_0[\beta + \delta(T - T_0) + \gamma(T - T_0)^2], \quad (2)$$

where P_0 stands for the pressure of the buffer gases, β is the pressure shift coefficient, T is the atom cell temperature, T_0 is the reference temperature at which the coefficient δ is measured, and δ and γ are the first and second order of the temperature coefficient respectively. The relationship can be simplified in a small temperature range as

$$\nu_c = P_0[\beta + \delta(T - T_0)]. \quad (3)$$

ν_{ls} is the light shift, and both the RF modulation depth and the temperature will influence it, but generally we neglect the effect caused by the temperature. Every sidebands create light shift because the AC stark effect caused by the pump light. The AC stark effect is caused by a varying electric field, typically a laser, and leads to the shift of the atom energy levels. The contribution of each sideband to the total light shift can be measured as

$$\Delta\omega_n = \frac{1}{4}|\omega_R|^2 \frac{\Delta}{\Delta^2 + (\Gamma^*/2)^2}, \quad (4)$$

where ω_R represents the Rabi frequency, Δ is the lasers detuning from optical resonance and Γ* also stands for the decay rate from the excited state to the ground-state levels.

The total light shift can be calculated through a summation over all sidebands of the modulated laser which can be expressed as

$$\Delta\omega = \ldots\ldots + C_{-2}I_{-2} + C_{-1}I_{-1} + C_0I_0 + C_{+1}I_{+1} + C_{+2}I_{+2} + \ldots\ldots, \quad (5)$$

where Δω stands for the total light shift as same as the meaning of ν_{ls}, $C_{\pm n}$ means the coefficient of sideband ±n, and $I_{\pm n}$ is the intensity of each sideband. Taking the influence of all the sidebands into account, we can put the relationships in a simple way as

$$\Delta\omega = \alpha I, \quad (6)$$

With the changing of RF modulation depth, which will increase when RF power level goes up, the intensity will turn into another distribution, which means the coefficient α will change while the total light intensity is remaining the same.

III. Experiment Setup

In the experiment, the rubidium cell we used was 1cm in length and 1cm in diameter. The cell contained a mixture of natural rubidium, i.e. 72% ^{85}Rb and 28% ^{87}Rb [16-19], with buffer gases Ne and Ar. The temperature-controlled Vertical Cavity Surface Emitting Laser was modulated by the laser DC current and the RF generator, and these two parts were coupled by the Bias-Tee. The laser beam was collimated and was 3mm in diameter. After being circularly polarized and attenuated, it went through the rubidium cell which had magnetic shield and was temperature controlled.

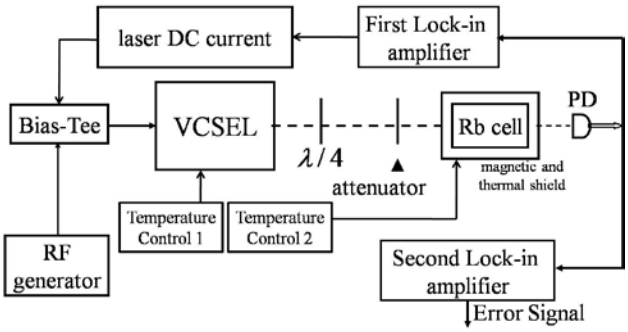

FIG. 2. Experiment Setup for measuring the shift of CPT frequency. RF generator and temperature control part can be used to adjust RF power level and temperature respectively.

The transmitted light was converted to electronic signal by a photo detector. Within the first lock-in loop, the laser's wavelength was locked on the ^{85}Rb D1 line absorption spectrum. The RF generator (model Agilent E8257D), which was phase locked into a commercial rubidium clock, was modulated at 190Hz. As a result of the difference between the CPT resonance frequency and the microwave frequency, an error signal was given. When the error signal was tuned to zero, the output RF generator frequency was the same as the CPT resonance frequency. We used full hyperfine frequency modulation in our experiment [20].

IV. Experiment Results

In FIG.3, it is shown that in the range -8~-3 of RF power, the CPT frequency shift is getting bigger with the increasing of RF power and the curve is approximately linear. However, the shift has a sharp reduction in the range of -3~-1 dBm. It's because that the increase of RF power in this range leads to an increase of intensity on the ±2 or other high-order sidebands which are not the pump light. As a result, the intensity of the pump light is reduced, the CPT phenomenon is weak, and the CPT frequency shift is small correspondingly. So the range of -8~-3 dBm is suitable for emerging CPT resonance since the pump light has enough intensity in that range.

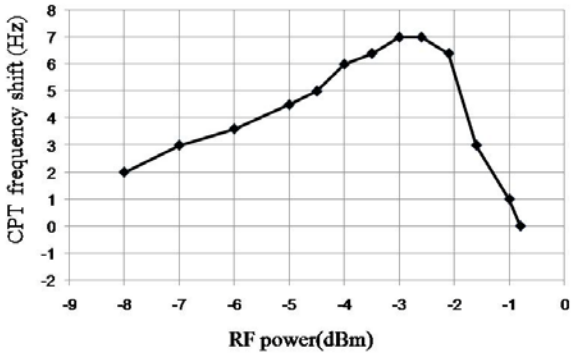

FIG. 3. CPT frequency shift with RF power level.

Figure 4 shows that the CPT frequency shift goes up when the temperature increases [21]. The amplitude of the CPT signal is given by

$$S \propto n \frac{\omega_{1R}^2 \omega_{2R}^2}{\left(\Gamma^*\right)^3} \frac{1}{2\left(\gamma_2 + \frac{\omega_{1R}^2 + \omega_{2R}^2}{2\Gamma^*}\right)}. \quad (7)$$

Here n is rubidium atom vapor density, ω_{1R} and ω_{2R} are rabi frequencies, γ_2 is the ground-state relaxation rate of the coherence and Γ^* is the relaxation rate. When the cell temperature is lower, the number n will become smaller. So the CPT signal is weak when the temperature is too low. However, as a result of the absorption of the light, the signal will become weak with a high cell temperature as well. So we have to control the temperature in a proper range, i.e. from 35℃ to 55℃ in FIG.4 with the size of cell considered.

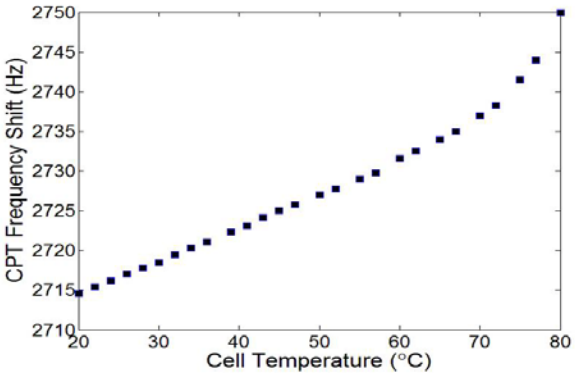

FIG. 4. CPT frequency shift with cell temperature.

As analyzed above, we can choose the range -8~-3 dBm of RF power and the range 35℃ to 55℃ of the temperature change to implement the compensation we proposed. For instance, we can set the initial work conditions at -5 dBm and 45℃, the middle values of the two curves. It is can be seen from FIG.3 that the CPT frequency shifted by around 3Hz with the RF power varying from -5 to -3. In FIG.4, the CPT frequency shift changed by about 3HZ with the cell temperature varying from 40 ℃ to 50 ℃. From the results and data, we can find that both of the curves had approximately linear areas and the variance of the frequency shift was comparable.

The results which show CPT frequency shift changing with the RF modulation depth and the cell temperature prove that the variance of the frequency shift is comparable and almost linear in some range. So considering the positive relationship between RF power level and modulation depth, adjusting RF power level can be used to compensate the CPT shift caused by the change of temperature.

In addition, in order to obtain the same modulation depth, the RF power may be adjusted differently in different lasers. But based on the observation in other related experiments, the trend of the CPT frequency shift changing with the RF power is the same in substance.

V. CONCLUSION

In this paper, we propose a new method to reduce the CSACs' temperature sensitivity and demonstrate it through theory analysis and experiment results. The total CPT frequency shift can be reduced by the compensation of the light shift varying with the RF power and the collision shift caused by the change of temperature.

Reducing the temperature sensitivity is crucial for the long term stability of CSACs. It may enhance the commercial feasibility of CSACs and also improve their reliability, especially when they are used in harsh application environmental conditions where it is difficult to improve the temperature stability of the cell. And this also can relax the requirement on the accuracy of the buffer gas pressure.

***Abstract*—In view of a novel miniature atomic clock with low power consumption, we investigate on the potential for a laser-pumped double-resonance atomic clock based on a micro-fabricated Rb vapor cell. We obtain a clock short-term stability of $2\times10^{-11}\,\tau^{-1/2}$ and the stability stays below 1×10^{-11} up to $\tau = 10^4$s, which demonstrates the feasibility of the approach.**

I. INTRODUCTION

Developments towards miniaturized or even chip-scale atomic clocks (CSAC) [1] up to today were mostly based on the Coherent Population Trapping (CPT) scheme [2]. This all-optical technology has the advantages of being compact with low power consumption. The alternative Double-Resonance (DR) scheme [3] has been widely abandoned for arguments of power consumption and size of the microwave cavity required. However, implementation of laser optical pumping can replace the bulky and power-consuming discharge lamp [4, 5], and micro-fabrication has opened new ways in microwave structure design [6]. These facts make it interesting to investigate further on the DR clock scheme, which avoids several issues of the CPT approach such as higher signal background or the difficulty to control precisely the spectrum of the modulated laser over time. It has also been demonstrated that DR short term stability is roughly 5 times better than CPT's in comparable experimental conditions [7].

II. CELL PRODUCTION

The fabrication process for the micro-fabricated cell used in this study is similar to the anodic bonding technology reported previously [8] and is described in [9]. First, a silicon wafer is "drilled" by deep reactive ion etching (DRIE), and then is anodically bonded to a glass wafer. This wafer stack is diced to obtain preforms, that are then handled individually. Rb filling is done with a commercially available Rb dispenser from SAES getters, Italy. Finally cell sealing is achieved by anodic bonding of a second glass plate, performed in a buffer-gas atmosphere with appropriate gas mixture and pressure.

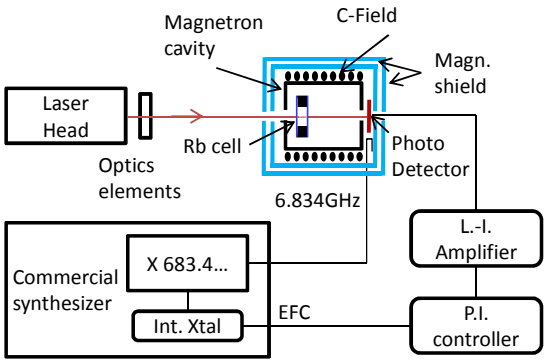

Figure 1. Experimental setup.

III. EXPERIMENTAL CLOCK SETUP

The setup is presented in Fig. 1. Pump light on the Rb D1 line is provided by a DFB laser stabilized to saturated-absorption lines obtained from a small in-house made glass-blown evacuated Rb reference cell. The light beam sent to the clock cell has 1mm diameter and is linearly polarized. The physics package is composed of the micro-fabricated cell placed in a compact magnetron-type microwave cavity [10] to orient and enhance the microwave field applied to the cell. The cavity is surrounded by a C-field coil that produces a static magnetic field parallel to the light beam to isolate the clock transition. Mu-metal shields are used to isolate the system from external magnetic fields. The 6.834 GHz microwave is produced from the 2.278 GHz output of a commercial synthesizer via a frequency tripler. This microwave frequency is modulated at $\approx$ 187 Hz to generate the error signal using a lock-in (L.-I.) amplifier. The clock loop is closed by sending the error signal to a Proportional/Integrator (P.I.) controller that acts on the EFC (Electronic Frequency Control) of the synthesizer.

IV. RESULTS

A typical clock signal is presented in Fig. 2. A contrast of nearly 2 % is achieved with a linewidth of 6.3 kHz (FWHM).

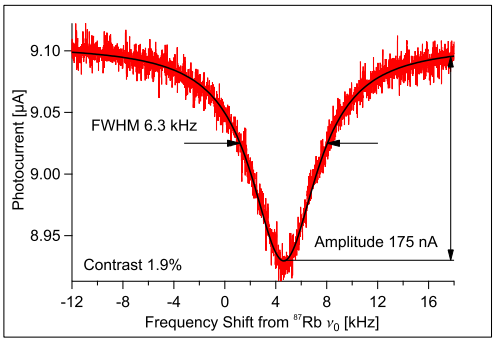

Figure 2. Typical double-resonance clock signal.

The corresponding error signal has a discriminator slope of D = 30 pA/Hz for a cell temperature of 373 K and a pump light power of 40 µW. Linewidth extrapolation to zero light intensity gives a value of 2.2 kHz. Using the formula [11]

$$\sigma_y(\tau) = \frac{N}{\sqrt{2}Df_0}\tau^{-\frac{1}{2}} \qquad (1)$$

where N is the total detection noise and f_0 the frequency of the microwave clock transition, a signal-to-noise limited short-term stability of $\sigma_y(\tau) = 1.8\text{x}10^{-11}\,\tau^{-1/2}$ and a shot-noise limit of $6\text{x}10^{-12}\,\tau^{-1/2}$ are calculated.

At medium and long-term timescales, the main degradations of clock stability result from fluctuations in temperature and light intensity. Fig. 3 shows the temperature shift of the clock frequency, consistent with predictions based on the buffer gases content of the cell [12]. A temperature-shift coefficient is measured as $8.2\text{x}10^{-10}$ /K (at the operating temperature of 373 K), which limits the clock stability to $4\text{x}10^{-12}$ at longer time scales. Straight-forward optimization of the buffer-gas mixture [13] will shift the point of minimized temperature sensitivity (currently around 76°C) towards the operating temperature and will result in an improvement of this stability limit by up to two orders of magnitude.

Intensity light-shift results for different laser frequencies (i.e. laser lock points) are shown on Fig. 4. With the laser locked to the $|F_g=2\rangle\longrightarrow|F_e=1\rangle$ sub-Doppler transition obtained from the reference cell (our experimental clock conditions) the intensity light-shift coefficient is $1.9\text{x}10^{-9}$ /µW, resulting in a clock instability contribution of $8\text{x}10^{-12}$ at 1000 s. This value can be reduced by a factor of 4 by locking the laser on

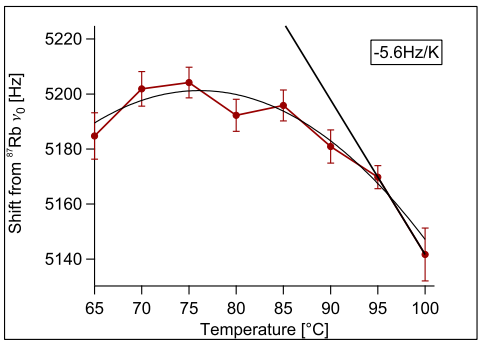

Figure 3. Measured temperature shift (data points) and parabolic fit to the data. The straight line is a linear fit at 100°C.

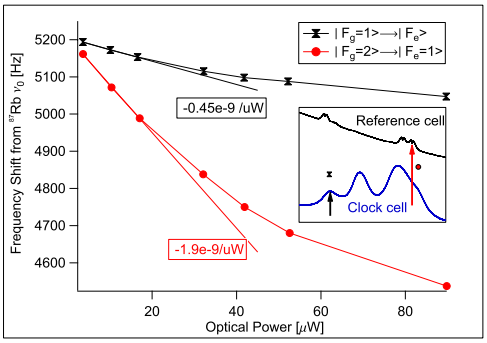

Figure 4. Light-shift measured for different laser frequencies. The inset shows the laser lock points used.

the buffer-gas broadened $|F_g=1\rangle\longrightarrow|F_e\rangle$ Doppler transition obtained on the micro-fabricated clock cell, but at the price of a reduced signal-to-noise ratio that degrades the short-term clock stability.

The measured clock frequency stability is $2\text{x}10^{-11}\,\tau^{-1/2}$ for τ < 100s, in excellent agreement with the signal-to-noise limit (see Fig. 5). The clock stability stays below $1\text{x}10^{-11}$ up to 10^4s averaging time, in agreement with the estimated limitations from the temperature and intensity light-shift effects. The main limiting factor here is the intensity light-shift.

V. CONCLUSIONS

We presented an experimental DR clock based on a micro-fabricated Rb vapor cell that already meets the typical stability requirements for a miniature atomic clock. The intensity light-shift is identified as the main factor limiting the long-term stability. Optimizing the cell's inner atmosphere (buffer gas and Rb isotopic ratio) will allow us to further improve on the clock stability. Combining these encouraging results with a new micro-fabricated microwave cavity will open the way for a novel extra small DR clock with competitive frequency stability.

***Abstract*—We present the investigation on the temperature dependence of the pressure (collisional) shift of the Cs clock transition in presence of buffer gases (Ne, N_2 and Ar). The temperature dependence of the signal amplitude and light shift are also investigated. From the obtained coefficients of temperature dependence it is possible to foresee the buffer gas mixture which cancels the temperature sensitivity at a given temperature. These results as well as the results of the investigation on the signal amplitude and the light shift can be useful for improving the frequency stability of the Cs vapor-cell clocks.**

I. INTRODUCTION

Compact and stable frequency standards are needed in many applications such as telecommunications or navigation. Alkali vapor-cell atomic clocks are currently used for this purpose. In such clocks a buffer gas is added to the alkali vapor in order to reduce the relaxation by collisions on the cell walls and to reduce the Doppler broadening by Dicke effect. However the collisions between alkali atoms and the buffer gas can shift the frequency of the clock transition by several kHz per torr, and this shift is temperature dependent. This effect can limit the long term frequency stability of cell clocks and indeed has limited the stability of our clock prototype which uses a pulsed coherent population trapping (CPT) scheme. That is why we have undertaken a metrological study of these shifts for some buffer gases of interest, with the aim of reducing or cancelling the temperature dependence.

We have measured the pressure and temperature coefficients of the clock frequency shift induced by three buffer gases: Ne, N_2, Ar, see Section II. This allows to foresee the composition of a gas mixture canceling the frequency temperature sensitivity at the wished working temperature. It is experimentally verified on a N_2-Ar mixture. The working temperature can be the one for which the signal amplitude is maximal. We show in section III that this temperature also depends on the laser intensity. In section IV we show that the light shift is also temperature dependent.

This work is partly supported by Direction Générale de l'Armement (DGA) under contract n° 2009 34 0052. O. K. was supported by DGA.

II. PRESSURE SHIFT AND TEMPERATURE DEPENDENCE CANCELATION

A. Pressure and temperature coefficients

The frequency shift, induced by alkali-buffer gas collisions, can be written [1]:

$$\Delta\upsilon = P_0\left(\beta + \delta(T - T_0) + \gamma(T - T_0)^2\right) \quad (1)$$

where P_0 is the buffer gas pressure in the cell at the reference temperature T_0, β is the pressure coefficient ($Hz \cdot Torr^{-1}$), δ is the linear temperature coefficient ($Hz \cdot Torr^{-1} \cdot K^{-1}$), γ is the quadratic temperature coefficient ($Hz \cdot Torr^{-1} \cdot K^{-2}$) and T is the buffer gas temperature.

Following our previous works [2, 3], we present here the results of the pressure and temperature coefficients for three buffer gases (Ne, N_2 and Ar). In order to avoid any bias we use 4 cells filled with Ne, 5 with N_2 and 5 with Ar made by three different suppliers. The cells are filled with different pressures ranging between 15 and 180 torr. The actual pressure in the cell after sealing is unknown, so the accuracy on the frequency shift rates measurements is generally limited by the uncertainty on the gas pressure. We have measured the pressure of the buffer gas in each cell by measuring the frequency shift of the optical transitions of the Cs D_1 line [3]. The pressure is then calculated using the published optical shift rates [4, 5] corrected for the temperature (for more details see [6]). Once the pressure of the buffer gas is determined, the temperature dependence of the clock frequency is measured for each cell with our CPT pulsed Cs clock described in [3].

TABLE I. EXPEREMENTAL PRESSURE AND TEMPERATURE COEFFICIENTS FOR CS WITH TRHEE BUFFER GASES

Buffer gas	**Pressure coefficient β, ($Hz \cdot Torr^{-1}$)**	**Linear temperature coefficient δ, ($Hz \cdot Torr^{-1} \cdot K^{-1}$)**	**Quadratic temperature coefficient γ, ($mHz \cdot Torr^{-1} \cdot K^{-2}$)**
Ne	686 ± 14	0.266 ± 0.006	-1.68 ± 0.05
N_2	922.5 ± 4.8	0.824 ± 0.006	-2.51 ± 0.03
Ar	-194.4 ± 1.6	-1.138 ± 0.010	0.0 ± 0.3

In Table I, measured pressure and temperature coefficients for Cs clock transition are shown. The accuracy of the present work is still limited by the uncertainty on the buffer gas pressure. We have precisely determined the quadratic coefficients for N_2 and Ne. The coefficient of Ar is much smaller and we have estimated an upper limit.

It is important to notice that gases with a quadratic coefficient exhibit an inversion temperature, where the temperature dependence vanishes, $T_{inv} = T_0 - \delta/2\gamma$. Ne buffer gas shows a strong quadratic temperature coefficient. The inversion temperature computed from the coefficients of the fitted polynomials for each cell, in order to avoid pressure additional uncertainties, is T_{inv} = (79 ± 3) °C, which confirms previous evaluations [7, 8]. It makes Ne very attractive for use in the Cs chip scale clocks which needs a high working temperature. The calculated inversion temperature with N_2 is (164 ± 13) °C, while no inversion temperature can be given for Ar.

B. Buffer gas mixtures

One can also cancel the temperature dependence at a chosen temperature by a mixture of gases with temperature coefficients of opposite signs [9, 10, 11, 12]. From the obtained coefficients for three buffer gases the mixture composition canceling temperature dependence at a given temperature can be calculated:

$$r(P_2/P_1) = -\frac{\delta_1 + 2\gamma_1(T_{inv} - T_0)}{\delta_2 + 2\gamma_2(T_{inv} - T_0)} \qquad (2)$$

where $r\ (P_2/P_1)$ is the pressure ratio of two buffer gases, $\delta_{1,2}$ and $\gamma_{1,2}$ are the temperature coefficients for buffer gases, T_0 is the reference temperature (0°C), T_{inv} is the inversion temperature.

We have calculated the equation (2) for three possible buffer gas compositions (Ar-N_2, Ar-Ne and N_2-Ne).

- $r(P_{Ar}/P_{N2}) = 0.724(12) - 0.00441(9) \cdot (T_{inv} - T_0)$
- $r(P_{Ar}/P_{Ne}) = 0.234(9) - 0.00295(11) \cdot (T_{inv} - T_0)$
- $r(P_{N2}/P_{Ne}) = -\dfrac{0.266(6) - 0.00336(10) \cdot (T_{inv} - T_0)}{0.824(6) - 0.00502(6) \cdot (T_{inv} - T_0)}$

Note that in case of mixture containing Ar buffer gas (for which the γ coefficient is zero) the equation (2) could be simplified to $r = -[\delta_1/\delta_2 + (\delta_1/2\ \gamma_2)\cdot(T_{inv} - T_0)]$. The Fig. 1, 2 and 3 illustrate the calculated dependences.

In order to verify the calculated values several cells with different Ar-N_2 mixture were carefully filled in the laboratory and studied. For each buffer gas mixture cell the inversion temperature was measured. Fig. 4 shows the temperature dependence of the clock frequency in the Ar-N_2 mixture cells with different proportion of two gases.

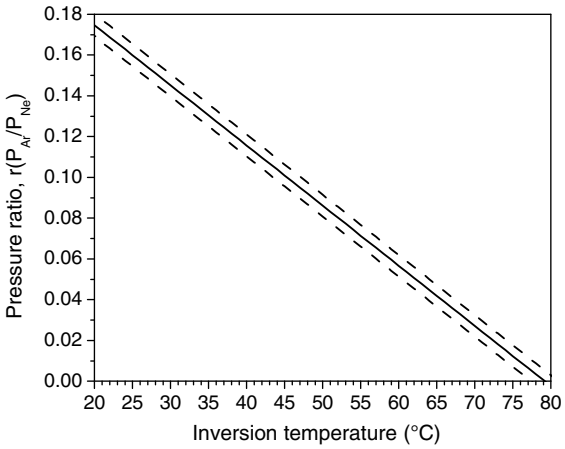

Figure 2. Ar-Ne pressure ratio versus inversion temperature. Black solid line - calculated values from the obtained temperature coefficients, black dashed lines – 1σ uncertainty for the calculated values.

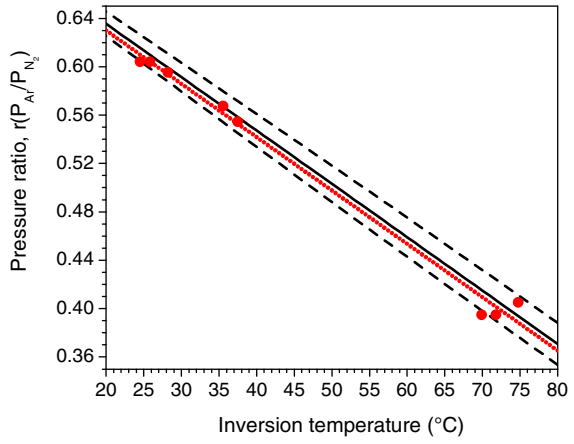

Figure 1. Ar-N_2 pressure ratio versus inversion temperature. Black solid line - calculated values from the temperature coefficients, black dashed lines – 1σ uncertainty for the calculated values. Red circles – experimentally measured inversion temperatures T_{inv} for 8 cells. Red dotted line – fitted line.

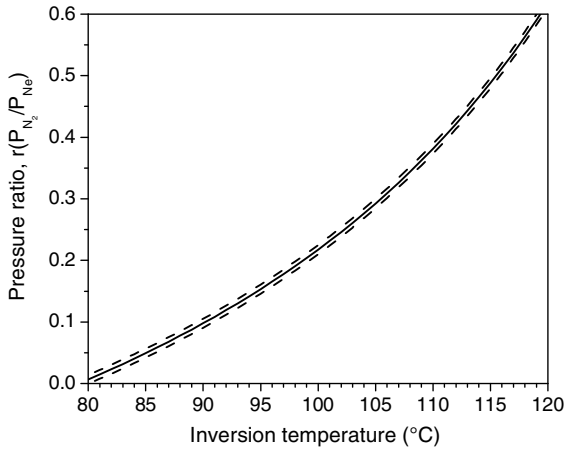

Figure 3. N_2-Ne pressure ratio versus inversion temperature. Black solid line - calculated values from the obtained temperature coefficients, black dashed lines – 1σ uncertainty for the calculated values.

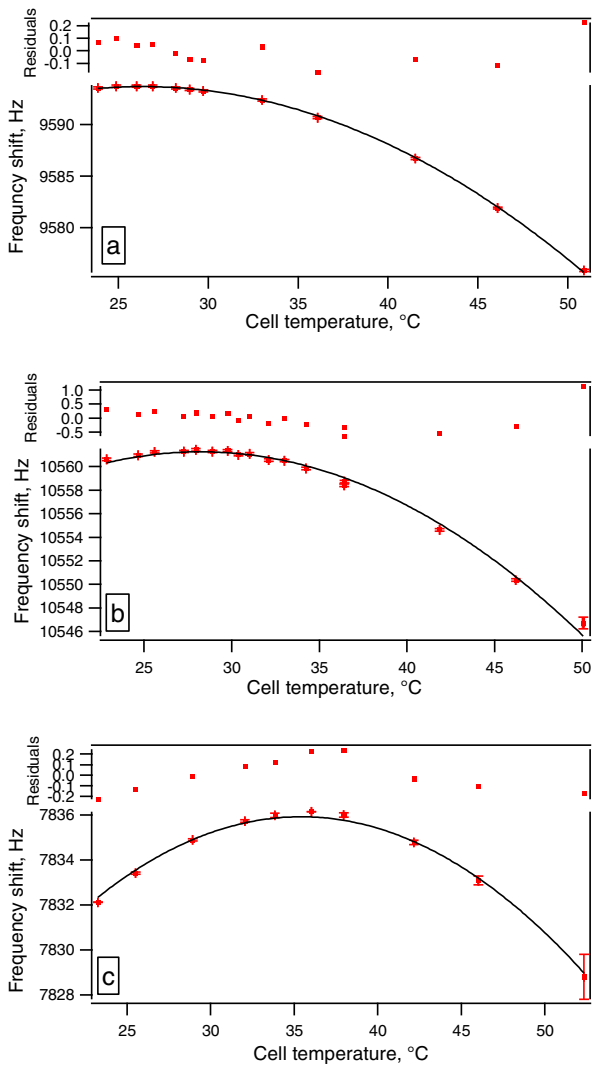

Figure 4. Temperature dependence of the clock frequency in Ar-N_2 Cs cells with different compositions: a) r = 0.608; b) r = 0.595; c) r = 0.568. Experimental points are fitted with N_2 pressure and the ratio r as free parameters, the pressure coefficients and temperature coefficients for both gases as fixed.

The comparison between calculated and experimentally measured values is presented on Fig 1.

The expression given by the fit of the experimental points is $r = 0.718(9) - 0.00441(18)\cdot(T_{inv} - T_0)$. The good agreement between calculated and experimental values confirms the validity of the measured microwave shift coefficients.

The coefficients values of Table I and the equations for the mixture gas composition can be a useful guideline for manufacturers of Cs vapor cell frequency standards.

III. SIGNAL AMPLITUDE

In order to determine the optimal working temperature the signal amplitude was measured as a function of the cell temperature, see Fig. 5. At low temperature the signal increases with the temperature, due to the increase of the Cs density. At higher temperatures the signal decreases because the medium becomes optically thick and also because of the increasing relaxation rate. We have notice that the maximum signal amplitude of the CPT resonance with cell temperature depends on the laser intensity (Fig. 5). Such dependence was observed in both CW and Ramsey interrogation modes.

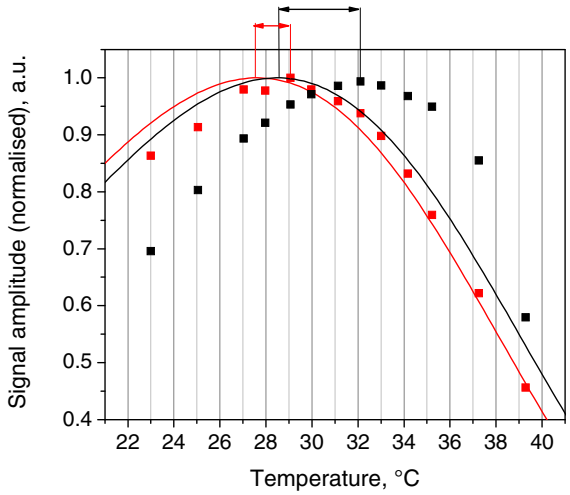

Figure 5. Signal amplitude versus cell temperature for two different laser intensities. Red and black points – experimental data for 60μW/cm^2 and 300μW/cm^2, respectively. Red and black curves – theoretical model for for 60μW/cm^2 and 300μW/cm^2, respectively. Red and black arrows show the discrepancy between theory and experiment. Cell with Ar-N_2 mixture, pressure ratio r (P_{Ar}/P_{N2}) =0.595. CW mode of interrogation.

A theoretical model was developed in order to explain this dependence. It is based on the calculation of two absorption coefficients: one on CPT resonance and the other off CPT resonance, both at optical resonance. Contrary to the model developed in [13], there is no empirical parameters (such as Cs density or Rabi frequencies) adjusted in our model. The developed model and the experimental data are in qualitative agreement: the temperature for which the signal is maximal increases with the laser intensity. We find better agreement for lower intensity (as in [13]). For the lower laser intensity (60μW/cm^2) the experimental value of the temperature for the maximal amplitude is 29.0°C, while the theoretical value is 27.7°C. For the higher laser intensity (300μW/cm^2) the experimental value is 32.0°C and the theoretical value is 28.5°C. Note that our model is sensitive to the value Cs density, which is known with maybe ~10% uncertainty [14, 15, 16], and this uncertainty limits our model. A fitted value of the Cs density is probably necessary. However this does not explain the unexpected large variation of the temperature of the maximum with the laser intensity. Further investigations are needed.

IV. LIGTH SHIFT

The light shift is one of the major effects, with the buffer gas pressure shift, which can limit the long-term stability of alkali vapour cell clocks [1]. It must then be well controlled. We have measured the light shift in cells with different buffer

gases, as a function of the laser intensity and the cell temperature. We have noticed that the light shift is sensitive to the cell temperature: the slope of the light shift versus laser intensity changes value and even changes sign (Fig. 6). So for a given temperature of the cell it is possible to have a zero slope and to cancel the light shift. Here we present the results for N_2 buffer gas, but the similar behavior was observed in cells with Ar and with Ar-N_2 mixtures.

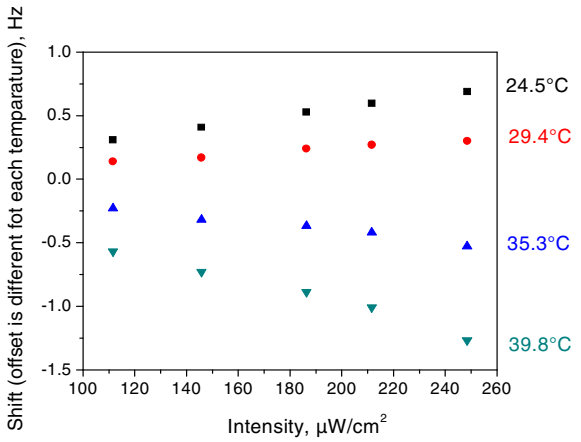

Figure 6. Light shift for different temperatures. For better visibility a different offset is applied for each temperature. Each color corresponds to the temperature (from 24.5°C to 39.8°C). Ramsey mode (T_r=4ms) interrogation. Cell 30 torr N_2.

Fig. 7 shows the slope of the light shift versus cell temperature. The slope should be null for a temperature of about 31°C in this case.

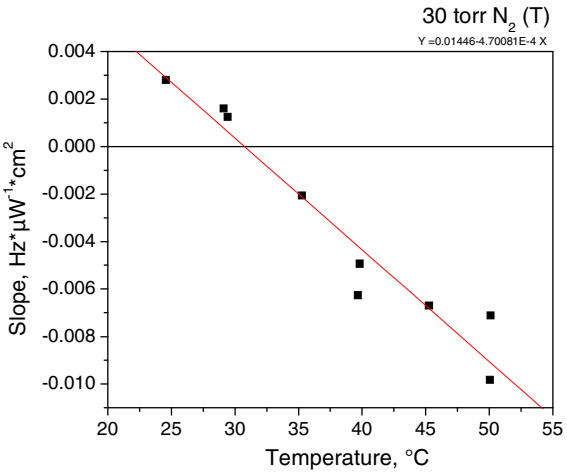

Figure 7. Slope of the light shift for different temperatures. Ramsey mode (Tr=4ms) interrogation. Cell 30 torr N_2.

This sensitivity can be explained by the temperature dependence of the detuning of the optical transitions. Indeed, the light shift is expected to have a dispersion line-shape with the detuning of the optical resonance [17], and the optical shift induced by the buffer gas is temperature dependent. But in these experiments the laser frequency was locked on the saturated absorption spectrum in another Cs cell, it was then fixed, independent of the temperature of the buffer gas-Cs cell of the clock.

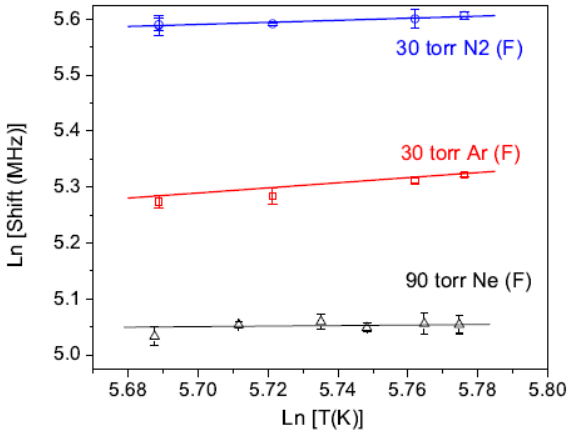

Figure 8. Temperature dependence of the shift of the D_1 line in presence of Ne, N_2 and Ar buffer gas, logarithmic units.

The temperature dependence of the optical shift induced by the buffer gas can be written [18, 19]:

$$\frac{S_m}{S_r} = \left(\frac{T_m}{T_r}\right)^n, \qquad (3)$$

where S_m and S_r are the shifts measured at the temperature T_m and T_r respectively, the value of n is determined by the Cs-buffer gas interactions and the energy dependence of the cross section. We have measured the temperature dependence of the optical shift for three buffer gases, Ne, N_2 and Ar, see Fig. 8. The obtained values for n are: 0 ± 0.2 (Ne), 0.18 ± 0.03 (N_2), 0.56 ± 0.07 (Ar) [6].

When n is known, we can plot again Fig. 7, but as a function of the laser detuning instead of temperature. Fig. 9 shows the slope of the light shift versus optical detuning. The value of the optical detuning is calculated for each temperature according to (3).

Note that the zero slope of the light shift does not correspond to the zero optical detuning (the zero slope corresponds to the optical detuning 4 – 5 MHz). In fact the absorption spectrum in the cell with buffer gas is broadened by Cs-buffer gas collisions. In our case (30 torr N_2) this broadening leads to a Lorentzian width in the Voigt profile of about 460 MHz. For the temperatures used in the experiment the Doppler width is about 360 MHz. As the light shift depends also on the width of the optical transition, another temperature dependence is induced by the width variation. Moreover the half of the hyperfine splitting of the excited state is 584 MHz, so the overlapping of the profiles of two excited states is possible. This could explain why the light shift cancels for a detuning different of zero.

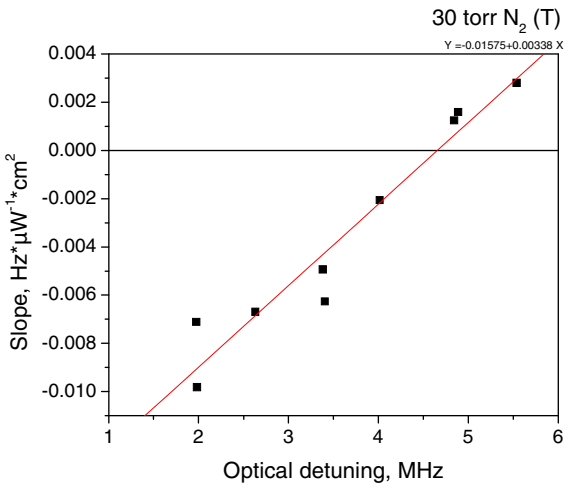

Figure 9. Slope of the light shift for the optical detuning. The value of the optical detuning is calculated for each temperature from the temperature dependence of the optical shift. Ramsey mode (Tr=4ms) interrogation. Cell 30 torr N_2.

Besides of the temperature dependence of the optical transitions, it is probably necessary to take also into account the increasing absorption of the incident laser intensity and the effect of optical thickness. Further studies are needed for a full theoretical explanation. However it is worth to note that the light shift can be canceled by tuning the laser frequency, or also by tuning the cell temperature.

V. CONCLUSION

We have reported here results of the measurement of the pressure and temperature coefficients for Cs ground state transition in presence of Ne, N_2 and Ar buffer gases measured with CPT pulsed clock. From the obtained coefficients the composition of mixtures of buffer gases (Ar-N_2, Ar-Ne and N_2-Ne) is calculated as a function of the wished temperature canceling the temperature sensitivity of the Cs clock frequency. This prediction was experimentally checked and confirmed in the case of an Ar-N_2 mixture. The obtained results will allow one to choose appropriate gas or a mixture of buffer gases to cancel the temperature dependence of the Cs vapor cell clock at a working temperature.

The working temperature can be chosen to maximize the signal amplitude. We have observed that the cell temperature of maximum signal amplitude of the CPT resonance depends on laser intensity. A preliminary theoretical model qualitatively describes this behavior, but with a much smaller temperature variation.

The temperature dependence of the light shift was observed. This dependence could be explained by the temperature dependence of the collisional shift of the optical transitions and then the detuning of the laser. This temperature dependence was measured for three buffer gases Ne, N_2 and Ar.

The results of the investigation on the signal amplitude and light shift would be useful to optimize the working parameters of the CPT pulsed clock. Further investigations are in progress.

ACKNOWLEDGMENT

We are pleased to acknowledge P. Bonnay and A. Gérard for very careful manufacturing of Cs cells. We are grateful to Michel Lours and the SYRTE electronic team for their help.

***Abstract*—We describe the progress towards the realization of a cold-atom frequency standard based on coherent population trapping (CPT). We explain our particular CPT configuration and give details on the experimental setup.**

I. Introduction

The performance of atomic clocks based on coherent population trapping (CPT) has improved considerably over the last few years in terms of stability and reliability [1], [2], [3]. Frequency stabilities in the low $10^{-10}\ \tau^{-1/2}$ range are now realized within package volumes of a few tens of cubic centimeters [3]. Nevertheless, a significant frequency drift ($\geq 10^{-12}$/day) is observed in these devices. The use of wall coatings and buffer gases, which are required for high-contrast narrow-linewidth CPT resonances, degrades the long-term stability through cell aging and large temperature-dependent pressure shifts. Light shifts also contribute to the drift of CPT-based clocks.

To circumvent these issues, we began a study of a microwave CPT frequency standard based on laser-cooled atoms (CA-CPT). Cold atoms can provide good long-term performance, while the all-optical CPT interrogation enables good stability through narrow atomic resonances [1] and allows miniaturization of the physics package by eliminating the microwave cavity. This project aims at reaching a frequency stability of better than $10^{-11}\ \tau^{-1/2}$ and an accuracy of around 10^{-13} within a miniaturized physics package. Our work focuses both on the experimental realization and the metrological evaluation of a CA-CPT clock and on efficient ways of producing a cold atom sample in a millimetric volume (see [4]). Consideration of the expected systematics, including light shifts, second-order Zeeman effects and Doppler effects are given in [5].

II. CPT interrogation

Many schemes and configurations with differing atom types, optical excitation lines, light polarization, etc., have been proposed to improve the metrological properties of a clock based on a CPT resonance [1]. Improvements can be made, for example, by use of a polarization configuration that does not involve so-called "trap states" (extreme m_F sublevels) [6], [7], [8], and by use of a larger intensity in the CPT beams to increase the pumping rate into the "dark state".

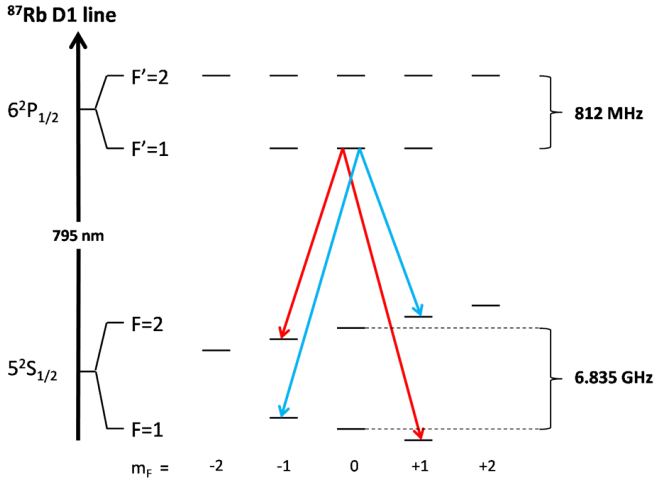

Fig. 1. Energy diagram of the ^{87}Rb D1 line at 795 nm and transitions involved in the $lin||lin$ configuration.

However, this latter option has two major drawbacks. A large intensity broadens the resonance, so that the high contrast is quickly counter-balanced by a broader linewidth $\Delta\nu$; secondly, it increases the magnitude of the second-order Stark shift (light shift).

The sequence and configuration that we propose, a pulsed Ramsey-like sequence on a cold ^{87}Rb sample combined with a $lin||lin$ configuration [8], can achieve high contrast without being limited by power broadening and large light shifts. The advantages of this approach are described in the following.

A. *lin parallel lin configuration*

The $lin||lin$ configuration was first proposed and studied by Taichenachev *et al.* in [8] and then investigated further in [9], [10], [11], [12], [13]. The CPT resonance is the superposition of two Λ systems (see Fig. 1) connecting the ground state sublevels $|F=1, m_F=\pm 1\rangle$ and $|F=2, m_F=\mp 1\rangle$ through the excited level $|F'=1, m_F=0\rangle$. Because this configuration does not involve any "trap state" we expect an increased contrast. Indeed, contrasts of up to 40 % have been reported in [8] and of 25 % in [11]. From an experimental perspective,

this scheme is well suited for a frequency modulated diode laser, as both beams have the same polarization.

B. Pulsed interrogation

Ramsey-like pulsed interrogation with CPT interactions was first performed in the late eighties with a thermal sodium beam and spatially separated interactions [14], [15], [16]. More recently, several groups have used the technique in alkali vapor cells [7], [17] and on cold atoms [18] with two optical pulses separated in time by T_R. The first pulse pumps the atoms into the "dark state" (duration τ_p); then the atoms evolve freely for a period of T_R, after which the second pulse (duration τ_m) measures the accumulated phase. An absorption measurement gives rise to an interference pattern typical of Ramsey interrogation. In this scheme, because the atoms evolve most of the time in the dark, the linewidth $\Delta\nu$ no longer depends on the atomic saturation but is Fourier limited and scales as $1/(2T_R)$. For a miniaturized cold atom clock, the interrogation period is limited by the atomic free fall under gravity to about 10 ms duration ($500\ \mu m$ displacement), leading to a 50 Hz linewidth.

III. Experimental Setup

The experimental apparatus has been fully assembled. This section presents some aspects of our designs and ideas concerning the vacuum chamber and the optical bench.

A. Vacuum chamber

We use a vacuum chamber produced by *Cold Quanta*[1] for atom-chip Bose-Einstein condensation experiments. The chamber is shown in Fig. 2 and described in detail in [19], [20]. The main chamber, where a 3D optical molasses is realized, is separated from a 2D-MOT zone containing a Rb dispenser by two pinholes of 1 mm diameter, ensuring differential pumping. The vacuum level in the main chamber is currently below 10^{-7} Pa, thanks to a 2 l/s ion pump and a getter pump.

The whole chamber is mounted horizontally to realize CPT interrogation parallel or perpendicular to gravity. A set of three pairs of Helmholtz coils is used to cancel the residual magnetic field and to define a proper quantization axis along the CPT beams.

B. Laser cooling setup

We use a single diode laser to feed both the 2D-MOT and the 3D-optical molasses regions. We have about 16 mW of power after a double-pass AOM and fiber coupling. The light is tuned about 2 Γ below the $|F=2\rangle \rightarrow |F'=3\rangle$ transition of the ^{87}Rb D2-line, where Γ is the resonance linewidth. The 2D-MOT is generated by use of two elliptical retroreflected beams of area 12 $\times$ 25 mm^2 with 5 mW of power in each beam. The quadrupole field is produced by two permanent magnets (12 G/cm). A 1 mW push beam (1 cm diameter) provides a 2D$^+$-MOT geometry. For the optical molasses we use retro-reflected 3 mm beams (diameter @ $1/e^2$) with about 1.5 mW in each pair. With this setup, we are able to capture a few $\times 10^6$ atoms per second, which is currently limited by laser power. The fluorescence is collected with a fresnel lens (NA = 1) with an efficiency of about 4 % on a high-gain photodiode.

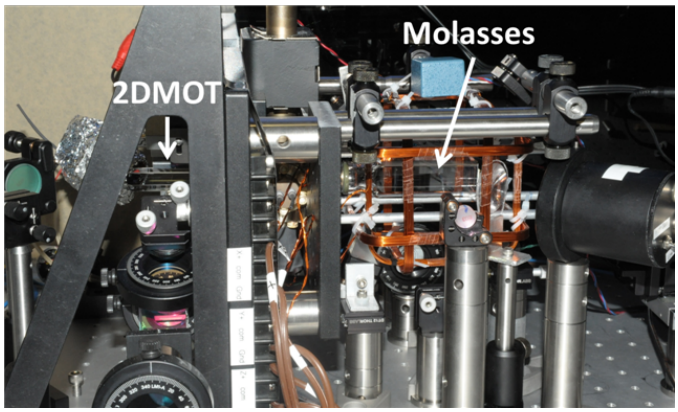

Fig. 2. Picture of the current apparatus.

C. Optical PLL setup

In many cases, the bichromatic laser field needed for excitation of the CPT resonances is generated by modulating the injection current of a diode laser. This produces a comb of optical frequencies of varying amplitudes. The unwanted residual sidebands degrade the clock performance by contributing to detection noise and the AC Stark shift, but they do not contribute to the CPT signal.

To avoid spurious sidebands in the CPT light we use two independent phase-locked diode lasers. We phase-lock two commercial DFB/DBR lasers at 795 nm with measured Lorentzian linewidths of 1 MHz and 0.6 MHz respectively. The optical beat note is realized around the ^{87}Rb hyperfine splitting at 6.8 GHz. The design of the optical phase lock loop is shown in Fig. 3. The amplified optical beat note is mixed with a 6.65 GHz signal coming from a microwave synthesizer (referenced to a 10 MHz H-Maser signal), filtered, amplified, and compared with a 150 MHz signal coming from a direct digital synthesizer inside a digital phase frequency detector (DPFD AD9901). This DPFD provides an error signal that is filtered and fed back on the slave laser's current. By use of high-speed electronics and through careful measurement of the FM response of both lasers to determine the best master/slave combination, we are able to achieve phase-locked operation with a bandwidth of about 8 MHz. We measured the fractional power in the coherent carrier to be about 70 %, which corresponds to a phase error variance of $0.35\ \mathrm{rad}^2$ over a 20 MHz integration bandwith. We measured the phase noise of the optically generated signal by comparing it to an external RF synthesizer, as shown in Fig. 3. The results are shown in

[1]Products or companies named here are cited only in the interest of complete scientific description, and neither constitute nor imply endorsement by NIST or by the US government. Other products may be found to serve equally as well.

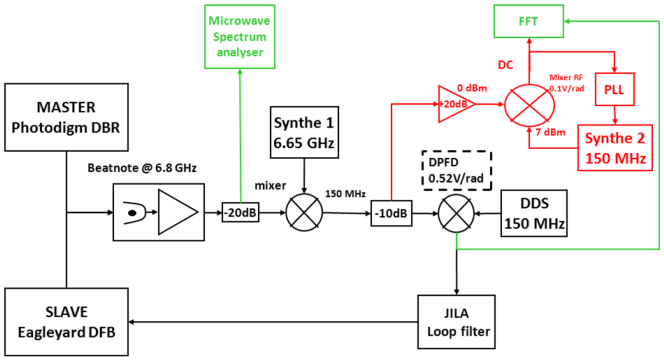

Fig. 3. Optical phase-lock-loop design

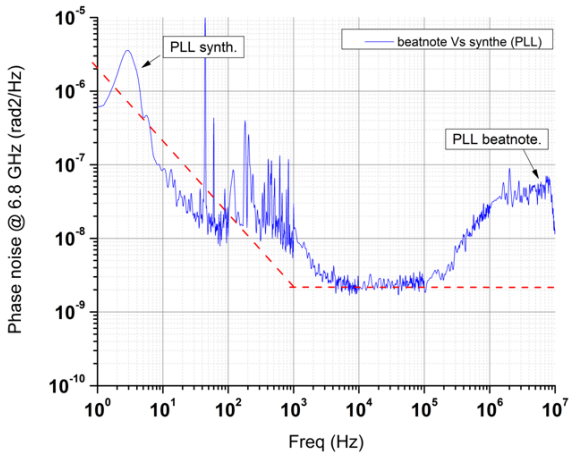

Fig. 4. Measured phase noise of the optically carried 6.8 GHz signal. The small bump around a few hertz is an artifact due to the very narrow band PLL used in the phase noise measurement.

Fig. 4. Out to several kilohertz, the phase noise is determined by joint contribution of the DDS and Synth2, and then we observe a noise floor corresponding to the PLL residual noise. Above 100 kHz the increase in the noise spectrum is due to the loss of PLL gain. With such phase noise, we estimate that the Dick effect will degrade the clock stability at a level of $5 \times 10^{-12}\tau^{-1/2}$. Because the sensitivity function of a pulsed CPT interrogation has yet to be derived, we used the appropriate function for a standard microwave Ramsey interrogation. The parameters used are a cycle duration of 100 ms, $T_R = 10$ ms and $\tau_m = \tau_p = 50$ μs.

ACKNOWLEDGMENT

***Abstract*—We report on the current status of the LNE-SYRTE fountain clock ensemble composed of three fully operational fountain, one of which is a dual Cs/Rb clock. We focus on the comparisons between them and their impact as primary frequency standards contributing to the accuracy of TAI..**

I. MOTIVATIONS

The LNE-SYRTE clock ensemble comprises three atomic fountain clocks FO1, FOM and FO2 [1]. FO2 is a dual fountain using both rubidium and cesium [2]. FOM is a transportable cesium fountain. The clock ensemble also includes an ultra stable frequency reference based on a cryogenic sapphire oscillator (CSO) and disseminated to all three fountains [3].

The main application of this fountain clock ensemble is to contribute to the realization of the S.I. second by calibrating of national and international timescales. All three fountains are primary frequency standards regularly contributing to TAI.

Developments during the last years focused on improving long term stability and accuracy, and ability to operate unattended for extended periods of time. This is an important step towards the completion of the ground segment for the PHARAO/ACES space mission scheduled for 2014. The second important goal of the fountain clocks is to perform fundamental tests, such as the test of the stability of the fundamental constants [4]. Here the Cs/Rb dual alkali fountain clock provides an original tool. A third application is the utilization of the fountains as frequency references for absolute frequency measurements of optical clocks. At SYRTE this concerns the two strontium lattice clocks now fully operational, and in near future the Hg clock under development. In addition, other optical clocks in foreign laboratories have been measured against the transportable fountain FOM. This is an important step in preparation for a redefinition of the SI second.

Here we give an overview of the current status of the clock ensemble, and present long term fountain comparisons performed over the last three years.

II. FOUNTAIN PERFORMANCES AND COMPARISONS

The four fountain clocks operate near the quantum noise limit using the CSO as an interrogation oscillator [3]. The CSO ultrastable reference at 12 GHz is down converted to 9 GHz and 1 GHz. The FO2 fountain being located near the CSO uses directly the ultrastable signals to generate the Cs/Rb clock frequencies. For FO1 and FOM, as well as the optical clock laboratory, located in distant buildings within SYRTE, the 1 GHz and 9 GHz signals are disseminated through actively compensated fiber links, which are simplified versions of the link described in [5]. Since the CSO drifts above 1000 s, it is slowly phase-lock to one of the four SYRTE H-masers, the one that is linked to BIPM through GPS and TWTFT links. Thereby, each fountain measures the maser frequency.

Each fountain uses optical molasses beams for atom loading and cooling starting from a 2D-MOT cold atomic beam presource, except the FOM which loads from a vapour source. Each fountain, except the FOM, is operated in differential mode HD/LD (high/low density) with atom numbers $N_{HD} = 2N_{LD}$ using adiabatic passage [6] to allow for real-time evaluation of the collision shift with about 1 % accuracy. This limits the fountain stability to $\sigma(2\nu_{BD} - \nu_{HD})$. Typical instability at high density is 3.5×10^{-14} at 1s for FO1 and FO2, and 7×10^{-14} for FOM using the CSO interrogation signal.

Each fountain clock synthesis is operated in a pulsed mode using a dedicated interferometric switch [7] with Rabi pulses durations adjusted to eliminate potential microwave leaks during the Ramsey interrogation. We regularly check the absence of phase transients synchronous with the fountain cycle, or induced by the switching process, using a heterodyne phase transient phase analyzer [7].

Each fountain produces measurements, corrected for all systematics, at 1 measurement per cycle. The individual fountain measurements are averaged over each $1/100^{th}$ of day (864 s) to serve as a synchronous basis to make the frequency

This research is funded in part by CNRS and by LNE.

differences between them, taken two by two. This direct comparison eliminates the local oscillator noise.

An example of frequency instability between FOM and FO2 over 50 effective days of comparison is presented in Fig. 1. A stability of about 2×10^{-16} is obtained at $\tau = 4.5$ days.

The typical accuracy of the fountains is 3.8×10^{-16} for FO1 and FO2-Cs, 4.5×10^{-16} for FO2-Rb, and 7×10^{-16} for FOM, wherein the leading uncertainty of 3×10^{-16} comes from first Doppler effects associated with distributed cavity phase shifts. Recent quantitative evaluation of this effect with FO2 reduces this error to 8.4×10^{-16} for FO2-Cs [8].

Fountain comparisons are now performed regularly. The frequency differences of the three Cs fountain clock pairs over years 2008-2010 is presented on a monthly basis in Fig.2. The data corresponds to a total number of days of comparison of about 800 days. The error bars are total uncertainties for the clock pair which are dominated by the systematic uncertainty U_b. The weighted average differences D and related U_b are given in Table 1. We see that the FOM-FO1 and FOM-FO2 differences are well within the U_b, while the FO1-FO2 is slightly larger than one U_b. Although uncertainties are mainly of systematic origin, we test the statistical significance of these mean differences. To this aim, we evaluate the χ^2 of the weighted differences with respect either to the mean D or to zero. The goodness-of-fit Q and Q_o respectively, as defined in numerical recipes [9], are given in Table I. The Q's very close to 1 indicate that fluctuations about the means D's are much smaller than the total uncertainties. Q_o which tests deviations (and/or fluctuations) from a null difference shows that FOM-FO2 and FOM-FO1 agree within total uncertainties, while the low Q_o for FO1-FO2 would indicate a slightly underestimated systematic effect, of a few 10^{-16}. Similar analysis for a comparison of worldwide fountain primary frequency standards exploiting their calibrations of TAI is reported in [10].

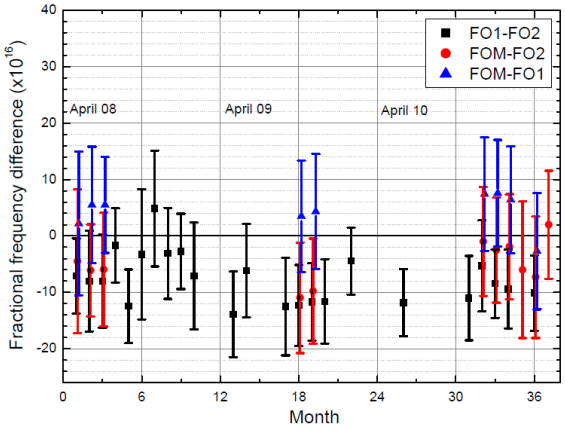

Figure 2. Fractional frequency differences between the three SYRTE Cs fountain pairs over the last three years. Error bars are total uncertainties dominated by the systematic uncertainties.

TABLE I. χ^2 TEST OF THE CS FOUNTAIN DIFFERENCES PLOTTED IN FIG.2

	D (x 10^{-16})	U_b (x10^{-16})	D/U_b [a]	Q	Q_0
FOM-FO2	-4.85	9.1	0.53	0.999	0.935
FOM-FO1	4.65	9.2	0.50	0.999	0.95
FO1-FO2	-8.1	6.2	1.31	0.999	0.037

a. D/Ub represents the difference in unit of standard deviation.

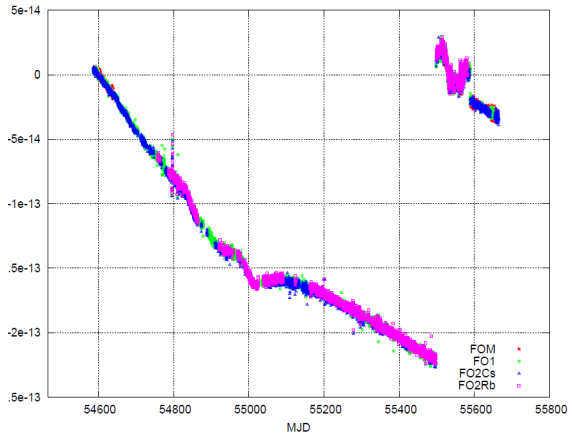

Figure 3. SYRTE fountain measurements of one H-maser at SYRTE (H 140-0890 from Kvarz, then 140-0816 from Symmetricom and again 140-0890). Changes in reference maser occurred due to failure.

III. SYRTE CS FOUNTAIN CONTRIBUTIONS TO TAI

Since 2007 the four fountain clocks, including FO2-Rb, are measuring the frequency of one of the SYRTE H-masers almost continuously, as shown in Fig. 3. These data were exploited to participate to the accuracy of TAI. Since 2007, about 75 formal reports have been transmitted from SYRTE to BIPM over a total of 161 reports from all standards worldwide, *i.e.* the contribution is by almost 50%. Each report

corresponds to the measurement of the H-maser by one fountain over 20-30 days, reaching a statistical uncertainty of about 1.2×10^{-16} and uncertainty of 1.5×10^{-16} due to dead times.

IV. SUMMARY AND SOME OUTLOOKS

In summary, we have presented long term comparisons between the SYRTE fountain clocks down to the $1x10^{-16}$ level. The fountains differences are consistent with the total stated uncertainties for each clock pair, except for the FO1-FO2 pair for which a systematic effect of a few 10^{-16} may be slightly underestimated. This is under current investigation. Recent improvements in the fountain operation and for long term comparison are provided by monitoring softwares capable of assessing the status of the overall system and automatically preprocessing clock data. These recent developments also result in an enhanced capability to contribute to International Atomic Time (TAI). Operational compensated fiber links within SYRTE allows for reliable comparisons between the fountain clocks and the optical lattice Sr and Hg clocks.

Disciplined Rubidium Oscillator For Harsh Environments

T. McClelland, I. Shtaerman, E. Zarjetski, R. Baransky, M. Khurgin
Frequency Electronics, Inc.
Uniondale, NY/USA
tomm@freqelec.com

***Abstract*— A disciplined rubidium (Rb) oscillator has been developed for use in harsh environments. This oscillator operates from -40°C to +82°C, in the presence of random vibration of up to 19 g RMS; while continuously maintaining lock of both the Rb control loop and the disciplining loop. Performance under vibration is enhanced by incorporation of a quartz oscillator with active MEMS accelerometer based vibration compensation. The device warms up in less than 15 minutes, and can be disciplined to a 1 pps input, such as the signal from a GPS receiver. One of the unique features of this device is the capability to align the internally generated RF and 1 pps signals to the input 1 pps signal with a resolution of < 1 nsec. This is accomplished using a novel PLL approach for locking the internal RF signals to the disciplining 1 pps input. A number of design refinements to the Rb physics package have also been implemented which significantly improve the performance during "holdover" conditions when no disciplining signal is present. A major design goal of this device is to reduce the accumulated time error during a 24 hour holdover period to < 245 nanoseconds.**

The design of this device is described, and performance data is presented to demonstrate actual performance of initial production units compared to the design objectives.

I. INTRODUCTION

A Rb oscillator designed for use in harsh environments has been developed. The device is also capable of being disciplined by an external one pulse per second (1 PPS) signal, such as is typically available from a GPS receiver. This Rb oscillator utilizes a conventional, lamp excited vapor cell physics package, but with some key updates to the electronics, which make possible significant improvements to the performance generally obtained from this class of oscillator [1], [2], [3].

Photographs of this device are shown in Figure 1. , and Figure 2. , and an outline drawing, showing dimensions is provided in Figure 3. The unit is 4 x 6 x 1.5 inches, and weighs 29 ounces (820 grams).

Figure 1. Photograph of disciplined rubidium oscillator

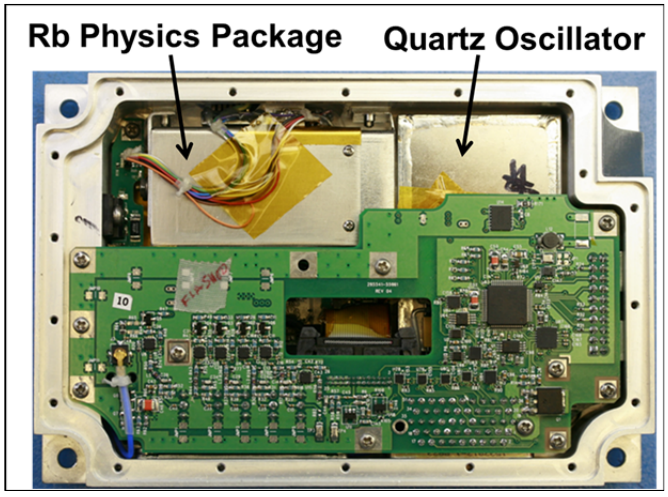

Figure 2. View of Rb oscillator with cover removed

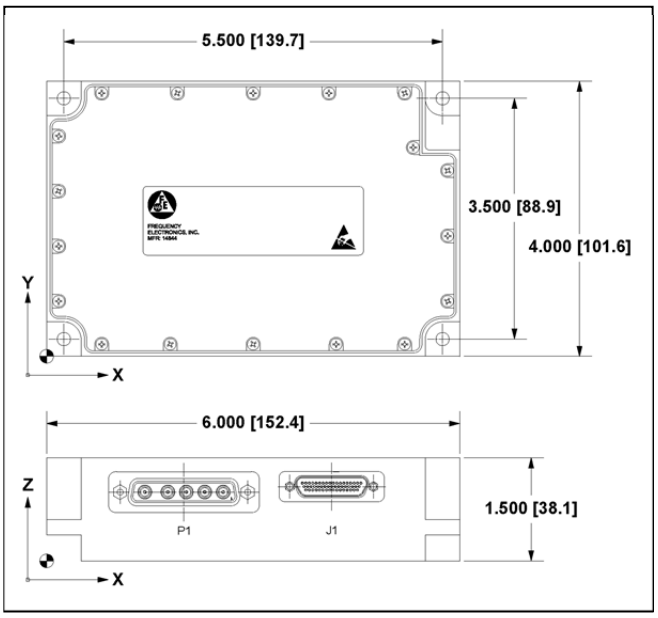

Figure 3. Outline drawing of Rb oscillator. Dimensions are in inches [millimeters].

II. DESIGN

A functional block diagram is provided in Figure 4. The device accepts a 1 pulse per second (PPS) input as a disciplining input, and provides both 10 MHz and 1 PPS outputs.

The 10 MHz outputs are derived from a quartz oscillator which incorporates active acceleration compensation in order to improve the performance during vibration. This active compensation is achieved by using the signals from MEMS accelerometers attached to the quartz resonator to correct for the acceleration induced frequency shifts in the resonator. A block diagram showing this is provided in Figure 5.

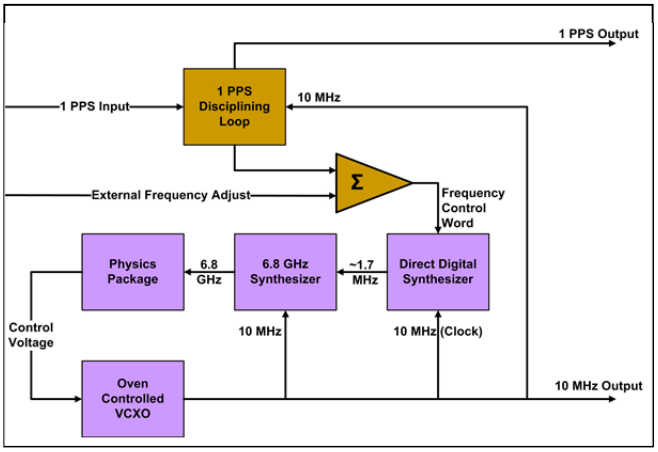

Figure 4. Block diagram of Rb oscillator

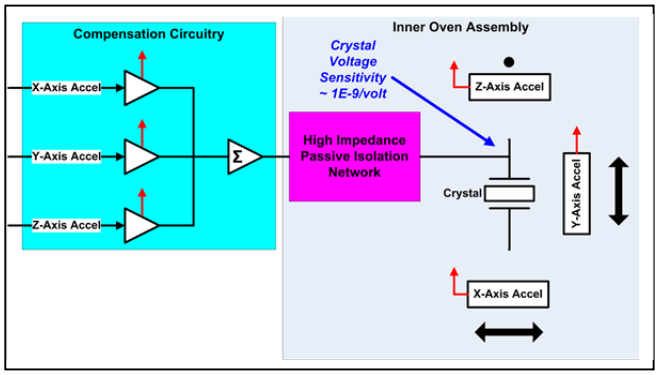

Figure 5. Block diagram of acceleration compensation circuitry

The rubidium control loop utilizes a direct synthesis approach to generate a signal at the Rb hyperfine resonance frequency of ~6.8 GHz. This signal is synthesized external to the Rb physics package, eliminating the need to incorporate any microwave circuitry inside the physics package. Previous designs of this type incorporate a step recovery diode comb generator inside the physics package, which generally involves the placement of components with ferromagnetic (kovar) packages near the Rb resonance cell. This magnetic material, when present, causes frequency variations which limit the achievable frequency stability.

The microwave excitation of the physics package modulates the transmitted light optical signal, which is used to steer the VCXO.

The 1 PPS disciplining loop adjusts the Rb frequency based on the 1 PPS input. This phase locked loop (PLL) utilizes a proprietary time interval counter which employs a direct digital synthesizer (DDS) clocked by the 10 MHz internal reference. The PLL measures the phase of the DDS output at the time of arrival of the input 1 PPS signal. The phase of the DDS output can be measured/adjusted with 12 bit accuracy, which allows the phase of the *output* 1 PPS signal to be aligned with the *input* 1 PPS signal with an accuracy of < 0.8 nanoseconds.

This PLL adjusts the output frequency of the Rb oscillator by adjusting the frequency of another DDS which is part of the microwave synthesis chain. The frequency can be adjusted in this way with a resolution of $<1 \times 10^{-14}$.

With a 1 PPS input, the disciplining loop adjusts the Rb oscillator frequency by steering the DDS frequency. With no 1 PPS input, manual frequency adjustment of the Rb oscillator is similarly accomplished; by external command which controls the frequency of the DDS.

III. PERFORMANCE

Considerable efforts (e.g. chip scale atomic clock programs) have recently been directed to driving down the size, weight, and power of Rb standards, while accepting performance compromises[4], [5]. This effort has a different goal. Rather than trying to achieve the smallest possible size, weight, and power, the goal is to achieve the best possible performance; while not significantly increasing the size, weight, and power compared to typical commercially

available Rb oscillators. Certainly, progress has been made toward this end.

A. Short Term Frequency Stability

The short term frequency stability of this Rb oscillator over a 5 day period of time is shown in Figure 6. , and Figure 7. This data is for an un-disciplined unit, and thus represents a measure of the capability of the free running Rb system. The fact that the Allan deviation exhibits $1/\sqrt{\tau}$ behavior out to 10,000 seconds is an improvement over what has generally been achieved in the past with this class of Rb oscillator [1], [2], [3].

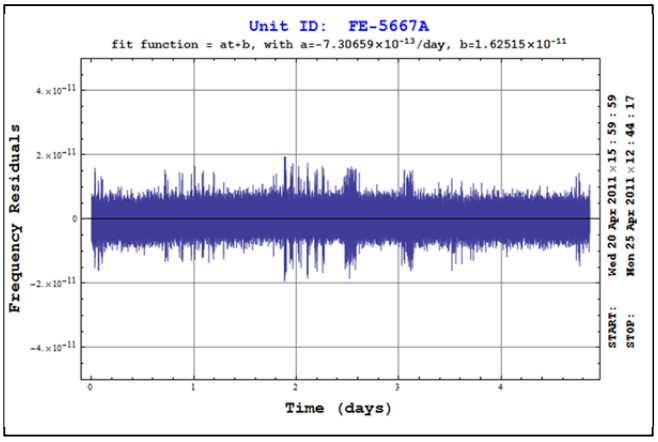

Figure 6. Frequency stability of ***un-disciplined*** Rb oscillator over a 5 day time period, at constant temperature (25°C). A linear drift of -7.3 x 10^{-13}/day has been removed from the data.

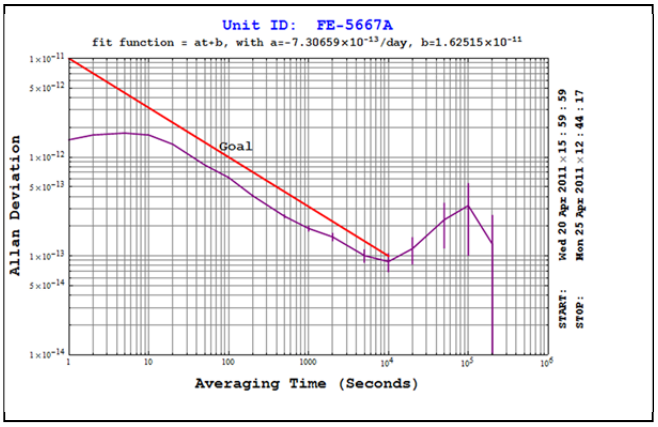

Figure 7. Allan deviation of ***un-disciplined*** Rb oscillator, from frequency data plotted in Figure 6. Performance at $\tau = 1$ second reflects the quartz oscillator noise, while the $\tau = 10$ to 10,000 second performance reflects the Rb loop white frequency noise.

B. Frequency vs. Temperature

Frequency vs. temperature for this device, again while un-disciplined, is provided in Figure 8. From -25°C to +75°C the frequency variation is <3 x 10^{-11}, performance which is an order of magnitude better than what has typically been achieved in the past [1], [2], [3].

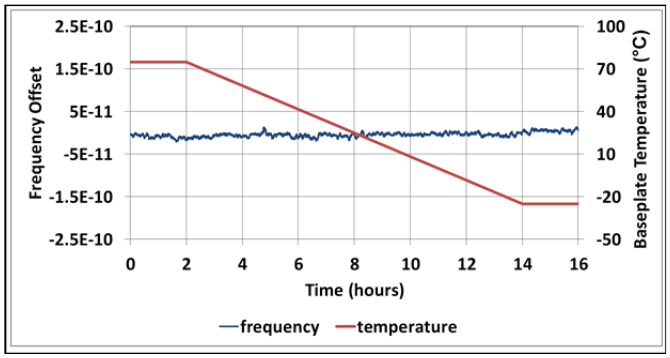

Figure 8. Frequency vs temperature of Rb oscillator from +75°C to -25°C. Test performed with ***no*** disciplining input

C. Holdover

Disciplined Rb oscillators are often used as primary frequency and time references in communication networks. One of the major concerns in this type of application is the behavior of the oscillator during brief periods of time ("holdover") during which the disciplining source is not available; for instance due to local jamming of GPS signals, urban canyon loss of GPS signals, or antenna failure. Depending on the application, holdover times for Rb oscillators are specified anywhere from 15 minutes to 100 days, but most often for a period of 24 hours.

Accumulated time error for this Rb oscillator during a 24 hour holdover period is shown in Figure 9. The test results shown in the figure demonstrate performance under simulated worst case temperature conditions given a maximum diurnal temperature variation of 17°C. In this case, the time error accumulated in 24 hours is under 25 nanoseconds. The unit is designed to be able to maintain <245 nanoseconds time error during any 24 hour holdover period. This performance is more than an order of magnitude better than what has generally been achieved in the past with compact Rb oscillators.

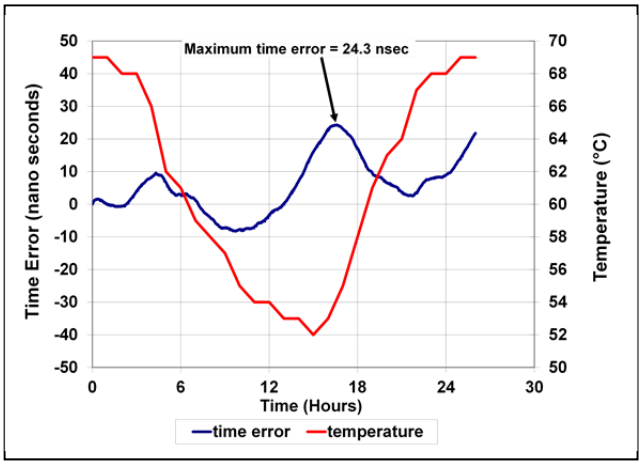

Figure 9. "Holdover" test to determine accumulation of time error while Rb oscillator is ***un-disciplined***. Time error accumulated over 24 hours is shown. Unit was subjected to a diurnal temperature variation of ~17°C, simulating a worst case condition, during this test.

D. Vibration

This Rb oscillator is designed not only to survive, but to function while undergoing severe vibration. As described above, the quartz oscillator incorporates active vibration compensation in order to improve performance under vibration conditions. Performance under extreme conditions (vibration = 19 g_{RMS}) is shown in Figure 10. The figure shows performance under vibration both with and without the active compensation circuitry enabled. For the results shown in the figure, the unit was subjected to vibration shown in TABLE I. From the figure, it is clear that active compensation improves the performance by more than 20 dB for vibration between 10 and 100 Hz.

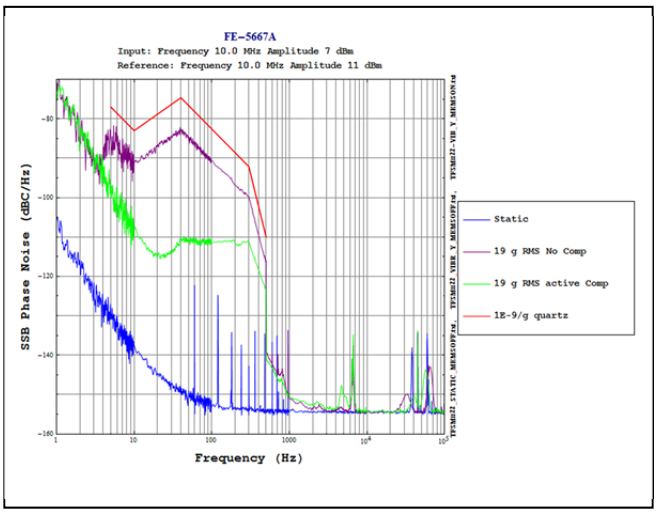

Figure 10. Phase noise of Rb oscillator. Both static phase noise and phase noise under vibration along x-axis are shown. The vibration profile used to collect this data is shown in TABLE I. These tests were performed on an ***un-disciplined*** Rb oscillator

TABLE I. RANDOM VIBRATION PROFILE

Frequency (Hz)	PSD (g^2/Hz)
5	0.01
10	0.01
40	1.1
300	1.1
500	0.05
total	**19 g RMS**

E. Warm-up

Fast warm-up is critical for many applications in which relatively short periods of operation may occur. This is the situation for units deployed in wheeled vehicles and aircraft. Performance immediately after turn-on is a challenge for Rb oscillators due to the fact that the major physics package elements must be ovenized. Disciplining to an external 1 PPS signal compounds the difficulty, especially when the disciplining source is a typical GPS signal with 20 to 120 nanoseconds of jitter.

Warm-up of this Rb oscillator is shown in Figure 11. During this test, the unit is continuously disciplined by a 1 PPS input signal. From the figure it is seen that 15 minutes after turn-on, the phase of the Rb oscillator generated signals are aligned with the phase of the input 1 PPS to within 10 nanoseconds. The frequency is accurate to within a few parts in 10^{-11} at the 15 minute point.

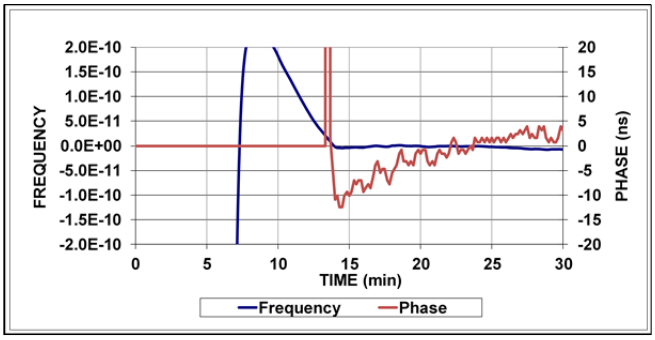

Figure 11. Warm-up of Rb oscillator at -40°C with 1 PPS input. Test performed ***with*** disciplining input signal.

F. Magnetic Field Sensitivity

Performance under conditions of varying magnetic field is often overlooked in Rb oscillators of this type. However, this is actually quite important in many of the dynamic environment applications such as moving vehicles, and aircraft. This Rb oscillator has exceptionally good performance in changing magnetic field conditions, as demonstrated in Figure 12. This figure shows that for a magnetic field variation of ±4 gauss, the frequency variation is less than 1 x 10^{-11}. This is at least 5 times better than other similar units.

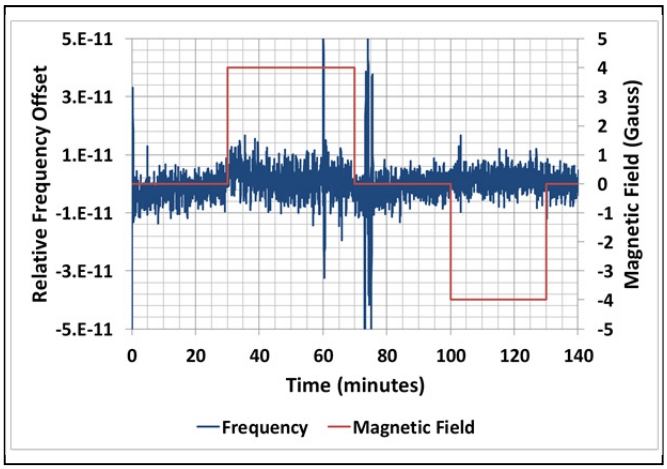

Figure 12. Magnetic field sensitivity of Rb oscillator, ***un-disciplined***. Frequency change is shown on the left axis, corresponding magnetic field on the right axis.

IV. CONCLUSION

A disciplined rubidium oscillator for use in harsh environments has been developed. This oscillator achieves much better performance than comparable devices currently available. The emphasis in designing this unit has been to

improve performance; not, as is the case for chip scale atomic clock efforts, to reduce size, weight and power even if performance compromises are necessary. Short term frequency stability, warm-up, holdover time error capability, performance over temperature, vibration operation, and magnetic field sensitivity five to ten times better than other Rb oscillators of this type have been demonstrated.

Stability of Relaxation Processes in a Quantum System as a Main Factor for Achieving the High Long-Term Frequency Stability of a Standard

Abstract **– The processes of synchronous Zeeman's relaxation are investigated with simultaneous observing population difference, M_z (τ_1) – and coherence, M_x (τ_2), - components within a spin of system of ^{87}Rb atoms in cells with antirelaxation coating, when changing cell *volume*, operating *temperature* and pumping *light intensity* with D_1 – line.**
The existence of total relaxation 'degeneracy' is experimentally determined which is characterized through ($\tau_1 \approx \tau_2$) – condition being necessary [1] for achieving a high long-term frequency stability of standards (in particular, quantum magnetometers).
The procedure for investigating relaxation processes developed by the author could be useful for the realization of atomic frequency standards with a high long-term frequency stability.

I. INTRODUCTION

Of all atomic frequency standard's parameters the major one is the long-term frequency stability. All efforts of frequency standards' researchers and creators are ultimately directed to achieve a high long-term frequency stability.
The central unit providing a long-term frequency stability is the atomic discriminator. Whatever the quantum system is used, two main factors affect obtaining the maximum value of atomic discriminator's long-term frequency stability:
1. Technique for exciting a resonance '0-0' – transition which implies the realization of the regime of atomic system's forced oscillations by means of, in particular, the external alternating magnetic field, $H_1 \cdot \cos\omega t$.
2. Dynamics of relaxation processes within a quantum system.

II. Impact of the Regime of Quantum System's forced Oscillations on Long-term Stability.

1.1. It is found that the resonance exciting field, $H_1 \cdot \cos\omega t$, shifts a resonance frequency of the quantum system, $\nu_{0\text{-}0}$, by a small value, $\delta\omega^{(2)}_{b\text{-}s} \sim \gamma H_1^2 / 4H_0$, which is a constant correction of the second order for the field amplitude H_1, and is known as the Bloch-Siegert shift. At frequencies of hyperfine '0-0' – transitions, this correction is small ($\sim 10^{-15}$), not accounted for in practice and does not affected a value of long-term stability.
1.2. One should consider as a success of the recent decade such a point as the detection of a drift varying-in-time correction of the first order of $\delta\omega^{(1)}_{ch\text{-}p} = (\gamma \cdot H_1 \cdot z/a) \cdot \cos\vartheta$ – kind made E.Pestov and A.Chirkov [1]. This correction caused by a forced oscillations' regime itself, is always presents in frequency standards. It cannot be removed in practice and is a source of the long-term drift of resonance frequency's center, $\nu_{0\text{-}0}$, with a long period – from several units of day to tens or more. The variable correction, $\delta\omega^{(1)}_{ch\text{-}p}(t)$, affects significantly the standard's long-term frequency stability.

III. Impact of Relaxation Processes' Dynamics within a Quantum System on Long-Term Stability of a Standard. Results of the Investigation

For providing a stability of various quantum systems' states, it is necessary in practice to solve a number of difficult technical tasks. Let us consider a problem related to the need in supporting the stability of relaxation processes within absorption cells of rubidium frequency standards (RFS) and point out the ways to improve a long-term stability of frequency standards of this type.

As is shown in the same work [1], achieving the ultimate long-term stability of any quantum system when exciting a resonance by the harmonic field, $H_1 \cdot \cos\omega t$, is only possible when realizing within this system a regime of stationary oscillations (RSO) in which a drift variable correction of the resonance frequency, $\delta\omega^{(1)}_{ch\text{-}p}(t)$, tends to a negligible value. For providing RSO existence and steadiness (under conditions of frequency detuning, $\Delta\omega = |\omega - \omega_0| = 0$), resonance signal's amplitude, a_s , population difference, z_s , and phase difference, ϑ_s , between phases of resonance field and atom should be supported with a super high accuracy during the operation of a frequency standard. It is difficult to solve this task in practice, in particular, with respect to ϑ_s [1]. In addition, RSO steadiness is significantly affected by relaxation processes disturbing a frequency of the clock atomic transition.

From [1] it follows that, for improving RSO steadiness (and, consequently, improving a high standard's long-term stability), it is necessary to realize within a quantum system the equal intensity of relaxation processes as regards population component (M_z) and coherence component (M_x) of operating states, i.e. to provide a condition of equality for efficient relaxation times, $\tau_1 \approx \tau_2$, respectively. The distinction in intensities of this processes (at $\tau_2 < \tau_1$) which takes place in practice is an additional source of lowering the long-term stability of a standard (AFS).

As will be shown later, for realizing the case $\tau_1 \approx \tau_2$, we recommend to use gas cells with anti-relaxation wall (ARW) coating. For example, Cs cells with ARW-coating were for the first time used as early as 1971 in the USSR within Cs magnetometer at "Cosmos-355" geophysical satellite [2]. The Cs quantum sensor operated under conditions of open space and demonstrated super results.

The manufacture of cells and wide-scale investigations of relaxation processes in ^{133}Cs, ^{87}Rb, ^{39,41}K cells with ARW -coating were conducted in IZMIRAN (USSR). [The author of this work participated in these investigations].

In recent years the interest is growing as regards the use of cells with ARW-coating in frequency standards due to more efficient optical pumping and lower intensity of relaxation processes compared to those in buffer gases. It manifests itself as increase in SNR value and decrease in resonance line width, $\Delta\nu$. For example, when using Rb - cylindrical cells of our manufacture (coating is tetracontane) with dimensions of Ø22x22, the width of '0-0'-resonance line decreased by 4-5 times compared to the lines within the similar cells with buffer gases. The absorption cells with ARW-coating have a larger value of the figure of merit, $Q \sim [S(\tau_1)/N]/\Delta f(\tau_2)$, and this opens a prospect for creating the competitive ^{87}Rb frequency standards.

On the strength of this data, such a problem becomes actual as conducting investigations of relaxation processes' dynamics in the ^{87}Rb cells with ARW-coating for detecting a condition of relaxation times equality, $\tau_1 \approx \tau_2$, when changing cell *volume*, operating *temperature*, optical pumping *intensity*.
In this work, the results are presented as regards experimental investigations of Zeeman's relaxation times of population difference, τ_1, and coherence, τ_2, [3], in $F_g = 2$ state of ^{87}Rb atomic spin-system within cells with ARW-coating as functions of pumping lamp's light intensity, $I_1(D_1)$, and temperature, t^0C.

τ_1 (I_1, t^0)- and τ_2 (I_1, t^0) - dependences within cylindrical ^{87}Rb cells of various dimensions are obtained using a technique developed by the author for measuring τ_1 and τ_2 *synchronous* relaxation in spin systems [4] which allows to simultaneously observe both relaxation processes – population difference component, M_z, and coherence component, M_x. Analysis of current works on relaxation investigation in spin systems shows that these investigations are only restricted by a single relaxation component – population difference, M_z [5,6].

Fig. 1 shows dependences of relaxation times τ_1, τ_2 on a change in pumping light's intensity with D_1-line, $k \cdot I_1$, for ^{87}Rb cells of various dimensions:
plots 1 (τ_1), 2 (τ_2) – sphere, Ø38 (inner 36.5); cylinders, 3 (τ_1), 4 (τ_2) – Ø22x22 (inner Ø19x19) mm;
5 (τ_1), 6 (τ_2) – Ø15x15 (inner Ø12x12) mm. $I_1 = 1 \sim 25$ $\mu W/cm^2$; here k = 0.1; 0.15; 0.32; 0.5; 0.7 – transmission factors of neutral light filters. (1-6) curves characterize the relaxation processes' dynamics of M_z and M_x components depending on a change in cells' volume at the fixed cell temperature, $T \approx 23^0$C.

Fig. 2 demonstrates similar dependences of relaxation times, $\tau_1(k \cdot I_1)$, $\tau_2(k \cdot I_1)$, for cylindrical ^{87}Rb cell of Ø15x15 – dimensions. (1-4) dependences characterize the relaxation processes' dynamics of M_z and M_x components depending on a change in the cell temperature.
The high-melting paraffin $C_{40}H_{82}$ of high-degree purity was selected as coating.

Each event of atom's collision with a wall generates on this wall a fluctuating local field along all coordinates: $\overline{H_x^2}$, $\overline{H_y^2}$, $\overline{H_z^2}$ - are the average energies of the components of the variable magnetic field *induced* in the time of the atom's interaction with the cell wall-coating.
Microscopic relaxation theory (Redfield, Kubo, Tomita) gives expressions for relaxation times, T_1 and T_2 , [7]

$$1/T_1 = \gamma^2 [\, \overline{H_x^2} + \overline{H_y^2} \,] \cdot \tau_c / (1 + \omega_0^2 \cdot \tau_c^2) \qquad (1)$$

$$1/T_2 = \gamma^2 [\, \overline{H_z^2} \cdot \tau_c + \overline{H_y^2} \cdot \tau_c / (1 + \omega_0^2 \cdot \tau_c^2 \,)] \qquad (2)$$

These local fields, $\overline{H_x^2}$,.., are the cause of decrease of the population difference and resonance broadening.
It follows from the expression (1) that T_1 affects only the population, Δn, because of the transverse fluctuating fields, $< H_x^2 >$ and $< H_y^2 >$, transfer the atom from one sublevel (m_F) to another one ($m_F \pm 1$) at the resonance frequency, ω_0 , and lower a signal value. The expression for T_2 (2) is of more complicated kind and characterizes a loss in phase coherence which is accompanied with a resonance broadening.
Let us consider some *specific features* of relaxation as regards populations (T_1) and phase (T_2) on coating.

1. When increasing in a cell temperature, the correlation time, τ_c , i.e. time of interaction with a wall, decreases. This means that T_1 and T_2 increase.

2. Rates of T_1 and T_2 growth due to a change in temperature are different. It follows from formulas (1) and (2) that the T_1 time will increase *faster* than T_2 with a decrease in the correlation time.

3. The addendum, $\overline{H_z^2} \cdot \tau_c$, for the phase relaxation (T_2) reflects the dipole-dipole interaction and causes a resonance broadening. It lowers also the T_2 increase velocity on coating when the temperature increases.

4. For wall relaxation times, T_1 and T_2, the inequality $T_1 \neq T_2$ is always satisfied, and $T_1 > T_2$.

Let us write the expressions for times τ_1, τ_2 taking into account spin-exchange and optical pumping.

$$1/\tau_1 = 1/T_1 + 1/\tau_{sp-ex}^{(1)} + 1/\tau_p \qquad (3)$$

$$1/\tau_2 = [1/T_2'(\overline{H_z^2}) + 1/2\,T_1 + 1/T_{S\text{-}N}] + 1/\tau_{sp-ex}^{(2)} + 1/\tau_p \qquad (4)$$

The addendums in the first brackets are responsible for the phase relaxation *on coating*, where $1/T_{S\text{-}N}$ is spin-spin relaxation due to the interaction of a working atom's spin with the coating's nuclear spin.
Let us rewrite the formula (3), (4) in a compact style.

$$1/\tau_1 = 1/T_1 + 1/\tau_{sp-ex}^{(1)} + 1/\tau_p \qquad (5)$$

$$1/\tau_2 = 1/T_2^* + 1/\tau_{sp-ex}^{(2)} + 1/\tau_p \qquad (6)$$

These formulas describes experimental dependences which will be presented below.
In the course of experiment, a pumping intensity, $k \cdot I_1$, is changed. When decreasing $k \cdot I_1 \rightarrow 0$, we obtain dark elaxation times, τ_1^* and τ_2^*, acting within a cell, which reflect wall and spin-exchange relaxations (7,8):

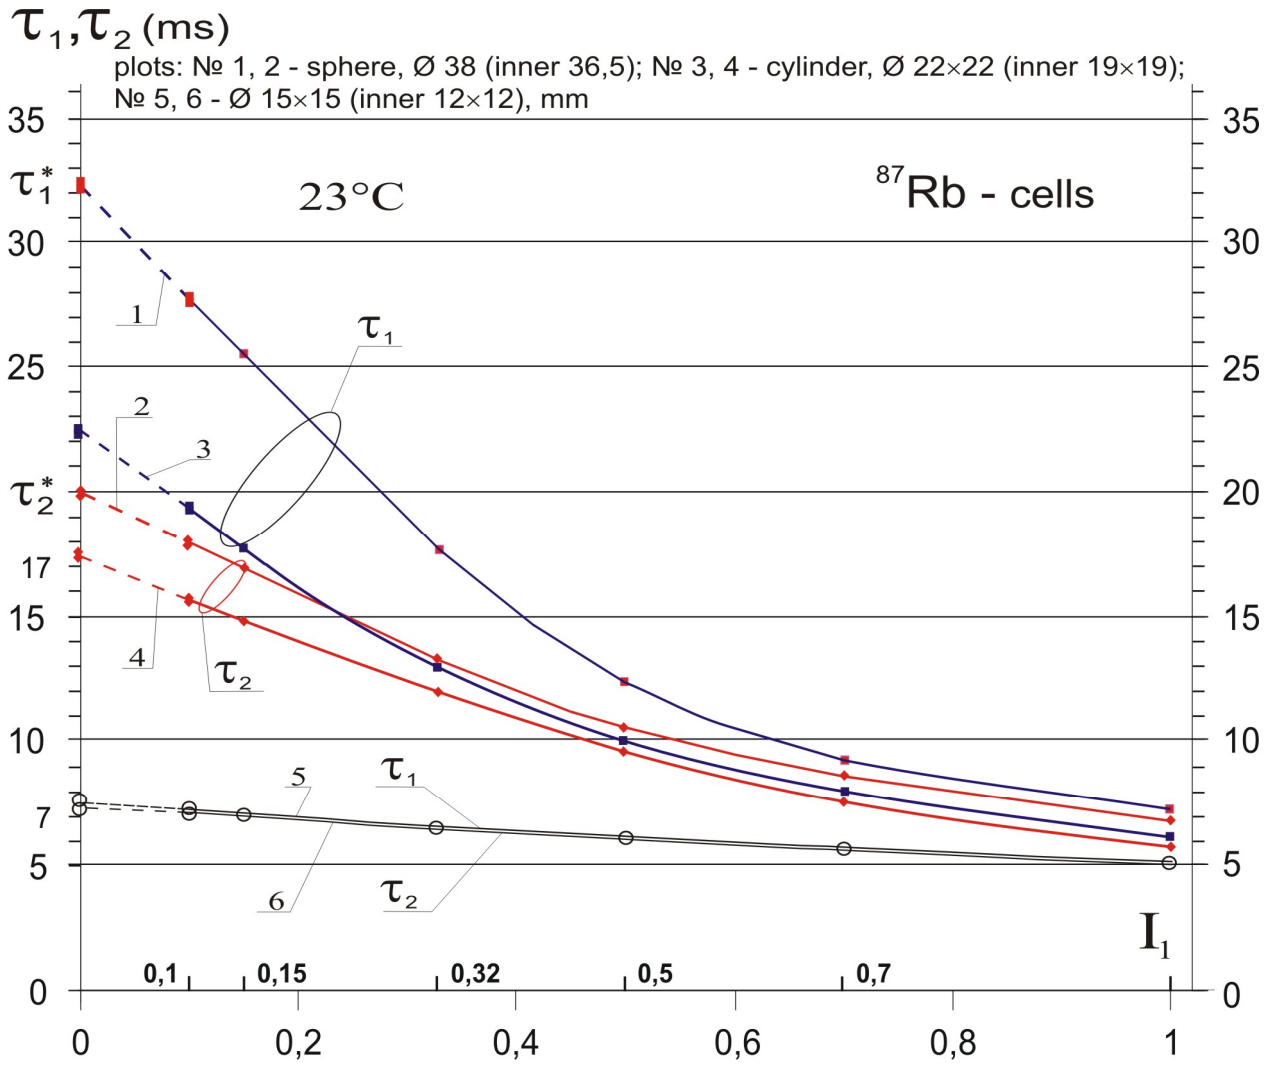

Fig. 1. Dependences of relaxation times τ_1, τ_2 on a change in pumping light's intensity with D_1 –line for ^{87}Rb cells of various dimensions

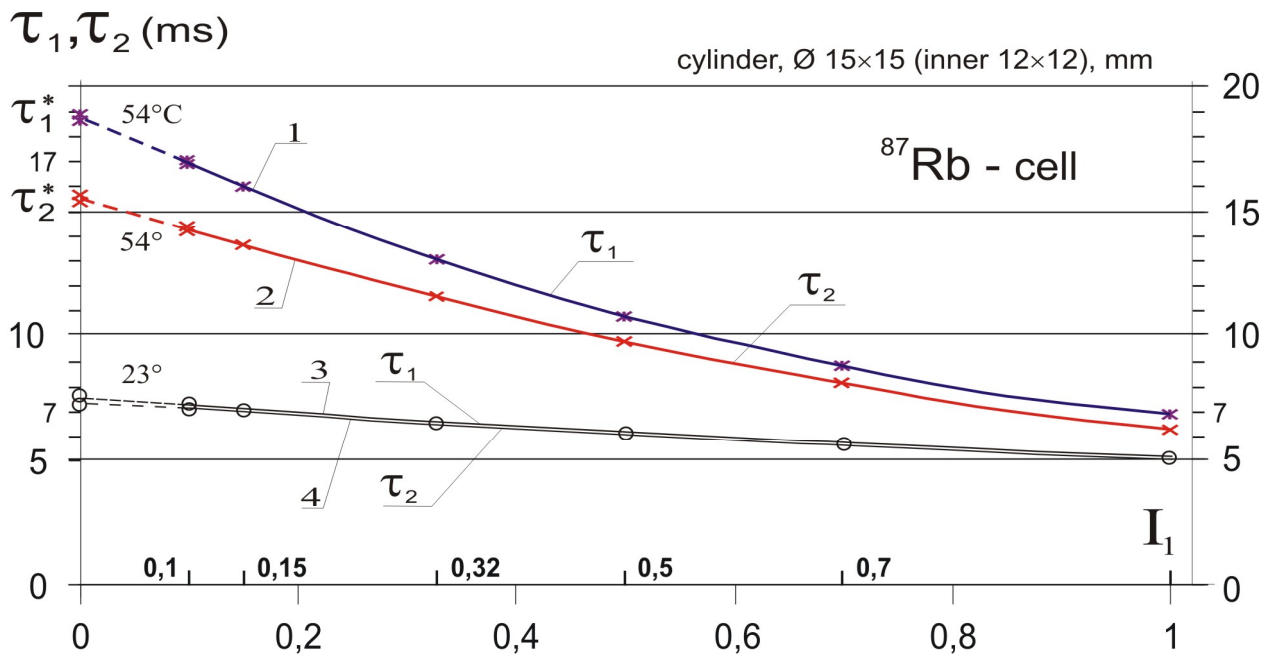

Fig. 2. Dependences of relaxation times τ_1, τ_2 on a change in pumping light's intensity with D_1 –line for cylindrical ^{87}Rb cell of Ø 15×15 (mm) in the various temperature

$$1/\tau_1^* = 1/T_1 + 1/\tau_{sp-ex}^{(1)}, \quad (7)$$

$$1/\tau_2^* = 1/T_2^* + 1/\tau_{sp-ex}^{(2)}, \quad (8)$$

where T_1, T_2^* are the relaxation time on the wall coating; τ_1^* and τ_2^* values are on the ordinate axis, Fig.1, 2.

Let us consider specific features of results obtained in this work.

1. Change in a cell volume (t^0 = const = 23^{0}C), Fig.1.

• When increasing a cell volume (cylinder, Ø15x15 → Ø22x22 → sphere Ø38, mm), a difference, $\Delta = \tau_1^* - \tau_2^*$, is increased between dark relaxation times, τ_1^* and τ_2^*, respectively:
$\Delta_{Ø15x15} \leq$ 0.5 ms; $\Delta_{Ø22x22} \sim$ 5 ms; $\Delta_{Ø38} \sim$ 12 ms. In so doing, τ_1^* time increases significantly faster than τ_2^*. These circumstances show that, then increasing a length of atomic free path, a frequency of atomic collisions with the wall and between themselves decreases. As a result, such a parameter decreases as the spectral power density of fluctuating local fields on the wall, $<H_x^2>$ and $<H_y^2>$, revealing in T_1 and τ_1^* increase.

• τ_2^* value is always less than τ_1^*, i.e. $\tau_2^* < \tau_1^*$. The reason is the presence of $1/T_2^*$ ($<H_z^2>$, $1/T_{S-N}$) addends in the formula for τ_2^* (4) which decrease τ_2^* and broaden the resonance.

• The interesting phenomenon is observed for a cylindrical cell with a lesser volume, Ø15x15 (curves no. 5, 6). For this cell, some *total* 'degeneracy' for relaxation times, ($\tau_1 \approx \tau_2$), takes place which is being characterized not only by the dark 'degeneracy', $\tau_1^* \approx \tau_2^*$, at $I_1 = 0$, but also by the 'degeneracy' within all range of pumping light's intensity change, $k \cdot I_1$. This state of the relaxation 'degeneracy' within a quantum system, according to [1], just provides a condition for achieving a high long-term frequency stability of a standard.

• The pumping light, while acting on a quantum system as the light relaxation, helps to generate a state being near to the relaxation 'degeneracy' ($\tau_1^* \approx \tau_2^*$). For example, for Ø22x22 cell (curves no.3, 4), this state occurs at $k \cdot I_1 \geq 0.5 \cdot I_1$ where $I_1 = 1$ corresponds to the emission power density ~ 25 μW/cm^2.

2. Change in a cell temperature (volume V = const), Fig.2

• Fig.2 gives an example of experimental dependences $\tau_1, \tau_2 = f(k \cdot I_1)$, for a cell of Ø15x15 (inner Ø12x12). It follows from this data that, for this cell, the dark relaxation 'degeneracy', ($\tau_1^* \approx \tau_2^*$), disappears at the temperature $t^0 \sim 54^0$C.

It is interesting in practice, however, to find τ_1, τ_2 (I_1) – dependences from the temperature change in the case of the total 'degeneracy' (similar with 5,6 – dependences, Fig.1) for determining a critical temperature, t^0_c, beyond which the dark 'degeneracy' is removed. It follows from these dependences, $\tau_1^*(t^0)$, $\tau_2^*(t^0)$ obtained and given in Fig.3, that a condition for the *total* relaxation 'degeneracy' for this cell is fulfilled up to the critical temperature, $t^0_c \sim 36^0$.

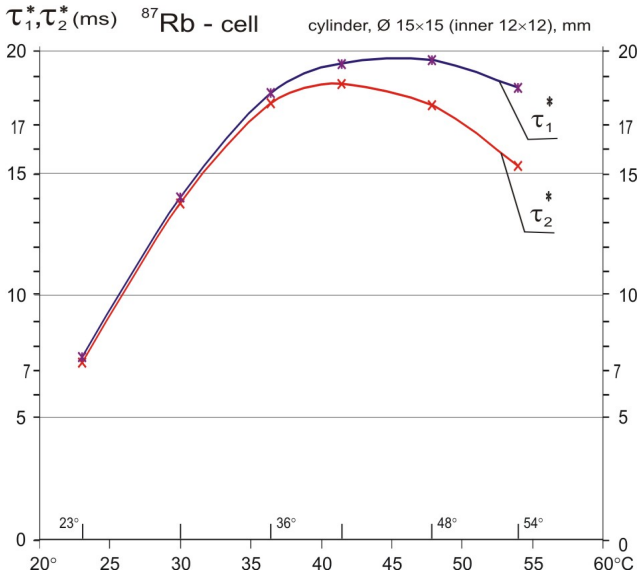

Fig.3. The example of the total 'degeneracy' τ_1^* and τ_2^*

Frequency Shifts of '0-0' Transition in RFS Caused by Action of Coating

This wall shift is negative and is of several hundreds Hertz. Preliminary investigations performed by us have shown that frequency shifts could be compensated through adding the buffer gas of small pressure to the cell.

IV. CONCLUSIONS

1. For a cylindrical cell with ARW-coating, the dimensions are found, ∅15×15 (∅12×12), at with a total relaxation 'degeneracy' is observed at temperature values up to critical, $t^0_c \sim 36^0$ C. This means, for example, that, when changing the parameters within a wide temperature range ($20^0 \div 36^0$C) and pumping light intensity, $k \cdot I_1$, within (0÷25) μW/cm^2, ($\tau_1 \approx \tau_2$) - condition is fulfilled which is necessary for achieving a high long-term frequency stability of standards (in particular, RFS and magnetometers).

2. The dynamics of relaxation processes within a spin system with hyperfine transitions is similar to processes of Zeeman's relaxation and differs only in values of relaxation time, τ_1 and τ_2. Therefore we believe that the procedure for relaxation investigation and results of this work would be useful, when performing similar investigations on hyperfine transitions in the course of developing atomic frequency standards.

3. The total relaxation 'degeneracy', ($\tau_1^* \approx \tau_2^*$), characterizes the isotropy of relaxation processes in the space.

4. The performed investigations enable one to determine conditions for achieving a high frequency stability

(short-term, medium-term, and long-term) and finding operating parameters for realization such stability values in practice.

Abstract— **It has been shown that pure thickness shear mode can be excited in thin film bulk acoustic wave resonators (FBARs) using AlN thin films with special *c*-axis tilt angles (46.1° and 90°). The pure shear mode FBARs may be used as sensors in liquid medium with improved sensitivity than the commonly used thickness shear mode quart crystal resonator. In this paper thickness shear mode FBAR has been investigated for viscosity sensor application. The equation for predicting electric impedance of shear mode FBARs with a liquid layer was derived from the basic piezoelectric constitutive equations. The viscosity sensitivity of AlN FBARS was achieved by calculation of resonant frequency shift due to the liquid loading layer. In the calculation, it is assumed that the FBAR is formed by AlN film with 2μm thickness, 300μm by 300μm electrode area and with mechanical quality factor of 400. Three different liquids (water, acetone and olive oil) were used as the loading layer to evaluate the sensitivity of FBAR viscosity sensors. It was found that the viscosity sensitivities of AlN FBAR with 46.1^0 and 90^0*c*-axis tilted angle are very close, and do not change much with different liquid materials. The simulation results can be used for design and application of AlN FBARs.**

I. INTRODUCTION

In the past years, FBARs have attracted much attention for application in RF and microwave frequency control and signal processing Fields [1-3]. In addition to applications in electronic circuits as frequency control and signal processing devices, FBARs were also investigated for sensor applications due to its high sensitivity [4-7]. AlN and ZnO thin films are widely used for FBAR fabrication, and they are usually with normal-plane *c*-axis orientation, which makes FBARs operated in thickness longitudinal mode. The damping of thickness longitudinal resonator in liquid is severe, inducing poor sensor response. While the damping of shear mode resonator in liquid is much less significant, hence, for liquid application FBAR operated in shear mode is promising.

It has been shown that thickness shear mode resonance can be excited besides longitudinal mode when *c*-axis of AlN thin film is tilted off the thickness normal direction. For example, *c*-axis tilted AlN thin films were achieved by Bjurström and Wingqvist et al using reactive magnetron sputter deposition system; they examined the variation of electromechanical coupling and the quality factor of the AlN resonators with *c*-axis tilt angle, and investigated the performance of resonator for sensor application in liquid [8-10]. Martin et al. presented dual mode resonators based on *c*-axis tilted AlN films with high resonant frequency, around 8GHz for longitudinal mode and 4 GHz for shear mode [11, 12]. Chuang et al. demonstrated solidly mounted dual mode FBARs based on 0^0, 15^0 and 30^0 *c*-axis tilted AlN films, and the effect of mass loading on the resonators were experimentally conducted.[13].

Our previous study [14] also shows that the tilted polar *c*-axis orientation in AlN and ZnO thin films will induce normal plane and in-plane polarization components, which leads to the coexistence of the longitudinal mode and shear mode in the resonators. Moreover, it was found that pure thickness shear mode exists when *c*-axis is tilted at a special angle. In the case of AlN FBAR, when *c*-axis is tilted at angle 46.1° or 90°, only thickness shear mode exist, which, as mentioned before, can be a very promising FBAR structure for sensor applications in liquid medium. At this point, theoretical analysis of FBAR sensors based on polar *c*-axis tilted AlN thin film is needed to guide device design and fabrication. To our knowledge, there is no theoretical study on *c*-axis tilted AlN FBAR for liquid viscosity sensing application from the literature. In this study, we focus on shear mode FBARs based on AlN thin film with 46.1° and 90° *c*-axis tilt angles. The electric impedance of pure thickness shear mode AlN FBAR with a liquid loading was derived by the basic piezoelectric equations. Then the resonant frequency shift for different liquid loading was examined. Finally the viscosity sensitivity of shear mode AlN FBAR was calculated and discussed.

II. THOERY

A. Dual mode AlN FBARs.

Before we discuss AlN FBAR for viscosity sensor application, we briefly present the theoretical analysis of dual mode FBARs using *c*-axis tilted AlN, which is the basis for analytical study of shear mode AlN FBAR with liquid loading. Following a similar procedure [15], the impedance equation for *c*-axis tilted AlN FBARs can be derived [14].

Fig. 1(a) shows FBAR based on AlN thin film with normal *c*-axis, and (x_1, x_2, x_3) is the original material coordinate system; Fig. 1(b) shows the schematic of FBAR based on *c*-axis tilted AlN thin film, where the top and bottom electrode

are ignored for model simplification. A rectangular Cartesian coordinate system ($x_1^{'}$, $x_2^{'}$, $x_3^{'}$) is chosen with top electrode on $x_3^{'} = h$ and bottom electrode on $x_3^{'} = 0$. The *c*-axis of AlN film is tilted at an angle θ to the $x_3^{'}$ direction. Coordinate system ($x_1^{'}$, $x_2^{'}$, $x_3^{'}$) can be treated as the result of rotation of (x_1, x_2, x_3) about x_2 with an angle θ, as shown in Fig. 1(c).

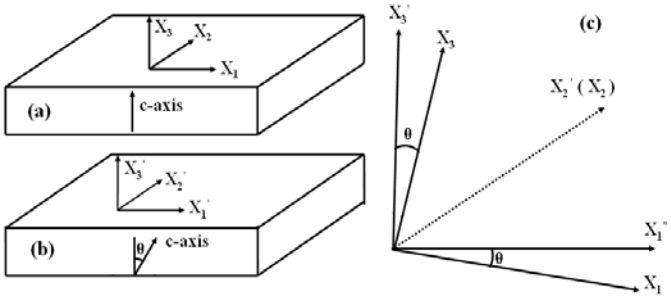

Fig.1 (a) FBAR based on AlN thin film with normal *c*-axis; (b) FBAR based on *c*-axis tilted AlN; (c) the relation of (x_1, x_2, x_3) and ($x_1^{'}$, $x_2^{'}$, $x_3^{'}$).

In ($x_1^{'}$, $x_2^{'}$, $x_3^{'}$), we have the following acoustic field equations and piezoelectric constitution equations[16]:

$$\frac{\partial T_1}{\partial x_1^{'}} + \frac{\partial T_6}{\partial x_2^{'}} + \frac{\partial T_5}{\partial x_3^{'}} = \rho \frac{\partial^2 u_1}{\partial t^2}$$
$$\frac{\partial T_6}{\partial x_1^{'}} + \frac{\partial T_2}{\partial x_2^{'}} + \frac{\partial T_4}{\partial x_3^{'}} = \rho \frac{\partial^2 u_2}{\partial t^2} \quad (1)$$
$$\frac{\partial T_5}{\partial x_1^{'}} + \frac{\partial T_4}{\partial x_2^{'}} + \frac{\partial T_3}{\partial x_3^{'}} = \rho \frac{\partial^2 u_3}{\partial t^2}$$

$$S_1 = \frac{\partial u_1}{\partial x_1^{'}}, S_2 = \frac{\partial u_2}{\partial x_2^{'}}, S_3 = \frac{\partial u_3}{\partial x_3^{'}}$$
$$S_4 = \frac{\partial u_3}{\partial x_2^{'}} + \frac{\partial u_2}{\partial x_3^{'}} \quad (2)$$
$$S_5 = \frac{\partial u_3}{\partial x_1^{'}} + \frac{\partial u_1}{\partial x_3^{'}}$$
$$S_6 = \frac{\partial u_2}{\partial x_1^{'}} + \frac{\partial u_1}{\partial x_2^{'}}$$

$$T_p = c_{pq}^{E'} S_q - e_{kp}^{'} E_k \quad (3)$$

$$D_i = e_{iq}^{'} S_q + \varepsilon_{ik}^{S'} E_k \quad (4)$$

where T_p, S_q, D_i and E_k are the components of stress, strain, electric displacement and electric field intensity, $c_{pq}^{E'}$ are the elastic stiffness constants under constant electric field intensity, $e_{kp}^{'}$ are the piezoelectric stress constants, $\varepsilon_{ik}^{S'}$ are the permittivity constants under constant strain, ρ is the density of AlN and u_i is the displacement in the direction of $x_i^{'}$ ($i, k = 1, 2, 3$ and $p, q = 1, 2, 3, 4, 5, 6$). For one dimension assumption, we have:

$$\frac{\partial T_i}{\partial x_1^{'}} = \frac{\partial T_i}{\partial x_2^{'}} = 0, E_1 = E_2 = 0, E_3 \neq 0, \frac{\partial D_3}{\partial x_3^{'}} = 0 \quad (5)$$

Under a sinusoidal excitation, the voltage V and current I across FBAR can be determined by

$$V = \int_0^h E_3 dx_3^{'}, \; I = j\omega A D_3 \quad (6)$$

where A is electrode area, ω is angular frequency. For traction forces at the boundary ($x_3^{'} = 0, h$) we have:

$$T_5(0) = T_3(0) = T_5(h) = T_3(h) = 0 \quad (7)$$

Also we found:

$$c_{34}^{E'} = c_{45}^{E'} = e_{34}^{'} = 0 \quad (8)$$

From equation (1)-(8), the impedance of dual mode FBAR can be solved:

$$Z = \frac{1}{j\omega C_0}(1 - (k^L)^2 \frac{\tan(\gamma^L / 2)}{\gamma^L / 2} - (k^S)^2 \frac{\tan(\gamma^S / 2)}{\gamma^S / 2}) \quad (9)$$

Here C_0 is the static capacitance; k_L^2 and k_S^2 are electromechanical coupling coefficients; γ^L and γ^S is phase delay for longitudinal (L) and shear mode (S), respectively.

Based on the impedance expression of FBAR (9), the resonator could be operated in a single mode when a tilt angle makes $k_L = 0$ (pure shear mode) or $k_S = 0$ (pure longitudinal mode). Our calculation results show when *c*-axis tilt angle is 46.1^0 or 90^0, AlN FBARs can be operated in pure thickness shear mode ($k_L = 0$).

B. Shear mode AlN FBAR with liquid loading

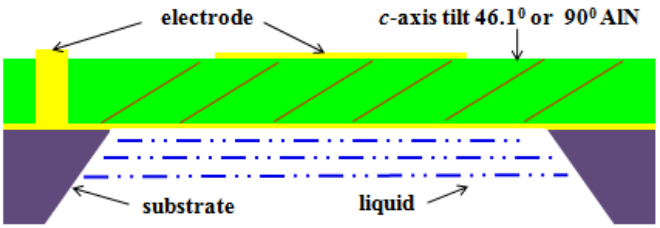

Fig. 2 Schematic of viscosity sensor based on *c*-axis tilted AlN FBAR.

As mentioned before, the existence of pure shear mode makes AlN FBARs possible for sensor application in liquid. Also, we know that for acoustic sensor, the higher resonant frequency usually means higher sensor sensitivity. Considering FBAR whose operation frequency can be up to tens of GHz, it is expected that sensor sensitivity will be

greatly improved. Fig. 2 shows the schematic of viscosity sensor based on AlN FBAR with *c*-axis tilt angle 46.1° or 90°.

For analyzing sensor performance of shear FBAR for viscosity measurement, we need derive the impedance expression of FBAR with liquid loading. Assume the interface of liquid and resonator is at $x_3' = 0$, now the boundary condition (7) changes to

$$\begin{aligned} &T_5(h) = T_3(h) = T_3(0)=0 \\ &T_5(0) = -j\omega Z_{Liquid} u_1(0) \\ &Z_{Liquid} = \sqrt{j\rho_{Liquid}\omega\eta_{Liquid}} \end{aligned} \tag{9}$$

where ρ_{liquid} and η_{liquid} are the density and viscosity of liquid. From (1)-(6), (8), and (9), the impedance of shear AlN FBARs with liquid loading can be solved,

$$Z = \frac{1}{j\omega C_0}\left(1-\left(\frac{(k^S)^2}{\gamma^S}\frac{2\tan(\gamma^S/2)-j\dfrac{Z_{Liquid}}{Z_S}}{1-\dfrac{Z_{Liquid}}{Z_S}\cot(\gamma^S)}\right)\right) \tag{10}$$

where Z_S and γ_S are the characteristic impedance and phase delay of AlN; C_0 is the static capacitance; Z_{liquid} is the acoustic loading of liquid.

III. RESULTS AND DISCUSSION

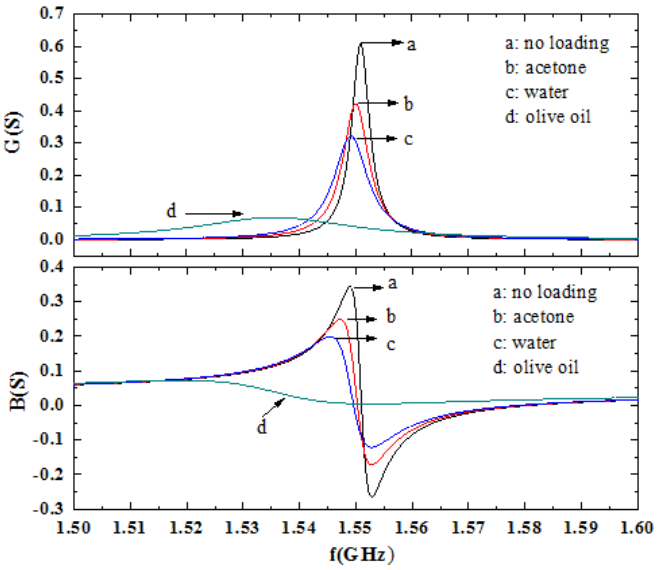
A. *Simulation of impedance spectra of shear mode AlN FBARs with liquids loading*

TABLE I. Parameters for simulation

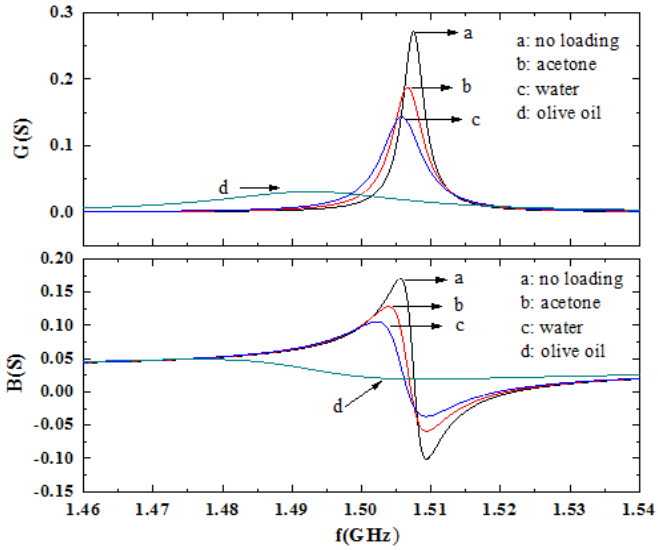
Piezoelectric layer	Mechanical quality factor	Thickness (μm)	Electrode area (μm×μm)
AlN	400	2	300×300
Liquid loading	**Temperature (^{0}C)**	**Density (kg/m^3)**	**Viscosity (mPa•S)**
Acetone	20	792.5	0.31
Water	20	1000	1
Olive oil	20	920	84

Using the electric impedance equation for FBAR with tilted polar c-axis orientation, the resonator spectrum with liquid loading can be simulated. The parameters used in the simulation are listed in Table I. Fig. 3 shows the calculated impedance spectra of FBARs with different liquid loadings. In the case of no liquid loading, it can be seen that the resonant frequencies of these two resonators (for tilt angle 46.1° or 90°) are quite similar. The resonant frequency is about 1.55GHz for AlN FABR with *c*-axis tilt angle 46.1°, and about 1.51GHz for AlN FABR with *c*-axis tilt angle 90°, respectively). The resonant frequency f_S for an acoustic wave resonator can be described by $f_S = \frac{\upsilon}{\lambda} = \frac{\upsilon}{2h}$, where υ is the acoustic velocity determined by material properties; the acoustic wave length (λ) is 2 times of the thickness (h) of resonator. Due to the crystal orientation dependence of material properties including elastic constants, piezoelectric constants and dielectric constants, the acoustic velocity changes with *c*-axis orientation. Hence the resonant frequencies of these two pure shear mode AlN FBARs are different, although they have same thickness.

In the case of liquid loading, for the two pure thickness shear mode resonators we can clearly see that the resonant frequency decreases due to liquid loading, and the resonant peak becomes small and broadened, indicating that the energy loss caused by viscous loading. The loading effect of olive oil on the FBARs is much more significant than that of water and acetone. This is attributed to the higher acoustic loading impedance of olive oil.



(a)



(b)

Fig. 3 Simulation of impedance spectrum of shear mode AlN (a) *c*-axis tilt angle 46.1^0; (b) *c*-axis tilt angle 90^0

B. Sensitivity of shear mode AlN FBAR viscosity sensor

The sensitivity (S) of shear mode AlN FBAR viscosity sensor can be defined as,

$$S = \frac{1}{f_0}\frac{df}{d\sqrt{\rho_{Liquid}\eta_{Liquid}}} = \frac{1}{f_0}\lim_{\Delta\eta\to 0}\frac{\Delta f}{\sqrt{\rho_{Liquid}(\eta_{Liquid}+\Delta\eta_{Liquid})}-\sqrt{\rho_{Liquid}\eta_{Liquid}}} \quad (11)$$

Here we assume that the liquid density does not change. f_0 is initial resonant frequency; Δf is resonant frequency shift due to viscosity change $\Delta\eta_{Liquid}$.

Table II lists the viscosity sensitivities of shear mode FBARs based on AlN thin films with *c*-axis tilt angle 46.1° and 90°, respectively, where the viscosity sensitivity was calculated through calculating resonant frequency shift for 1% viscosity change, and the resonant frequency is corresponding to the maximum conductance (G). It can be seen that the viscosity sensitivity of these two shear mode resonators are quite similar with a value of 1.12e-3 or 1.13e-3 $(kgm^{-3}Pa•S)^{-0.5}$, respectively, and they are almost same for different liquid loading material.

For comparison, we also calculated the viscosity sensitivity of a 6 MHz thickness shear mode quartz crystal resonator, which has a value around 1.43e-4 $(kgm^{-3}Pa•S)^{-0.5}$, also listed in Table II. It is found that the sensitivity of shear mode AlN FBAR is about 8 times as 6 MHz quartz crystal resonator, which seems a little bit low considering the huge difference between their resonant frequencies. One reason is that the definition of viscosity sensitivity given in Eq.(11), where the relative frequency shift is used instead of absolute frequency shift, which lowers the effect of resonant frequency on the value of viscosity sensitivity during calculation.

TABLE II. Viscosity sensitivities of thickness shear mode AlN FBARs

liquid	Viscosity sensitivity($(kgm^{-3}Pa•S)^{-0.5}$)		
	2um AlN FBAR (*c*-axis tilt 46.1°)	2um AlN FBAR (*c*-axis tilt 90°)	6MHz Quartz resonator
Acetone	1.12e-3	1.12e-3	1.428e-4
Water	1.12e-3	1.13e-3	1.428e-4
Olive oil	1.13e-3	1.13e-3	1.430e-4

IV. CONCLUSION

In summary, viscosity sensitivity of thickness shear mode AlN FBARs with *c*-axis tilt angle 46.1° and 90° has been theoretically studied. The electric impedance for thickness shear mode AlN FBARs with a liquid layer has been derived from the basic piezoelectric constitutive equations. Viscosity sensitivities for three liquid loading (water, acetone and olive oil) were achieved by the calculation of relative resonant frequency shift for 1% viscosity change. The viscosity sensitivities of shear mode 2um AlN FBARs with *c*-axis tilt angle 46.1° and 90° are similar, with a value around 1.12e-3 or 1.13e-3 $(kgm^{-3}Pa•S)^{-0.5}$, and they do not change much with these three different liquid loading. Viscosity sensitivity of 2μm shear mode AlN is found about 8 times as 6MHz TSM quartz crystal resonator. The simulation results can be used for FBARs design and sensor application.

***Abstract*—Quartz crystal microbalance (QCM) technique is widely used in in-liquid biochemical applications. The main challenges remain on the improvement of sensitivity and limit of detection, as well as multianalysis capabilities and reliability. The improvement of sensitivity has been addressed in the last decades by increasing the sensor fundamental frequency; following the increment of the frequency/mass sensitivity with the square of frequency predicted by Sauerbrey. However, this sensitivity improvement has not been completely transferred in terms of limit of detection. A new concept of sensor characterization has been recently proposed based on the phase/mass sensitivity equation: $\Delta\varphi/\Delta m \approx -1/m_L$, where m_L is the liquid mass perturbed by the resonator in its oscillatory movement; this mass reduces proportionally with the frequency square root. The validation of the new concept is presented in this work. An immunosensor application for the detection of the very low molecular weight insecticide, carbaryl, has been chosen for the validation of the characterization technique.**

I. INTRODUCTION

Acoustic sensing has taken advantage of the progress made in the last decades in piezoelectric resonators for radio-frequency (RF) telecommunication technologies. Acoustic sensor based techniques combine their direct detection, real-time monitoring, high sensitivity and selectivity capabilities with a reduced cost in relation to other techniques. The so-called quartz crystal microbalance (QCM) technique, where the AT cut quartz crystal resonator is extensively used, has been classically based on the proportional change in the resonance frequency experimented by the resonator due to a surface mass density change on the sensor surface; the theoretical absolute mass sensitivity for this frequency shift is proportional to the square of the resonant frequency according to the expression [1]

$$S_a = \frac{\Delta f}{\Delta m} = -\frac{2}{\rho v}\frac{f_n^2}{n} \qquad (1)$$

where Δf is the frequency shift, Δm is the surface mass density change on the active sensor's surface, ρ is the quartz density, v the propagation velocity of the wave in the AT cut quartz crystal, f_n is the frequency of the selected harmonic resonant mode and n is the harmonic number (n=1 for the fundamental mode). In QCM, acoustic waves are excited by a sinusoidal voltage applied to an electrode structure where the quartz crystal is sandwiched; shear waves are excited which makes the operation in liquids viable [2]. This has opened a great deal of applications in bio-chemical sensing in liquid media.

II. PHASE-MASS CHARACTERIZATION FOR IN-LIQUID QCM APPLICATIONS

According to (1), the improvement of sensitivity has been addressed in the last decades by increasing the sensor fundamental frequency. However, this sensitivity improvement has not been completely transferred in improvements of the resolution or limit of detection. The decrease on frequency stability in the measurement due to the increase in phase noise and unwanted frequency jumps to spurious inharmonic modes, particularly in the case of oscillators, seems to be the reason behind the difficulty to reach the expected maximum resolution [3-5].

In QCM based biosensors the experimental frequency shifts expected are usually small, in the order of tens of Hertz. Therefore, the great efforts performed to improve the sensitivity of the sensor by increasing the frequency, only would be useful if they were accompanied with an increase in the limit of detection [6]. Once external perturbations on the sensor have been minimized (temperature and pressure variations, external vibrations, etc.), resolution on the measurement relies directly on the interface characterization system, its noise and stability and the measurement uncertainty associated to it. In oscillators, a classical electronic interface system for QCM sensors, the origin of frequency instability is the phase instability [7]; the high quality factor of the crystal resonator in RF oscillators allows absorbing the phase instabilities in the circuitry with very small shifts in the

978-1-61284-110-6/11/$26.00 ©2011 IEEE

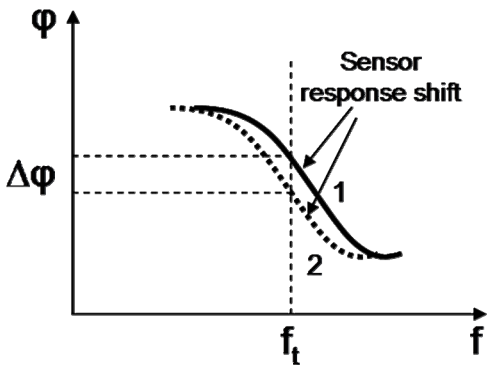

Figure 1. Phase-shift concept representation

oscillation frequency of the system. But in QCM sensor oscillators the resonator is not included in the circuitry with the main purpose of stabilizing the frequency of the oscillating system, although effectively it does it. Consequently, the oscillator circuitry should be as ideal as possible for not influencing the sensor phase shifts due to the processes to be monitored. Unfortunately to implement a very stable oscillator for high frequency QCM sensors, keeping in mind the low quality factors reached by these sensors in liquid conditions is not an easy and straightforward task.

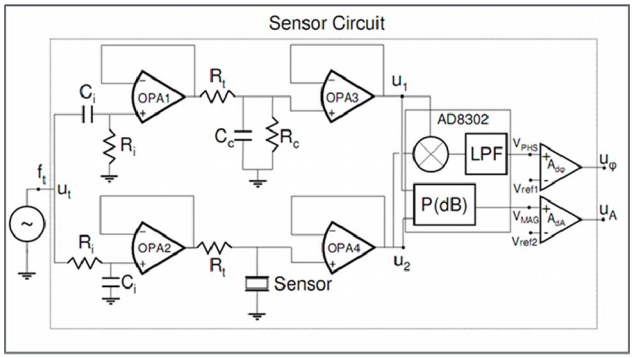
Having this idea in mind, a new concept of characterization, where the sensor is interrogated with a signal at constant frequency, has been recently proposed, based on the following phase-mass sensitivity equation for the sensor in liquid media [8]:

$$\Delta\varphi = -\frac{\Delta m_c}{m_q + m_L} \tag{2}$$

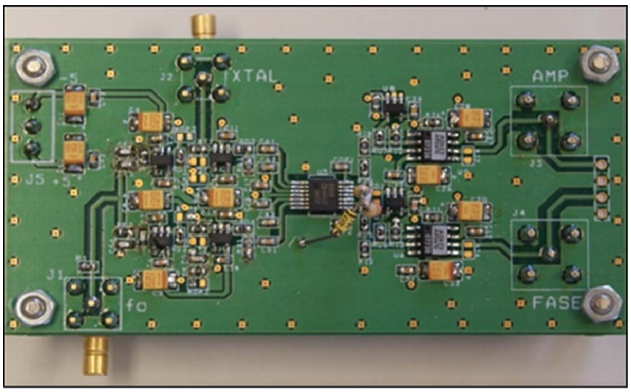
where m_c is the surface mass density of the coating, $m_q=\eta_q\pi/2v_q$, being η_q the effective quartz viscosity, v_q the wave propagation speed in the quartz and $m_L=\rho_L\delta_L/2$, where ρ_L and δ_L are, respectively, the liquid density and the wave penetration depth of the acoustic wave in the liquid. This last term, m_L, is the liquid mass surface density perturbed by the resonator in its oscillatory movement and reduces proportionally to the frequency square root due to the decrease of the penetration depth. As it was also described [8], when $m_L >> m_q$, (2) can be expressed in a simpler form,

$$\Delta\varphi \approx -\Delta m_c / m_L \,. \tag{3}$$

Taking into account that the expected frequency shifts in high resolution QCM applications are very small and assuming no variations on the liquid properties (conditions usually met in biosensor applications), it is possible to interrogate the sensor with a test signal of the appropriate constant frequency, in the resonance bandwidth, and measure the change in the phase response of the sensor due to the experimental process to be monitored, without leaving the maximum sensitivity region of phase response governed by (3). Fig.1 depicts this idea.



(a)



(b)

Figure 2. Characterization interface for in-liquid qcm sensor. (a) Schematics and (b) printed circuit board implemented

III. SYSTEM DESCRIPTION

A sensor interface circuit, which was theoretically proposed in [8], has been implemented to validate this characterization concept experimentally. Fig.2 shows the schematic diagram and the final implementation of the sensor interface. The circuit is mainly composed of two parallel and quite similar branches in order to form a differential circuit. Because the testing signal u_t has constant frequency, f_t, the only element in the circuit which contributes to a change in the phase difference between the reference signal u_1 and the signal u_2 is the change in the phase-frequency response of the sensor. This phase difference can be easily and continuously monitored by a phase detector, like the one found in the IC AD8302 from Analog Devices. Being a multiplier type phase detector, linearity and error in the measurement are maximum and minimum, respectively, for small phase differences around 90º between signals at its input. The networks formed by R_i and C_i at the input of the sensor circuit have been included to obtain this initial phase difference of 90º between signals at each branch of the circuit. These phase-shifting networks must be designed coherently with the resonant frequency of the sensor in order to obtain two signals 90º phase-shifted and of similar amplitude. In the case of the AD8302, the detector response is centered on 900mV, with a phase slope of approximately 10mV/º. A conditioning circuit, comprising a low noise differential amplifier and an adjustable reference voltage, is used to re-center and amplify the detector response around 0V with a response sensitivity of 100mV/º.

Figure 3. Experimental Setup

AD8302 also includes a matched pair of logarithmic demodulating amplifiers allowing measuring the magnitude ratio of the signals connected to it, with a response of 30mV/dB. The magnitude ratio voltage is also re-centered and amplified with similar conditioning circuits. Wide bandwidth operational amplifiers OPA1-4 are used to isolate the sensor and the reference network R_c-C_c from the rest of the circuit. At motional series resonance frequency (MSRF), the sensor reduces to a motional resistance, R_m, in parallel with the so-called static capacitance C_o. Therefore for optimum operation it is convenient to select R_c and C_c similar to R_m and C_0, respectively. Under these conditions and interrogating the sensor with a test signal of a constant frequency f_t around the MSRF, the voltage u_φ corresponding to the phase-shift measured should be the corresponding to the initial phase difference, 0mV, after proper reference adjustment.

IV. Experimental Setup

A real application based on an immunosensor for the detection of a low molecular weight pollutant, the insecticide carbaryl [9], has been chosen as validation model. The proposed system was compared with a QCM system based on an improved oscillator configuration [10] using 10MHz AT cut QCM sensors (International Crystal Manufacturing), the same validation protocol described elsewhere [9] and under the same experimental conditions. BSA-CNH carbaryl hapten conjugate was immobilized on the sensor surface through the formation of a thioctic acid self-assembled monolayer. The crystal was placed in a custom-made flow-cell and included in a fluidic system comprising also a peristaltic pump (Minipulse 3, Gilson), and loop injection and solution selection manual valves (Supelco). The sensor characterization circuit and the whole fluidic system, but the peristaltic pump, were placed in a thermostatic chamber. This thermostatic chamber was placed on an anti-vibration table in order to avoid external disturbances. The test signal was generated with a RF signal generation model Agilent-HP8664A (Agilent) and the voltage was measured with a multimeter HP34401A (Agilent) connected via GPIB bus to a PC running the NI-Visa Server Software (National Instruments) allowing a remote connection to the test equipment via Ethernet. Client software was developed to acquire and represent the data in a remote PC. This experimental setup is depicted in Fig. 3.

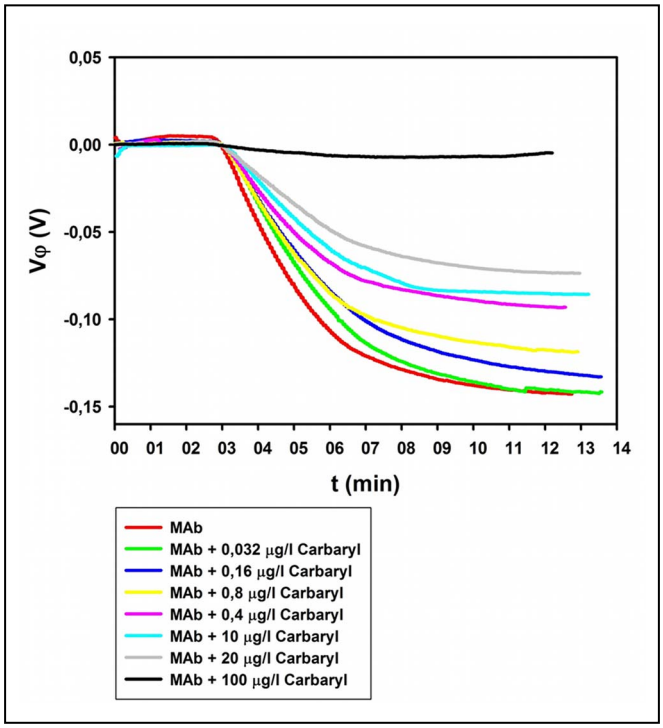


Figure 4. Piezoelectric immunosensor responses to different concentrations of analyte

The immunoassay developed was an inhibition test based on the conjugate coated format. Different standard concentrations of carbaryl were prepared and mixed with a fixed concentration of the monoclonal antibody LIB-CNH45 (I3BH-UPV) [11] in phosphate buffered saline (PBS). Since the analyte inhibits antibody binding to the immobilized conjugate, increasing concentrations of analyte will reduce the magnitude of the phase shift induced on the sensor. The phase shift was monitored in real-time for each sample injection during 12 min. A regeneration stage was performed after this reaction time by consecutive injections of hydrochloric acid (HCl) and phosphate buffered saline - tween 20 (PBST) at appropriate concentrations, breaking the antibody-hapten linkage and reaching the initial base-line.

V. Results

Fig. 4 shows the signals measured with the characterization system proposed for the injection of different standard concentrations of carbaryl. The voltage u_φ associated with the phase-shift, decays exponentially as soon as the molecular interaction occurs after each sample injection. As we can see, results show the typical response of a competitive immunoassay. The voltage decrease is lower as we increase the concentration of the analyte, due to the lower amount of antibody available in the sample being able to bind with the carbaryl hapten conjugate immobilized in the sensor surface.

These results validate the new characterization concept and the implemented interface. A similar behavior is observed when the resonant frequency shift is monitored. Moreover, a reduction of the noise in the new system was observed compared with the oscillator technique, under the same experimental conditions. The noise level for this phase-shift

interface was of 1mV for maximum signals that reached 200mV. Furthermore, it is important to notice that this improvement has been got even with relative low frequency sensors (10MHz), where electronic components and circuits have a very good performance in both, the oscillator and the phase-detector system. Therefore a significant improvement is expected to be found with very high fundamental frequency resonators.

VI. CONCLUSIONS

The new characterization concept, particularly useful for biosensor applications, has been experimentally validated in a real application, an immunosensor for the detection of the low weight pollutant carbaryl. The sensor is interrogated passively with an external source, which can be designed with high frequency stability and very low phase noise, even at very high frequencies. The interface is very simple and allows a straightforward noise analysis, simplifying the electronic design and implementation. This simplicity and its high integration capability would allow its use with multiple sensors working at the same fundamental resonance frequency, which could be characterized, in principle, with only one source, only repeating the sensor circuit, opening the possibility of working with sensor arrays for multianalysis detection.

Characterization of Rotational Mode Disk Resonator Quality Factors in Liquid

Amir Rahafrooz and Siavash Pourkamali

E-mail: amir.rahafrooz@du.edu

***Abstract*— This work presents several variations of microscale single and multiple coupled thermally actuated rotational mode disk resonators capable of high quality factor (Q) operation in liquid. All surfaces of a rotational mode disk resonator slide in parallel to the liquid interface (rather than stroking against it). This minimizes interactions with the surrounding fluid and therefore viscous damping. Quality factors as high as 304 have been demonstrated for rotational mode disk resonators in liquid, which is more than 3X higher than the highest values previously demonstrated for other types of microscale resonators. Based on the measurement results it is suggested that most of the energy loss into the surrounding liquid is through the sidewalls of the disks. This could be blamed on the sidewall roughness caused by deep reactive ion etching, off-center rotation of the disks due to fabrication induced asymmetries, and slight bending of support beams during resonance. Much higher Q values are expected to be achievable by minimizing such limiting factors.**

I. Introduction

As highly sensitive mass sensors, micromechanical resonators can potentially open up a wide range of new opportunities in biomedical and chemical sensing applications leading to more compact low cost instruments with real-time sensing capabilities. In addition, due to their small size, micro resonators can be integrated in arrays of hundreds to thousands sensing a variety of analytes simultaneously. Most of the biosensing applications require detection and measurement of certain molecules in a liquid solution (typically aqueous). However, the resonant behavior of microscale resonators drastically deteriorates in liquid lowering their sensitivity and mass resolution. This is mainly due to the larger surface to volume ratio for such small scale devices and consequently large viscous damping to elastic energy ratio in them.

Over the past decade efforts have been made to operate micromechanical resonators inside liquid. Magnetically actuated cantilever beams resonating in their out-of-plane flexural modes have been used for mass sensing applications in aqueous environments [1-4]. It is not hard to imagine that such a paddling motion faces a lot of resistance from the surrounding liquid leading to excessive viscous damping. This reduces the quality factor of such devices to values as low as 5[1], 23[2], 2[3] and 10[4] in water. Viscous damping can be reduced by operating cantilever beams in their in-plane flexural resonant mode. Quality factors as high as 67 have been demonstrated for such devices in liquid [5]. Higher quality factor of the in-plane resonant modes for such thin structures can be attributed to having a much smaller portion of their surface area stroking against the liquid interface compared to their out of plane modes. In an improved design by Seo, et al [6], a structure comprised of two half-disks resonating in an in-plane quasi rotational mode, demonstrated quality factors as high as 94 in water. Despite having improved quality factors, similar to the in-plane flexural modes of microcantilevers, the straight sides of the half disks in such structures still have a perpendicular motion against the liquid interface. In [7] we demonstrated full disk structures with two tangential support beams thermally actuated in their rotational resonant modes. In such structures all the surfaces slide in parallel to the liquid interface exhibiting Qs as high as ~200 in water.

In this work, five different variations of single and multiple-coupled rotational mode disk resonators are studied to further understand the loss mechanism and optimize the performance of such structures.

II. Device Operation

Figure 1 shows the schematic view of a single-disk with straight tangential support beams as well as the electrical connections used to operate such device. The support beams act as both thermal actuators and piezoresistive stress sensors simultaneously [7]. Thermal actuation occurs by passing a current between the two pads on the two sides of the structure. By passing a combination of a DC and an AC current, the ohmic power loss will have a component at the same frequency as the applied AC current: $P_{ac} = 2R_e I_{dc} i_{ac}$, where R_e is the electrical resistance between the two pads and I_{dc} and i_{ac} are the applied DC and AC currents respectively. Due to their higher electrical resistance, most of the ohmic loss and therefore heat generation is concentrated in the narrow support beams. The applied AC power produces

This work was supported by National Science Foundation under grants MRI-RAPID #1061489 and MRI #0923518.

periodic temperature fluctuations in the thermal actuators (Fig. 1) which in turn causes alternating stress and strain in the support beams, actuating the disk in its rotational resonance mode (periodically rotating back and forth). As the resonator vibrates the resulting periodic stress changes result in fluctuations in the electrical resistance of the resonator due to the piezoresistive effect. This modulates the DC current passing through the resonator leading to an AC output motional current component that can be used to monitor the resonator vibration amplitude.

While the disk is vibrating in its rotational mode, the support beams vibrate in their extensional mode (periodically elongate and contract). As a result, all the surfaces of both the disk and its support beams move in parallel to the liquid interface, minimizing the energy loss to the surrounding liquid. Figure 2a shows the COMSOL modal analysis results showing the mode shape for a 100µm diameter, 20µm thick disk with 4µm wide, 26µm long support beams.

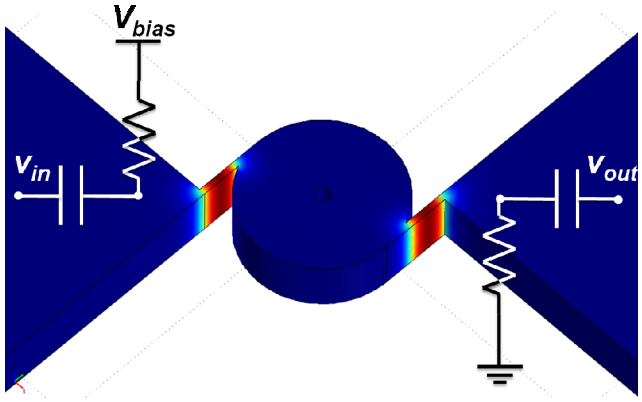

Fig. 1. Schematic view of a thermally actuated disk resonator showing the qualitative distribution of AC temperature fluctuation amplitude in the resonator (red being the maximum and blue minimum). The electrical connections required for one-port operation of the resonator are also shown.

III. Fabrication and Measurement Results

In this work, five different variations of single and multiple-coupled rotational mode disk resonators were fabricated and characterized (Fig. 2); 1. Single disks with straight tangential support beams, 2. Single disks with rounded support beams, 3. Parallel dual-disks, 4. Series dual-disks, and 5. Interconnected quad-disks. They were fabricated using the standard single mask SOI-MEMS process [8]. The fabrication process includes silicon DRIE to form the structures out of the silicon device layer, and releasing them by etching the underlying buried oxide (BOX) layer in hydrofluoric acid (HF). Resonators were fabricated on low resistivity N-type substrates with different device layer and BOX thicknesses. To optimize resonator electromechanical transduction, the support beams are aligned to the <100> crystalline direction where the longitudinal piezoresistive coefficients are maximum [8]. The holes in the middle of the disks are to reduce the undercut time in HF. Due to circular shape of the holes and relatively small vibration amplitude in the center of the disks such holes are expected to have negligible effect on viscous damping of the resonator.

The resonators were tested in a one-port configuration as shown in Fig. 1. The liquid tests were performed in heptane to provide better electrical isolation and avoid contamination resulting from electrolysis of water. Figure 3 shows the measured frequency responses for the 100µm single disk

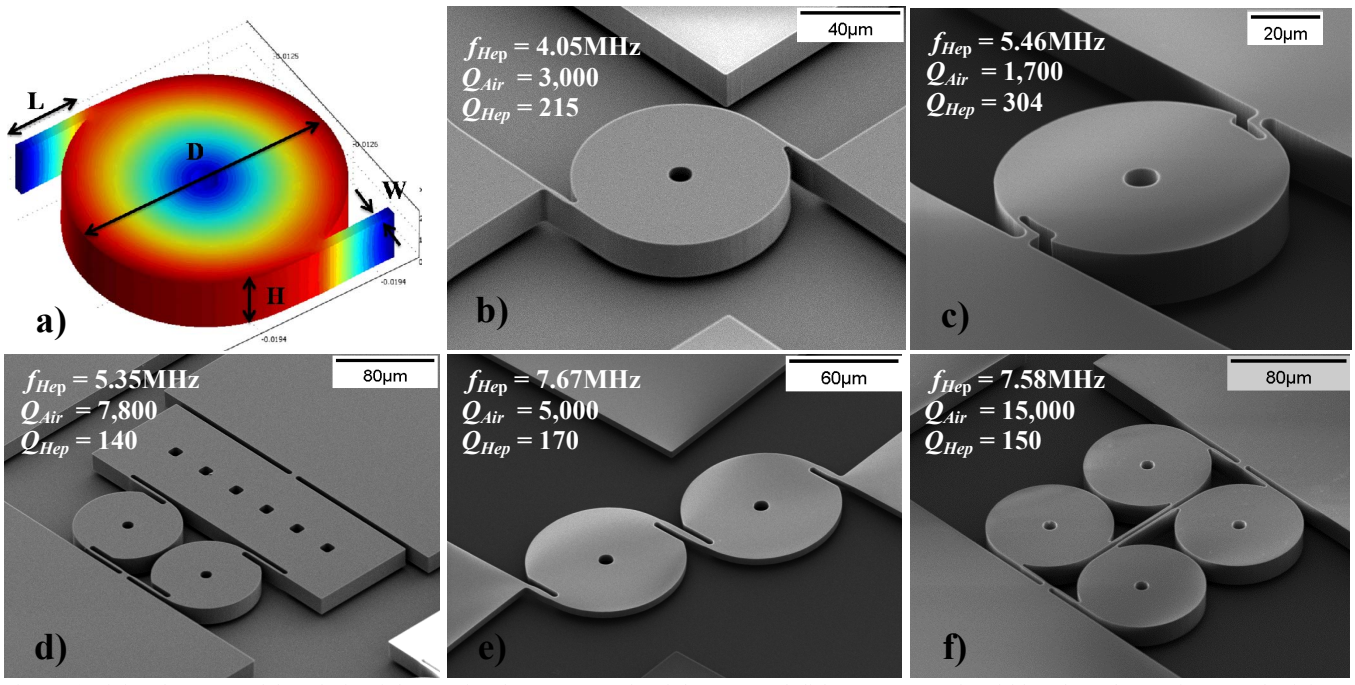

Fig. 2. a) Finite element modal analysis of the rotational resonant mode of the proposed disk structure. Red and blue show the maximum and minimum vibration amplitudes respectively. SEM view of fabricated devices along with their measured Q in both air and liquid for: b) single disk with straight tangential support beam, c) single disk with rounded support beam, d) parallel dual-disk, e) series dual-disk, f) interconnected quad-disk. The thermal actuators are along <100> crystalline direction for optimized transduction.

resonator of Fig. 2c with rounded thermal actuators both in air and heptane. As expected, the resonator has relatively low quality factors in air (due to excessive support loss), however, unprecedented quality factor of 304 was measured in heptane. Such high Q values in heptane confirm our hypothesis that elimination of the stroking surfaces from the mode shape can significantly improve resonator Q in liquid.

Table I summarizes the measurement results for a variety of resonators of different types with different dimensions in both air and liquid. It also shows the finite element modal analysis for different structures demonstrating the vibration amplitude at different parts of the structure. The modal analysis results show that unlike the other structures the interconnected quad-disks have an off-center rotation which justifies their lower Q in liquid despite their relatively high Q in Air.

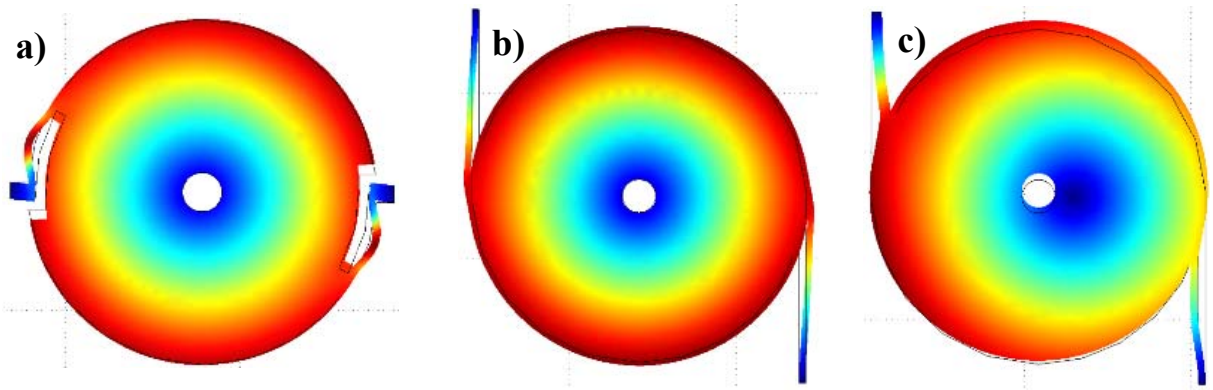

Fig. 4. Finite element modal analysis showing different effects potentially limiting resonator quality factors in liquid: a,b) bending support beams stroking against the surrounding liquid, c) mismatched support beams causing off-center resonance. In this extreme case, the support beams have widths of 2µm and 3µm and equal lengths.

The axial stress in all the support beams of the single disk designs and half of the support beams in dual-disks is directly transferred to their clamping points and consequently into the substrate. Therefore, in air, where Q is mainly limited by support loss, the Q of single disk designs is generally smaller than that of the dual-disks, which is in turn smaller than that of the quad-disks. In liquid however, viscous damping becomes the dominant source of loss and the Q for all designs drops to values in the 100-300 range. Although the highest Q of 304 in heptane obtained from the single disk structure with rounded supports of Fig. 2c, not much of a difference was observed between the performance of single disks with straight and rounded thermal actuators. Although higher quality factors are expected from the thicker resonators due to their smaller surface to volume ratio, measurement results do not show any significant improvement in quality factor of 20µm thick devices compared to 5µm thick devices. This suggests that most of the viscous damping is associated with the resonator sidewalls rather than their upper and lower surfaces. Resonator sidewall area is proportional to the resonator thickness and consequently the amount of elastic energy stored in the resonator. Therefore, if the sidewalls are the main source of loss no significant dependence of resonator quality factor to its thickness is expected. This could be blamed on the sidewall roughness caused by deep reactive ion etching, slight bending of support beams during resonance and off-center rotation of the disks due to fabrication induced asymmetries. Figure 4a and b demonstrate the bending of the rounded and straight support beams during the rotational vibration of the disks and Fig. 4c shows the effect of a fabrication induced asymmetry on the resonance mode of single disks which causes off-center rotation and therefore stroking against the liquid interface.

IV. Conclusions and Future works

Five different variations of single and multiple coupled disk resonators were fabricated and successfully operated in heptane with relatively high quality factors. The highest Q of 304 in liquid was obtained from a single disk structure with rounded support beams, which is 3X larger than the highest values previously reported for other types of micro-resonators. In addition, by studying the performance of different disk resonators with different structures and dimensions, the main energy loss mechanisms in liquid were further investigated. No significant improvement in the quality factor values for rotational mode disk resonators was observed by increasing their structural thickness. This suggests that such resonators mainly lose their energy through their sidewalls rather than upper and lower surfaces..

Micromechanical resonators with such high quality factors in liquid can enable direct high precision sensing of different analytes in liquid media paving the way towards label-free real-time biochemical sensors with fully electronic readout.

Future work includes further characterization and design optimization of the disk resonators to lower their energy loss in liquid. For instance, the structure of supporting beams can be optimized to reduce their stroking against the liquid.

***Abstract*—Comparison of 1pps signals has been applied in the relevant fields, such as time transferring, time keeping, and communication. Time comparison can be carried out in many methods with different precision and the time interval universal instrument is used usually. However, 1pps signals are generated from frequency standard sources so there is the relationship of multi-periods synchronization between 1pps signals comparison and frequency sources comparison, which restricts the improvement of the resolution of time comparison.**

The paper analyzes the relationship between 1pps signals comparison and frequency sources comparison. The precision of frequency sources comparison is far better than the direct comparison of 1pps signals, reaching ps. The indirect scheme of time comparison is proposed using frequency sources comparison. Utilizing the high precision of frequency sources comparison, the scheme has get round many disturbance factors from acquiring 1pps signals. Then, by the way of computation to get the comparison results, the better precision comparison can be obtained. The scheme has been tested by lots of experiments.

The scheme has simpler construction and higher accuracy. The comparison of atomic clocks is similar with the comparison of 1pps signals and the scheme also applies to it. Furthermore in time transferring, due to the definite phase relations between the local time signal and the master clock in Astronomical Observatory, the user can also acquire high accurate time transferring utilizing indirect phase comparison. The comparison procedure should be done with determining the initial state and continuous measuring, or the error will be increased. The further research is required for the scheme because the experiment model has a bit idealization and simplicity.

I. INTRODUCTION

At present, time comparisons are usually accomplished through the comparison between 1pps signals with high-precision time internal measurement. 1pps signals are generated from standard frequency sources, so there is the relationship of multi-periods synchronization between 1pps signals comparison and frequency sources comparison. Especially, for high-accurate time keeping, many technologies, such as atom clocks group, backup clocks, phase fine-tuning and international regular comparison and so on, are applied[1][2].

With the continuous development of time transferring technologies, the requirement of time comparison become more complex and more precision. In recent years, high-resolution time transferring needs higher performance for the relation with high-resolution positioning. The accuracy of time interval measurement should be concerned, while the error is less than ±100ps [3~5]. Many high-precision time interval measurement instruments mainly adopt analog interpolation, time-voltage conversion and delay quantization to reduce measuring error, even reaching the order of 10ps [3] [4] [6]. Compared with the above the comparison between sources has lower error, such as the comparison in 10s has less than ps error [7] [8]. On the base of the circuit stability, the period signal processing greatly reduces trigger error to reach higher resolution [9] [10].The paper mainly discusses how to utilize the relation of source comparison and 1pps signal comparison in order to get a high-precision time comparison method. Experimental results agree with theory analysis.

II. ANALYSIS OF TWO KINDS OF COMPARISON

Figure.1 shows the relation between comparison of frequency sources and comparison of 1pps signals.

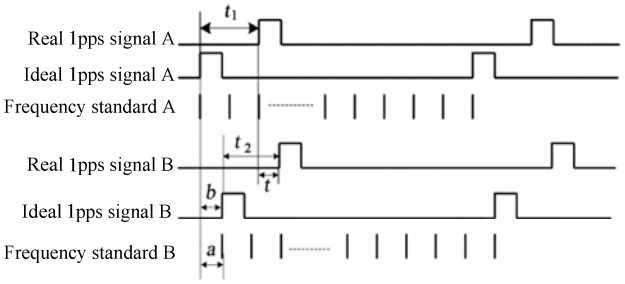

Figure1. Diagram of the relation between comparison of frequency sources and comparison of 1pps signals

In Figure.1, the 1pps signal is generated from counter's frequency dividing. a is the comparison result; b is the time difference of 1pps signals in ideal case; t_1 is the delay of

Project Supported by the National Natural Science Foundation of China (Grant No.60772135 and 10978017), the Fundamental Research Funds for the Central Universities China (Grant No.JY10000905015)

frequency standard A; t_2 is the delay of frequency standard B; t is the real time difference of 1pps signals. The comparison result of 1pps signals equals to the time internal of rising edges or falling edge.

Under ideal circumstance, without consideration of the delay of frequency divider, the comparison result just is the comparison of 1pps signals, shown as Eq.1.

$$a = b \tag{1}$$

Taking the delay of frequency divider into account, the edges of the frequency source and the 1pps signal have a difference, shown as Eq.2.

$$a - t = t_1 - t_2 \tag{2}$$

|t1 - t2| is the delay difference of two dividers. If |t1 - t2| is given, the comparison result can be obtained through analysis and processing of the phase comparison. Fig.1 shows a certain state, under which the states of two dividers are relevant. That is, they are electricity at the same time and generate a pulse after counting 10M to avoid the whole period error. Generally, the counters' procedure is closely related with its working state and starting time, while two counters are irrelevant. The difference of 1pps signals equals to phase difference adding the revision of integral units of periods. The revision value is a constant when the system is working continually.

III. EXPERIMENTS

A. Experiment Schemes

Through the experiment, the paper will show the close relation between the comparison of frequency sources and the comparison of 1pps signals. Under some certain condition, the former can be calculated from the later. As shown in Figure.2. 5585B is a high-accuracy Cs atom clock, with a 1pps signal output. SR620 is a high-accurate time interval measuring instrument. Experiment adopts EPM7032 to achieve 1pps signal based on frequency dividing counter.

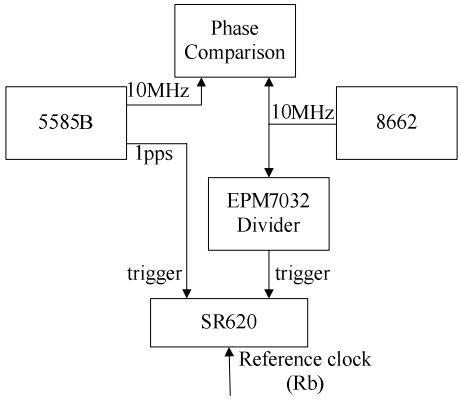

Figure2. Experiment system block

High-precision phase comparison instrument is used to measure the phase difference and record measuring data, while the time interval measuring instrument to compare 1pps signals and record data. Phase comparison method is utilized to measure the phase difference, with one data per 10 seconds. There are 116 data value in 150 seconds. Meanwhile, SR620 is used to measure the phase difference and record them, with one data per 10 seconds.

B. Experiment result analysis

Fig.3 is the curve of the output of the phase comparison. Experiment data is revised as follows: the data of the second period is subtracted by 100ns and the data of the third period is subtracted by 200ns, etc. 100ns is the whole period of 10MHz signals comparison.

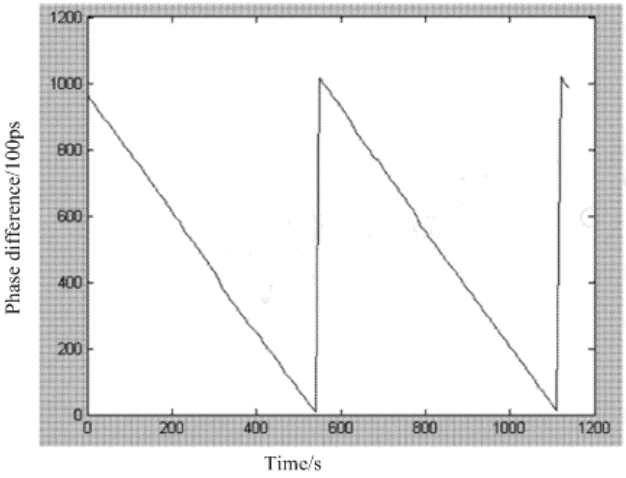

Figure3. Original result of output of phase comparison

For Figure.3, the phase difference in a period is reducing continuously, so the real data in the second period should be the measuring data subtracts the whole period, etc. Then the curve in Figure.3 becomes the middle line in Figure.4.

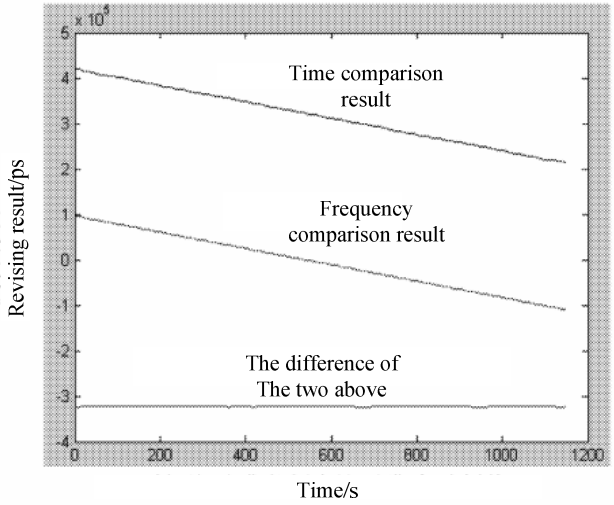

Figure4. Contrast diagram of time comparison and frequency comparison

Let w to be the difference of the phase difference and the 1pps difference. So Figure.4 is the curve of w. Combining with the definition of the 1pps signals difference, the delay difference of dividing circuit, w', can be derived from w.

Take the experiment for instance, w is revised for w'. The middle value of w' is 18.4ns, the relative change is about 8%. 18.4ns is the delay difference of dividing circuit, while 8% is

due to the instability of circuits. Experiments show that the delay of 1pps signals from EPM7032 is 34.77ns, while the delay from 5585B is 16.32ns. The difference is 18.45ns. Comparing with 18.4ns, the difference 0.05ns is caused by error. Figure.5 is the difference result of phase comparison result subtracting fitting line. Figure.6 is the difference result of time interval measured subtracting fitting line. The measuring result of time interval has poorer accuracy and stability. In the experiment, the phase comparison instrument used can reach the order of ps, simple construction, easy realization, high accuracy, comparing with SR620 [5].

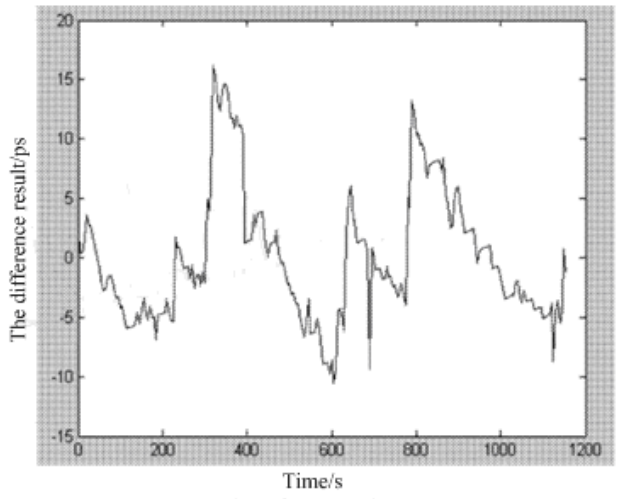

Figure5. Difference result of phase comparison result subtracting fitting line

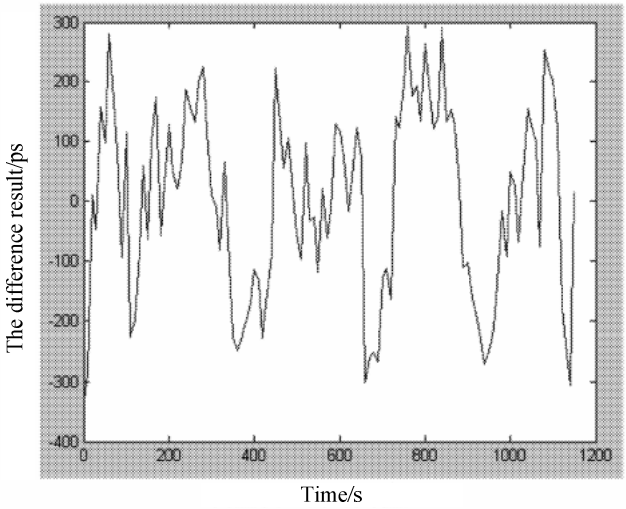

Figure 6. Difference result of time interval measured subtracting fitting line

IV. CHARACTERISTIC FEATURES

Based on the above analysis, combination with general-accurate time interval measuring instrument and high-precision phase comparison instrument can get a measuring result as a high-accurate time interval measuring instrument. If the delay difference of dividing circuit and the whole period difference, we also can use a high-accurate phase comparison. The method need to be developed furthermore because the experiment model is simpler and more ideal.

The atom clock comparison is similar as the above. As for time transferring, making use of the definite phase relation between the standard time signal and the main clock, high-precision can be obtained. The characteristic features are as follows:

A. Comparing with the traditional direct comparison method, the phase comparison is a indirect method. Its construct is simple and the accuracy is better.

B. The method can reflect the fine phase change between two 1pps signals, but the premise is determining high-precisely the original state and can measure continuously.

Breaking measurement may increase the whole period error and the initial state can be got by time interval measurement. The initial states are the whole period error and delays of dividing circuits.

V. CONCLUSION

Because 1pps signals are generated from frequency standard sources, the phase comparison of sources has a certain relation with the comparison of 1pps signals. Based on the relationship, the high-precision phase comparison can be attained through phase comparison. We can realize the phase comparison instrument with simple construction, relative cheap price. So, the combination of common time interval measurement and high-resolution phase comparison instrument can reach high-precision time comparison. Furthermore, if the delay of dividing circuits and the initial whole period error, etc, is given, a high-precision phase comparison instrument can even get the result of time comparison.

***Abstract*—Two-way satellite time and frequency transfer is a precise time transfer method and has being used to generate the TAI since 1999. Nowadays, TWSTFT links have formed a worldwide network and the utilization of the highly redundant TWSTFT data become an important topic. In our pervious study, a feasible method has been proposed, with full time transfer network data, to improve the results of TWSTFT network.**

Besides, NICT has recently developed the software-defined radio based two-way time transfer modems using the dual pseudo random noise (DPN) signal. The first DPN two-way time transfer experiments, using these modems, were performed between NICT(Japan) and TL(Taiwan) from March to December 2010 and its ability in improving the time transfer precision was approved on the Japan-Taiwan baseline. In compare with the conventional NICT-TL TWSTFT link, the DPN time transfer results have higher precision and less diurnals.

Since the DPN results show better performance than the conventional TWSTFT time transfer, we would adopt the DPN results for the NICT-TL link, and solve the TWSTFT+DPN network solution by using our proposed method. The numerical results about how the DPN data can benefit the performance of TWSTFT network will be illustrated in the paper.

I. INTRODUCTION

Two-way satellite time and frequency transfer (TWSTFT) [1] is a precise time transfer method and has developed into a widely used technique in those laboratories contribute to the generation of International Atomic Time (TAI) and realization of UTC [2], [3]. Rules of data taking, processing, and reporting, for TWSTFT direct-link, are laid down in the recommendation ITU-R TF.1153-2. However, the TWSTFT were usually measured as a network but its data were used as single base lines, so a lot of measured data may be wasted.

In recent years, the number of point-to-point two-way time transfer links is growing, so the concept of network time transfer has been proposed [4]–[6] and the utilization of the redundant data of each indirect link in the TWSTFT network becomes an important topic. Besides, combining different time transfer results techniques is also a solution for the high redundancy in the TAI network so as to fully use the total potential of different time link data. Because more and more new techniques are coming, e.g., Glonass, Galileo, Compass, etc, the question of how to combine different techniques is inevitable and we cannot evade this trend. For example, Jiang *et al.* [7] has proposed an idea, combining the advantages of both TW & PPP methods, to improve the time transfer results. By using the TWSTFT+PPP method, the diurnals in TWSTFT results can be reduced.

Moreover, National Institute of Information and Communications Technology (NICT) has recently developed the software-defined radio based two-way time transfer modems [8]-[10] and their ability in improving the time transfer precision by using the dual pseudo random noise (DPN) signal was approved on the Japan-Taiwan baseline [11]. The DPN two-way time transfer experiments, using these modems, were performed between NICT(Japan) and TL(Taiwan) from March to December in 2010. During this period, the Asia-Pacific rim region TWSTFT network performed continuously. Numerical analyses show that the DPN time transfer result of NICT-TL experiment has higher precision and less diurnals in compare with the conventional TWSTFT experiments.

In our previous study, a feasible method was proposed utilizing full data of the TWSTFT network for data processing [12]. The numerical results show that better short-term stabilities and uncertainties of most links in the network can be obtained. Therefore, we are curious about how the results of a single DPN link can benefit the TWSTFT time transfer network.

In this study, we would try to include the time transfer data of DPN experiment in solving the TWSTFT network solution

This work is support in part by the Bureau of Standards, Metrology & Inspection, Ministry of Economic Affairs, Taiwan under Grant number BSMI 100-1403-05-05-13.

with our proposed method. One will see that, for most links in the "TWSTFT+DPN" network, not only the short term stabilities but also the diurnals are effectively improved.

II. Theoretical Background and Method

A. Solving the Time-Transfer Network Solutions

First of all, we would briefly describe our previous proposed method for solving time-transfer network solutions. To calculate the time difference T_1-T_2 between two stations 1 and 2, the time interval readings at stations 1 and 2, i.e., TIC_{12} and TIC_{21}, can be applied. The related equation for TWSTFT is as the following

$$\begin{aligned} T_{12}&=(T_1-T_2)=N_{12},\\ \text{where } N_{12}&=\tfrac{1}{2}(TIC_{21}-TIC_{12})\\ &\quad+\tfrac{1}{2}[(TU_1-TD_1)-(TU_2-TD_2)]\\ &\quad+\tfrac{1}{2}(\tau_{12}-\tau_{21})\\ &\quad+\tfrac{1}{2}[(\tau_1^{TX}-\tau_1^{RX})-(\tau_2^{TX}-\tau_2^{RX})]+\Delta\tau_{R12} \end{aligned} \tag{1}$$

Equation (1) is the formula for calculating the time difference between each pair of TWSTFT stations. In equation (1), TU_i and TD_i denote satellite propagation delays of up-link from station i and down-link to station i. The third term $1/2(\tau_{12}-\tau_{21})$ is the non-reciprocity due the satellite equipment delays. The fourth term is the difference of the differential delays of the transmitting and receiving parts (equipment delays) of earth stations 1 and 2. The last term $\triangle\tau_{R12}$ is a correction of Sagnac effect.

For the case of 4-station TWSTFT network, we adopt the condition of zero closure sums and get the following linear equations

$$\begin{cases} T_{12}=N_{12}=Y_1\\ T_{13}=N_{13}=Y_2\\ T_{14}=N_{14}=Y_3\\ T_{23}=T_{13}-T_{12}=N_{23}=Y_4\\ T_{24}=T_{14}-T_{12}=N_{24}=Y_5\\ T_{34}=T_{14}-T_{13}=N_{34}=Y_6 \end{cases}, \tag{2}$$

with $N_{ij}=Y_k$ just for simplifying the subscript. Equation (2) can be written in matrix notation [13] as

$$X\,T=Y, \tag{3}$$

with $X=\begin{bmatrix}1&0&0\\0&1&0\\0&0&1\\-1&1&0\\-1&0&1\\0&-1&1\end{bmatrix}$; $T=\begin{bmatrix}T_{12}\\T_{13}\\T_{14}\end{bmatrix}$;

$$Y=\begin{bmatrix}Y_1\\Y_2\\Y_3\\Y_4\\Y_5\\Y_6\end{bmatrix}=\begin{bmatrix}N_{12}\\N_{13}\\N_{14}\\N_{23}\\N_{24}\\N_{34}\end{bmatrix}$$

It is well known that the performances (e.g., stability) of every TWSTFT links are different. According to the TDEV value of each link Y_i at averaging times of 1 hour, we determine the weighting value as

$$w_i=\frac{1/\sigma_i^2}{\sum_{k=1}^{N}\left(1/\sigma_k^2\right)}, \tag{4}$$

where $\sigma_i = TDEV\ [Y_i]$ and $N = n(n-1)/2$.

Applying the weighting to (3), we get

$$WX\,T=WY, \tag{5}$$

where $W=\begin{bmatrix}w_1&0&0&0\\0&w_2&0&0\\0&0&\ddots&0\\0&0&0&w_{n(n-1)/2}\end{bmatrix}$.

Equation (8) can be solved by the weighted least squares method：

$$T=(X^T WX)^{-1}X^T WY. \tag{6}$$

B. Utilization of new time transfer data

To improve the two-way time transfer precision, NICT has developed a novel modem with a new timing signal. A pair of pseudo random noises (DPN) signal, based on the binary offset carrier (BOC) [1], separate in frequency domain is introduced. Since the experiment results of DPN show better short-term stability and less diurnal, it will be helpful in improving the network performance if we include the DPN results in the analysis of TWSTFT network solution.

In the following numerical analysis, we would not combine the numerical results of the TW and DPN time transfer links. We calculate the average value of the differences between TW link and DPN results, and shift DPN data by this value to align with the regular TWSTFT data. Then direct TW and shifted DPN results of NICT-TL link can be used separately in solving the network solutions of simple TWSTFT network and TWSTFT+DPN network (see case (a) and case (b) in Fig. 1.). By doing this, we will be able to distinguish the improvement effects caused by simple TWSTFT network analyses or including a DPN link in it.

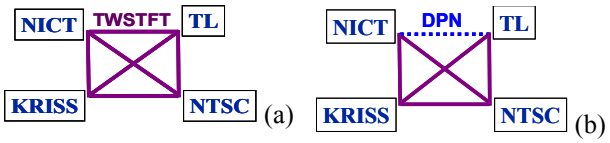

Fig. 1. The TWSTFT network connection among four stations. (a) simple TWSTFT network (b) TWSTFT+DPN network.

III. Numerical Results

The NICT-TL DPN experiment was performed from March 2010 to Dec. 2010. In the forepart of this period, some discontinuities exist in the measured results due to the power blackout, rain fade, and some other unexpected events. Since DPN is a novel technology to TWSTFT and this is the first international DPN link, many parameters (e.g. the transmitting power level) were not properly adjusted, and the performance of the current DPN results was not optimal. However, according to the observation and numerical analyses, we think DPN method is very potential and comparable to GPS PPP.

Let us consider the network constructed by links among four stations, including NICT, TL, the National Time Service Center of China (NTSC) and the Korea Research Institute of Standards and Science of Korea (KRISS). We select the results of the latter part (MJD 55515 to MJD 55532) of the DPN experiment for data analyses, because the DPN data continuity in this period is better. One can see that the TDEV values of all direct TWSTFT links (see the second row marked as "Direct" in Table-I) are small which means all the TWSTFT links have good stabilities.

The TDEV values of all direct TW link data, TWSTFT network and TWSTFT+DPN network solutions, are calculated and summarized in Table I. TWSTFT+DPN network mean that DPN results, instead of regular TWSTFT data, of NICT-TL link are used to solve the network solutions.

TABLE I
TDEV VALUES OF ASIA-PACIFIC TWSTFT DIRECT LINK, TWSTFT NETWORK RESULTS, AND TWSTFT+DPN NETWORK RESULTS. RELATED GAIN VALUES ARE ALSO SHOWN.

Link / TDEV (/1hr)(ps)	NICT-TL	NICT-NTSC	NICT-KRISS	TL-NTSC	TL-KRISS	NTSC-KRISS
Direct	104	157	179	140	84	125
TWSTFT Network	104	138	120	119	89.5	129
Gain(Net)	0%	12.1%	33%	15%	-6.5%	-3%
TWSTFT +DPN	47	122	94	116	88	129
Gain(DPN)	54.8%	22.3%	47.5%	17.1%	-4.8%	-3%

* TDEV value of NICT-TL DPN link is 48 ps in this case.

The Gain values of TWSTFT network and TWSTFT+DPN solutions at one-hour averaging time are also illustrated. One can see that the range of positive gains in TWSTFT network results is from 0% to 33%. Because all links are stable and their TDEV values are already small, the improvements upon their TDEV values through network analyses are limited, and two negative gains (-6.5% for TL-KRISS link and -3% for NTSC-KRISS link) are obtained. Besides, the Gain of network analyses for NICT-TL is zero.

For the TWSTFT+DPN networks, the Gain values for most links are obviously increased and the range is extended to from 17.1% to 54.8%. Actually, the NICT-TL DPN link already shows better stability (TDEV (/1hr) value is about 48 ps) than the regular NICT-TL link. The improvement caused by including the DPN results in network analyses is very obvious. Due to the equally stable performance of all links, we still have two negative Gains, but the values are reduced a bit.

Fig. 2 shows the TDEV comparisons among direct TW, TWSTFT network and TWSTFT+DPN network results of the NICT-TL link. The network solution of NICT-TL link is almost the same with the direct link (i.e. Gain = 0%). This is reasonable, as we have mentioned that all these links are stable, so limits the improvement to the results through TWSTFT network analyses.

After including the DPN results into the network analysis, the improvement of its short-term stabilities is obvious. Moreover, the diurnal effect is also reduced.

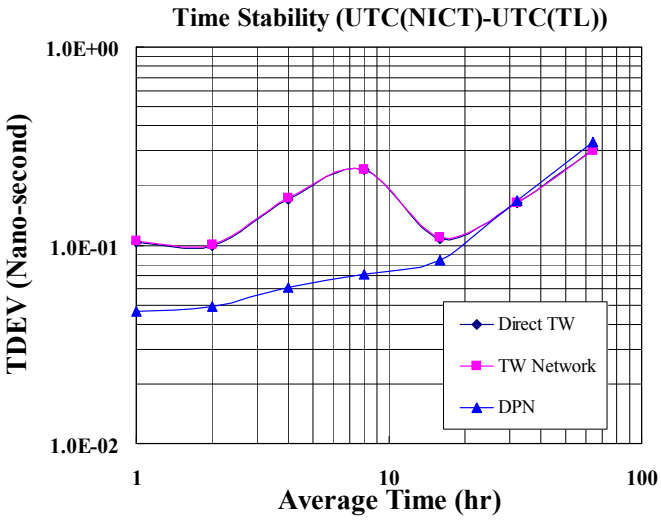

Fig. 2. TDEV values of the direct link data, and TWSTFT network and TWSTFT+DPN network solutions of NICT-TL link.

Now we check another time transfer link, say NICT-NTSC link, with obvious diurnal. It's a regular TWSTFT link and is included in our case study. The results of the direct link, TWSTFT network and TWSTFT+DPN network analyses for NICT-NTSC link are shown in Fig.3. The network result has better short-term stability than that of direct link and the Gain value is 12.1% (see the row "Gain(Net)" in Table I). By using the TWSTFT+DPN network analyses, the Gain value increases to 22.3% (see the row "TWSTFT+DPN" in Table I). In Fig. 3, we can also see that the diurnal effect is reduced. Therefore, including the DPN link for the TWSTFT+DPN network analyses will benefit to the reduction of diurnal.

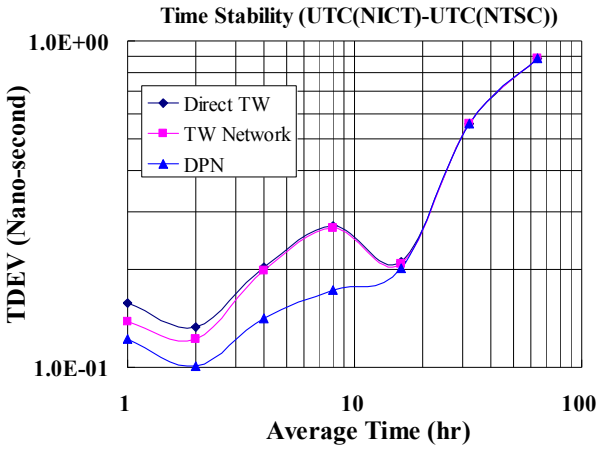

Fig. 3. TDEV values of the direct link data, and TWSTFT network and TWSTFT+DPN network solutions of NICT-NTSC link.

IV. CONCLUSION

The first international DPN experiment was performed between NICT and TL from March 2010 to Dec. 2010. Its results show better performance, with smaller TDEV value and less diurnal, than regular NICT-TL TWSTFT link. So we are curious about how the DPN results can benefit the TWSTFT time transfer network.

In this paper, our previous proposed method, with full time transfer network data by using weighted least squares method, is used to solve the TWSTFT network solutions. Because the TDEV values of these regular TWSTFT links are already small. We get two small "negative Gains" in six links, and the maximal Gain is up to 33%.

Replacing the direct NICT-TL link results by the DPN data, the TWSTFT+DPN network solutions can be solved with our previous proposed method. In compare with the TWSTFT network results, the positive Gains are further increased and the negative Gains are decreased a bit in TWSTFT+DPN network. This confirms that including the single DPN link is helpful in improving the stabilities of the links in TWSTFT network. We also find that the DPN link has less diurnal effect and can help to reduce the diurnals of other links in TWSTFT+DPN network.

ACKNOWLEDGMENT

Special thanks to Mr. Tadahiro Gotoh, Jun Amagai, Thomas Hobiger and related staffs of NICT for developing the GPU-based DPN modem. We would also like to express our gratitude to NICT colleagues for their devotion to the Asia-Pacific TWSTFT network and the arrangements for the NICT-TL DPN experiment.

***Abstract*—An optical-fibre network is being planned for distribution of optical and microwave reference frequencies in Australia. This network would connect a number of research facilities and the National Measurement Institute (NMI), allowing long-range comparison of frequency standards to high precision and providing reference signals for a wide range of applications. First results for transfer in the laboratory achieve a fractional frequency stability of 7×10^{-17} at an averaging time of 10^4 s for the distribution of an 80 MHz radio frequency signal. We present details of the technique used to cancel noise introduced by the fibre, describe the all-digital radio-frequency phasemeter used to characterise performance, and outline plans for the further development of the network.**

I. INTRODUCTION

Optical fibre links have long been used to distribute radio frequency reference signals across large facilities [1], and more recently over longer distances using dedicated dark fibre [2]. With the advent of optical frequency standards [3], optical fibre links have emerged as one of the few methods capable of transferring the very high levels of accuracy and stability of these standards in practical averaging times [4]. In consequence, large-scale projects are already underway in Europe demonstrating optical frequency transfer up to 900 km [5, 6], and combining transfer of reference frequencies with other data traffic on commercial networks [7].

Australia is well placed both to contribute to and to benefit from the continuing development of optical fibre frequency transfer. Within Australia, fibre links can be tested across a transcontinental baseline. The National Measurement Institute (NMI) in Sydney on the east coast and the University of Western Australia (UWA) on the west coast are separated by over 3000 km. Both institutions operate atomic frequency standards, ultra-stable microwave oscillators and optical frequency combs. NMI and UWA already participate in GPS and two-way satellite time transfer, and are preparing for the Atomic Clock Ensemble in Space (ACES) mission [8] which will characterise new transfer techniques. UWA leads an Australian collaboration awarded significant funding by the Australian Government for ACES ground-station infrastructure, including a high-performance station clock.

Australia also has significant fibre network infrastructure. The Australian Academic Research Network, operated by AARNet, provides a number of options to connect laboratories within a proposed national network, including short (NMI to Macquarie University in Sydney, less than 10 km), intermediate (NMI to the Australian National University in Canberra, about 300 km) and very long (NMI to UWA) links. Fibre is currently being laid for trial sites within a new National Broadband Network, planned to connect over 90% of Australian premises.

Finally, Australia has major potential applications for timing and frequency signals delivered over fibre, particularly in the area of radio astronomy. For example, the Australia Telescope National Facility operates three radio observatories across New South Wales including the 64-m Parkes telescope. Very Long Baseline Interferometry is conducted using these and other radiotelescopes across the country. Australia is also one of two candidate hosts for the Square Kilometre Array (SKA), one of the largest research facilities ever devised [9]. Development of the Australian SKA Pathfinder (ASKAP) telescope is already in progress at the Murchison site in

Western Australia [10], and new fibre infrastructure to connect proposed SKA nodes is in preparation.

II. Apparatus

A. *Fibre-based radio-frequency distribution system*

As a first step towards planned long-range networks, we demonstrate transfer of radio-frequency signals over a fibre spool in the laboratory. Our system is illustrated in Fig. 1, with some components omitted for clarity to illustrate the basic design. The system uses commercial off-the-shelf components, and is designed to be relatively low-cost and scalable.

The local site has a stable master oscillator (in this case a hydrogen maser) which produces a reference radio frequency signal, RF_M, for dissemination to and stabilisation of a remote slave oscillator output, RF_S. The optical system consists of two RF-modulated lasers, one 'local' and the other 'remote', counter-propagating through the same optical fiber. Propagation through the fiber is subject to mechanical and thermal fluctuations, with the resulting phase noise suppressed as follows.

Commencing at the remote site, the remote signal RF_S is sent through the fibre acquiring the phase noise term *Fiber*. At the local site, the master oscillator output RF_M is frequency doubled and mixed down with the photodetector signal, $RF_S + Fiber$. The mixer output signal $2\,RF_M - RF_S - Fiber$ is then modulated onto the local laser and sent back through the fiber. The detected signal at the remote site is given by $2\,RF_M - RF_S$ only, since the additional *Fiber* noise term added on propagation cancels algebraically. The remote photodetector signal is then mixed with the slave oscillator RF_S to yield an error signal for feedback control.

As in all such fiber-noise cancellation schemes, cancellation requires that the fiber noise introduced is the same for the two counter-propagating beams. The practical performance of microwave components can also limit the effectiveness of cancellation; the design in Fig. 1 is chosen to improve isolation of unwanted sidebands, noting again that additional filters have been omitted for clarity. Finally, the bandwidth of the cancellation is limited by the fibre round-trip time, as in other schemes.

B. *All-digital radio-frequency phasemeter*

The design of the phasemeter has been presented previously [11]. As shown in Fig. 2, it uses front-end analog-to-digital conversion with dual phase-locked loops implemented digitally on a commercial field-programmable gate array (FPGA) platform. The digital implementation gives excellent timing coherence and signal isolation, and allows rapid prototyping and optimisation of control characteristics.

The noise floor of the phasemeter was measured by applying the same electronic signal to both reference and signal inputs in Fig. 2. The spectral density of phase fluctuations is well below 1 μrad/√Hz at frequencies above 0.1 Hz. The improvement over the earlier results [11] is due to improved synchronisation within the FPGA implementation, yielding greater rejection of common-mode noise.

III. Results

We measured the fractional frequency stability of our fiber-based radio frequency transfer system using the digital phasemeter. For this test, the remote oscillator was located in the same laboratory as the master oscillator. As shown in Fig. 1, the out-of-loop phase check-1 measures the stability of the master oscillator with respect to the slave oscillator.

Results for this measurement are shown in Fig. 3, together with the measured stability of typical reference oscillators for comparison. (The out-of-loop phase check-2 in Fig. 2 measures the fiber phase noise directly; however, this signal is

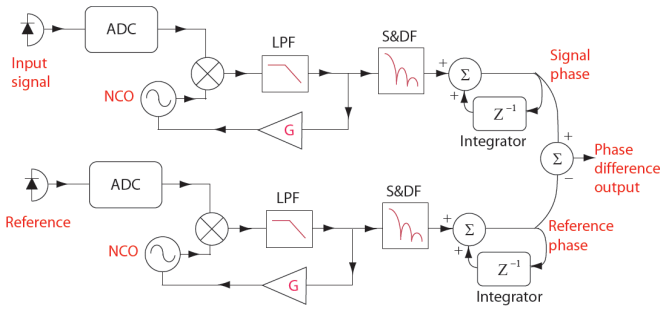

Figure 2. All-digital RF phasemeter [11], implemented on a commercial FPGA platform. NCO, numerically-controlled oscillator, LPF low-pass filter, and S&DF, sum-and-dump filter.

above the Nyquist limit for the phasemeter, and modifications to complete this measurement are currently under way.)

Operating at a carrier frequency of 80 MHz through a 20-km fiber spool, the transfer system achieves a fractional frequency stability of 7×10^{-17} (measured at 20 MHz) at an averaging time of 10^4 s. This is sufficient to transfer a reference signal from a hydrogen maser without degradation, as is evident from the direct comparison of two NMI hydrogen masers shown in Fig. 3. The noise floor of the transfer system was measured using a very short fiber link of 10 m, yielding a frequency stability of 4×10^{-17} at 10^4 s. We interpret these results as indicating that the system was operating close to the noise floor, for this length of spooled fibre and these averaging times.

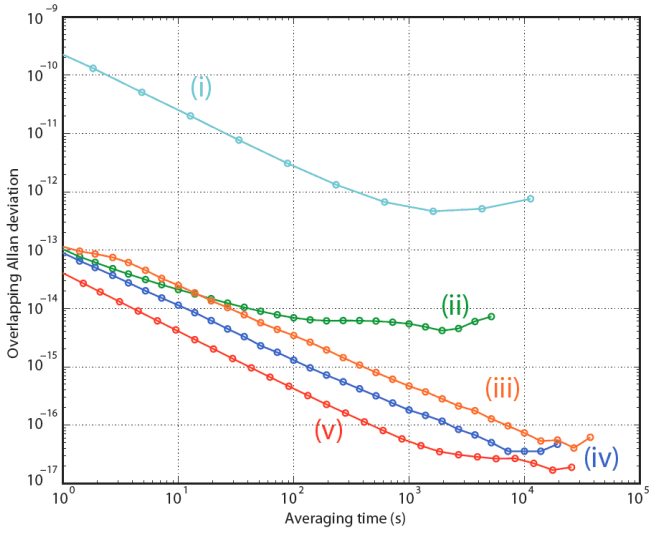

Figure 3. Fractional frequency stability results for (i) commercial rubidium and cesium oscillators, (ii) two hydrogen masers, fiber frequency distribution system through (iii) 20 km and (iv) 10 m of fiber, and (v) electronic noise floor of the phasemeter.

IV. Further Work

The initial work presented here is the first stage of a larger program, working towards a national network for transfer and dissemination of reference frequencies across Australia. The goals of the next stage of the program are to extend RF transfer to longer distances, in particular to connect existing Australian radio observatories, and to extend the transfer to optical frequencies.

At the time of writing first light has recently been transferred over the 10-km link between NMI and Macquarie University. A number of other fiber links have been identified for longer-range testing, with work already under way to establish access.

Abstract— **KRISS (Korea Research Institute of Standards and Science) has been operating the standard time and frequency broadcasting station (call sign: HLA) since 1984. The station HLA broadcasts continuous time and frequency signals on 5 MHz carrier frequency and 2 kW transmit power. But the poor reception due to radio interference is decreasing users. Therefore to increase the radio reception, a digital modulation method and an increase of bit rate are introduced additionally to the present amplitude-modulated radio signal. We describe a digital modulation method for improving radio reception of the standard time and frequency by shortwave.**

I. INTRODUCTION

The radio reception of a shortwave broadcasting is low due to a signal fading easily and is susceptible to environment, while a shortwave broadcasting reaches to long distance owing to ionosphere reflection (a phenomenon known as skywave propagation). Shortwave radio is used for broadcasting of voice and music, and long-distance communication to ships and aircraft, or to remote areas out of reach of wired communication or other radio services. Amateur radio on these frequencies can provide hobby, educational and emergency communication [1].

But the reception is becoming inadequate by a bad environment such as complicated radio propagation, many tall buildings and so on. Thus it is necessary to develop the modulation method in order to enhance the radio reception against these conditions. KRISS has broadcasted the Korea Standard Time on 5 MHz carrier frequency with IRIG-H time code format [2] by amplitude modulation (AM). We introduce a digital modulation method to enhance the radio reception of the standard time and frequency broadcasting at KRISS, and carry out simulations to find out an optimal digital modulation method [3]. And we design a modulation method combined BPSK-DSSS (Direct Sequence Spread Spectrum) with AM for the existing AM users.

Goal of this study is to enhance the radio reception by application of a digital modulation method. And the Scope is as follows:

- Design an optimal digital modulation method for improving the radio reception by analysis of the conventional modulation method and suitability evaluation through the analysis of various digital modulation methods
- Verify the radio reception enhanced by digital modulation with a simulator by selection of the indexes for the comparison of reception performance and comparison with the conventional method
- Preparation of a digital modulation system and its performance test

II. ALTERATION OF BROADCSTING STATION AT KRISS

A. Current Station

The specifications of current station are as follows:

- Carrier frequency: 5 MHz
- Modulation: AM
- Time code format: IRIG-H
- Band width: 6 kHz
- Transmit power: 2 kW
- Antenna type: conical

The drawbacks in current system are vulnerable to fading and environmental noise, besides low power and outdated equipment such as vacuum tube amplifier. Therefore we have tried to replace with solid-state device (SSD) amplifier and will change the modulation method.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

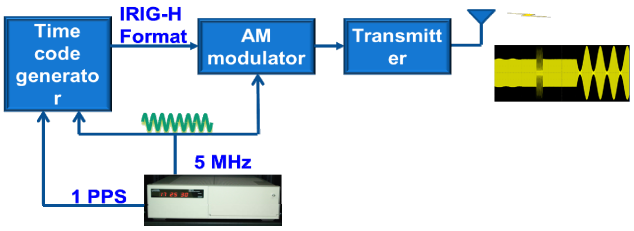

Figure 1. Block diagram of current system for the broadcasting timing signal.

B. *Modification of the Station*

For the modification of the station, as shown in Fig. 2, we adopt the BPSK digital modulation, and increase the bit rate by IRIG-B time code format and the transmit power up to 5 kW, and extend the bandwidth to 10 kHz. At preset we have equipped new timing system such as SSD power amps, have been making the time code generators and digital modulators combined analog modulation and so on.

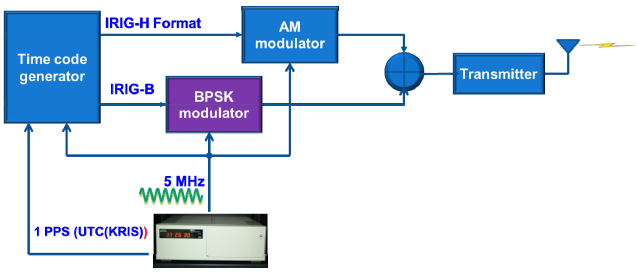

Figure 2. Block diagram of transmission system combined AM and BPSK-DSSS.

III. VERIFICATION OF TX AND RX BY SIMULATION

We carried out the simulation so as to select an optimal modulation method as shown Fig. 3. In order to analyze reception performance corresponding to the addition of the digital modulation scheme, we designed a simulation program. The program is divided into two parts as the transmitting part and the receiving part. In the transmitting part, the transmitting signals are generated by combining the AM modulated with the IRIG-H time code and the BPSK-DSSS modulated with the IRIG-B time code signals. In the receiving part, the demodulations are performed for the AM and BPSK-DSSS signals in which the additive white noise is added generated from the channel. Fig. 4 and 5 show the results of the monitored spectrums in the transmitting and the receiving parts, respectively.

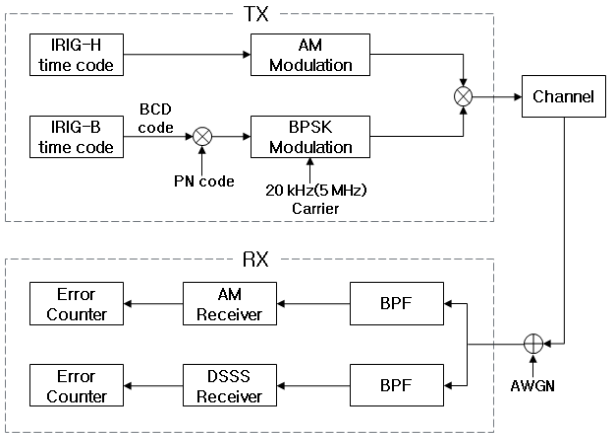

Figure 3. Simulation design of transmit and reception with DSSS

In the case of employing the bit error rate (BER) as the reference of the receiving performance, tremendous amount of symbol data are required in order to get reliable results. The carrier frequency of the standard time and frequency broadcast signals is 5 MHz, however, a tremendous amount of time is required to generate the large symbol data with the 5 MHz carrier frequency. Thus, we set the carrier frequency as 20 kHz instead of 5 MHz and sampling frequency as 80 kHz for efficient tests the in the simulations.

There are many referencing methods for comparing the performances of various digital modulation schemes. Among them, the BER and the bandwidth efficiency are generally used. Therefore, we use them for comparing the theoretical performances of the modulation scheme [4].

Fig. 6 shows the demodulated result when the AM modulated and the BPSK-DSSS modulated signals are transmitted together. From the results, it is observed that the required E_b/N_0 of the AM modulated signals is about 31 dB and that of the BPSK-DSSS modulated signals is about 7.5 dB when the BER is $1x10^{-2}$. This means that the required power of the BPSK modulation scheme is lower than that of the AM modulation scheme to get the same BER, and in other words the BER performance of the former is better than that of the latter under the same E_b/N_0 environment.

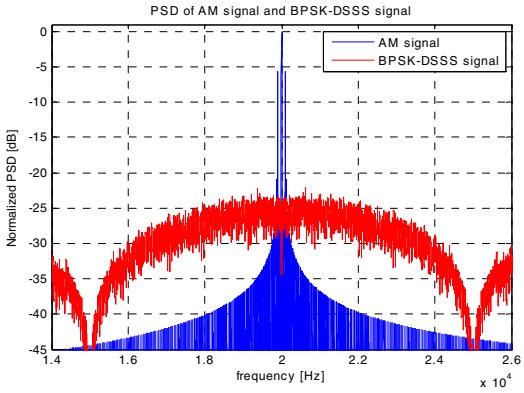

Figure 4. Power spectrums of AM and BPSK- DSSS at transmitting part in figure 3.

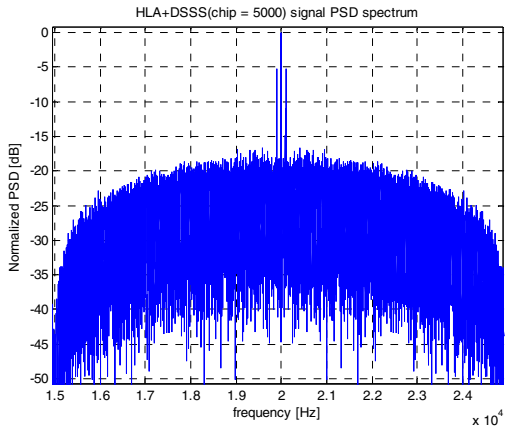

Figure 5. Simulation of the combinaton of AM and BPSK- DSSS at receiver input in figure 3.

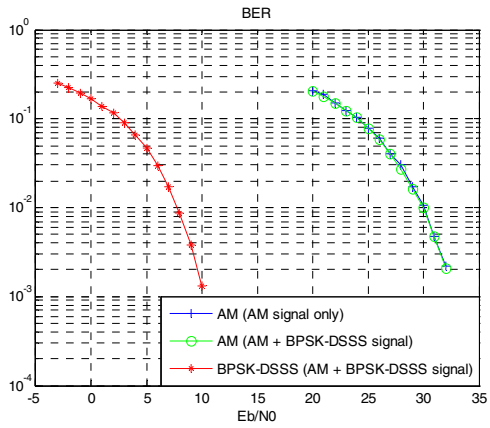

Figure 6. BERs of AM and BPSK-DSSS at each user receiver by simulation.

IV. CONCLUSIONS

We introduced a digital modulation method to enhance the radio reception of the standard time and frequency broadcasting at KRISS. And we carried out simulations to find out an optimal digital modulation method. And we design a modulation method combined BPSK-DSSS with AM for the existing AM users, and the IRIG-B and the IRIB-H time code format will be applied simultaneously to digital modulation and amplitude modulation respectively.

A modulator combining digital and analog signal will turns out in the near future. And we will fabricate a receiver for digitally modulated signal and verify the improvement by the comparison of the radio reception between an analog and a digital receiver at the field.

***Abstract*— Two-way satellite time and frequency transfer between Asia and Europe has been performed for many years first by a two-transponder and later by a one-transponder configuration on the IS-4 and the AM-2 satellites, respectively. A diurnal phase instability was observed in links established through IS-4, while such instability has not been observed when AM-2 was used. It could be shown that the diurnal variation are site-independent. An on-board path asymmetry due to the use of two transponders seems thus to cause it.**

I. Introduction

Today two-way satellite time and frequency transfer (TWSTFT) is one of the essential tools for time transfer made in context with International Atomic Time (TAI) calculation [1], [2]. In TWSTFT, paired earth stations transmit and receive pseudo-random-noise coded signals via a communication satellite to exchange timing information [3]. Because the transmission and reception paths are almost the same, the atmospheric and geometrical delays between earth station and satellite are generally canceled. Today's operational TWSTFT consequently enables precise time and frequency transfer down to the 10^{-15} uncertainty level for frequency comparisons and 1 ns for time transfers [4].

The first TWSTFT experiment connecting Europe (Eu) and Asia was between Telecommunication Laboratories (TL) and NMi Van Swinden Laboratorium B.V. (VSL) [5]. Subsequently a link between National Institute of Information and Communications Technology (NICT) and Physikalisch-Technische Bundesanstalt (PTB) was established using the geostationary telecommunication satellite Intelsat-4 (IS-4) at 72°E in July of 2005 [6]. The Korea Research Institute of Standards and Science (KRISS) joined the link in November of 2005 and the National Metrology Institute of Japan (NMIJ) joined in September of 2007. The number of the participants sharply increased after that: TL, National Time Service Center (NTSC), and National Institute of Metrology (NIM), the latter two from P.R. China, joined in March of 2008, May of 2008 and December of 2008, respectively. In March of 2009, Observatoire de Paris (OP) came in as the second station in Europe. The Asia-Eu link using IS-4 became one of the most active TWSTFT networks. Additionally the direct comparison of Cs atomic fountains was performed between NICT and PTB and an uncertainty of frequency transfer of 7×10^{-16} was achieved during a 15-days campaign [7].

In the intercontinental TWSTFT link, two transponders in the Ku band are typically used to cover a wide area. Diurnal phase variations were observed in the links with such configuration [8]. So far, the effects due to the atmosphere, instrumental delays and satellite motion have been studied [9], [10], [11]. The Asia-Eu TWSTFT network using IS-4 stopped working because of a satellite malfunction on February 1, 2010. After the switch to the satellite AM-2 at 80°E, the link was resumed on October 1, 2010. Since the AM-2 satellite has one wide beam, the link is now established by one transponder. The clear diurnals have no longer been observed in the new link. In this report, the link performances before and after the satellite switch are shown, with particular view on the different transponder configurations.

II. The Asia-Eu TWSTFT link

The Asia-Eu link was established using IS-4 and AM-2 from November 2005 to February 2010 and from October 2010 to the present, respectively. Table I shows the locations and antenna diameters of the participating stations. The used frequency bandwidth was 2.5 MHz in the Asia-Eu link. To transmit a 2.5-Mcp/s modulated signal, SAW filters whose 3-dB bandwidth was 2.3 MHz were applied in the transmission path to limit the bandwidth occupied by the signal. In the earth stations the same equipment was used in the IS-4 as well as later in the AM-2 link. Two Ku-band transponders were used to establish the link via IS-4. In other words, different uplink and downlink frequencies were assigned for Eu and Asia stations. Time transfer was performed once every hour. After the satellite switch to AM-2, the link with OP stopped because OP is out of the coverage of the AM-2 footprint. Time transfer among PTB, TL, NTSC and NIM is performed once every hour with a duration of 5-minutes per session between

978-1-61284-110-6/11/$26.00 ©2011 IEEE

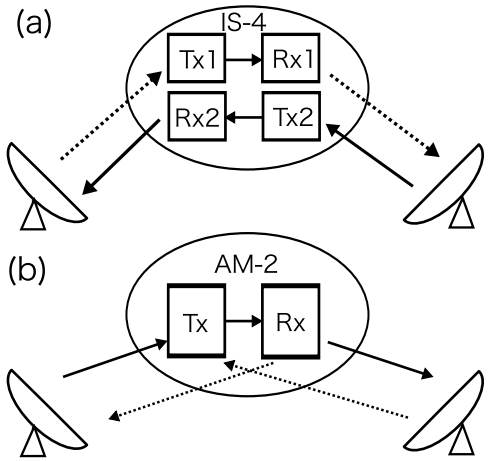

Fig. 1. Transponder configurations:(a) IS-4 link, (b) AM-2 link.

13 h UTC and 22 h UTC. The operation time is due to the limited working time of the satellite transponder. Only one Ku-band transponder is used to establish the link via AM-2 and thus the uplink and downlink frequencies are common for all stations. Fig. 1 shows the transponder configurations in the cases of IS-4 and AM-2. When two transponders are used, the signal paths involved in the on-board frequency conversion are different for the signals transmitted from Asia and Eu and vice versa, and a path asymmetry is induced accordingly.

TABLE I
LOCATION AND ANTENNA DIAMETER.

Abbr.	Location (LA, LO)	Antenna diameter[m]
NICT	(N 35.71, E 139.49)	2.4

OP	(N 48.84, E 2.33)	2.4

III. LINK PERFORMANCE

A. via IS-4

Fig. 2 shows the frequency instabilities in the IS-4 links expressed by the Modified Allan Deviation (MDEV) between H-masers at PTB, OP and the reference signals in the Asian laboratories. The data period is from MJD 55120 to MJD 55165. The reference signals of the Asian laboratories except NIM were local time scales generated from H-masers. A commercial Cs clock served as the reference clock for the NIM station. The instabilities seen in links to NIM were governed by the performance of the Cs clock. Other long-term instabilities can be attributed to the frequency adjustments of the local time scales. The short-term instabilities of PTB-NICT, PTB-TL and OP-NICT links reached the mid 10^{-14} level at an averaging time of 1 hour. Since small phase jumps were seen in the OP-TL link, the short-term instability became worse. In the links with NTSC, the deviation of the received data at PTB and OP were larger than those received from TL, NIM and NICT. It is thought that the SAW filter used in the Tx path of NTSC station caused it. Almost all frequency instabilities show a significant bump around an averaging time of half a day, indicating an instability with a diurnal pattern. The reason is discussed in the next section. The frequency stabilities of the PTB-TL, PTB-NICT and OP-NICT links reach the low 10^{-15} level at an averaging time of 1 day, nevertheless. It allowed us to perform meaningful frequency comparison between Cs atomic fountains [4].

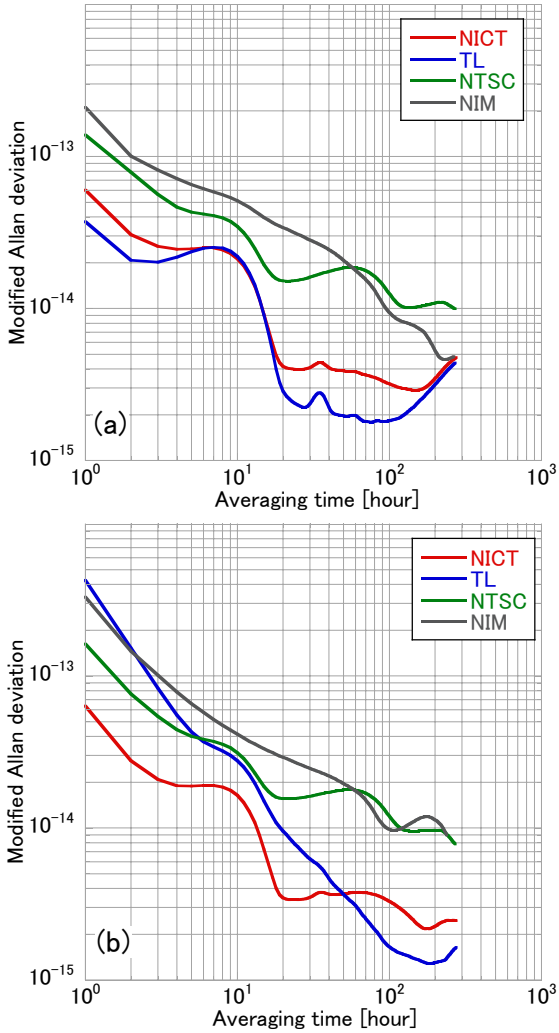

Fig. 2. Frequency instabilities with H-masers at PTB (a) and OP (b).

B. via AM-2

Fig. 3 shows frequency instabilities in the AM-2 links with PTB (a) and among Asian stations (b). The data period was from MJD 55617 to MJD 55630. The reference signals were local time scales generated from H-masers at PTB, TL and NTSC stations. Now the signal from a H-maser was also used

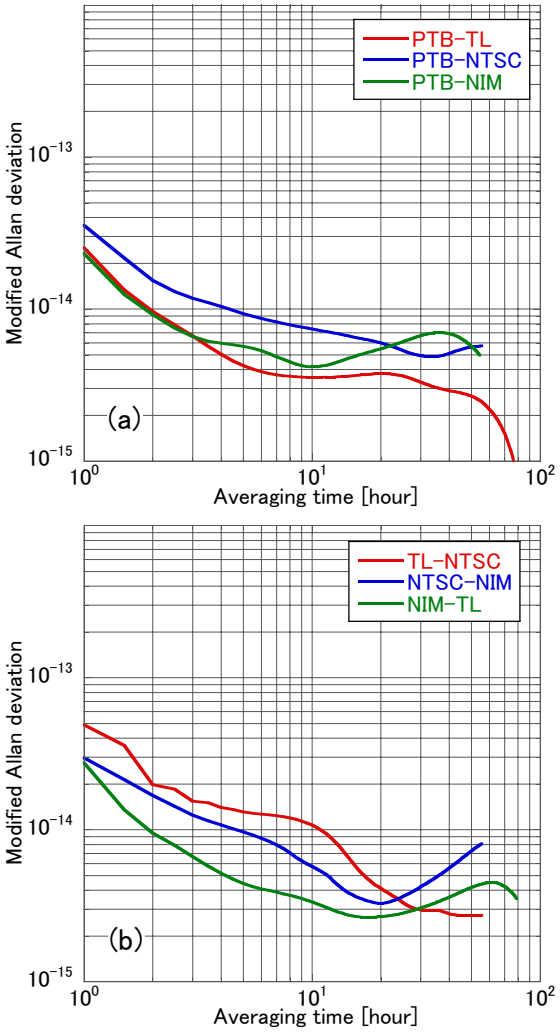

Fig. 3. Frequency instabilities in the AM-2 link with PTB (a) and among Asian stations (b).

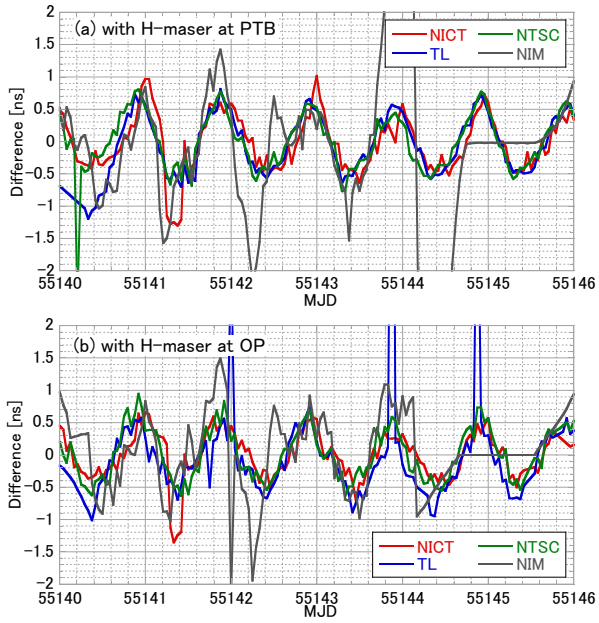

Fig. 4. Diurnal instabilities with H-masers at PTB (a) and OP (b).

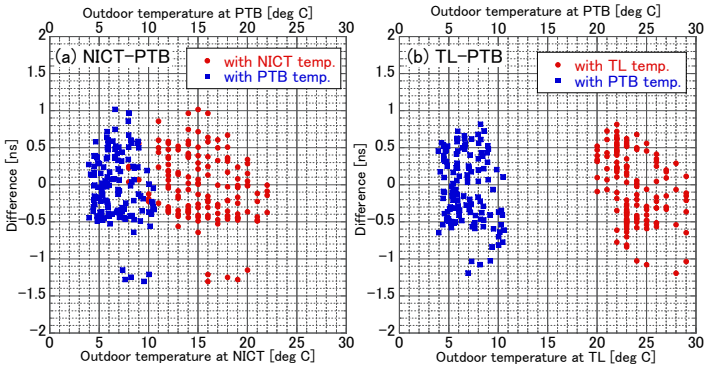

Fig. 5. Scattering plots between diurnal instabilities and outdoor temperatures.

at the NIM station. A bump indicating a diurnal instability is not seen in Fig. 3. The short-term instabilities are improved in comparison to those in the IS-4 link. The stabilities with NTSC look still worse because of the effect of the SAW filter, however. From the results shown in Fig. 3 (a) and (b), the frequency instabilities were similar in the links with PTB and among Asian stations. Although the elevation angle at PTB was as low as 3.7°, a detrimental effect has not appeared so far. The link performance was limited at first due to the limited (regularly interrupted) working time of the satellite transponder on AM-2. The regular interruption between the working times was linearly interpolated and MDEV was calculated. The frequency instability at an averaging time of one day was comparable to that of the IS-4 link. However, in this data procedure a bias is inserted to the MDEV, resulting that it may look better than it actually is.

IV. Diurnal Variation

A. via IS-4

1) Two transponders: To cover a wide area, multiple transponders are typically used in a communication satellite. Such configuration is shared in the intercontinental TWSTFT networks and causes an asymmetry in the signal paths between paired earth stations. It seems that this asymmetry causes an instability with diurnal pattern. The Asia-Europe TWSTFT network was established using two transponders on IS-4 as shown in Fig. 1 (a). Different uplink and downlink frequencies were assigned for Asia and Europe. From the beginning of the NICT-PTB link diurnal variations have been observed. The possible instability sources, as listed in Table II, have been discussed previously [10], [11]. The delays due to ionosphere, troposphere and the Sagnac effects were evaluated. Since their amplitude and phases were not synchronized with the observed instabilities, it was concluded that they were not the main sources of the instabilities. Fig. 4 shows the clock comparisons with H-masers at PTB (a) and OP (b) which are presented

in the form of the difference between raw data and moving-average data for 1 day to emphasize the diurnal pattern. Unfortunately some outliers are seen in the data with NIM and TL. It is apparent that the amplitudes, periods and their peak locations are almost the same and they look independent of the site. It is know that the instability due to the instrumental delay is highly related to the local temperature variation [13], [14], [15]. We thus computed the correlation factors between the outdoor temperatures and diurnal variations plotted in Fig. 4 (a). As shown in Fig. 5, the correlation was not larger than 0.2, and no systematic relation is visible. Consequently the diurnal patterns may be caused by a site-independent source, that is, the path asymmetry due to the transponder configuration, rather than being related with the instrument delays in each station.

Geostationary satellites orbit with a period of 23 hours 56 minutes 4 seconds together with the earth with respect to the stars. On the other hand, it takes 24 hours to return to the same position relative to the sun. If the diurnal instability would correspond to the former period, the phase of the variations would be shifted by 180° after half a year. The diurnal instabilities from MJD 54951 to MJD 54957, and from MJD 55131 to MJD 55137 on the TL-PTB link are shown in Fig. 6. The phase of the instability did not change, only the amplitudes slightly changed. One can conclude from this result that the period is likely determined from the relation between the sun and the satellite.

The NICT-PTB link was operational using IS-4 for about four years. The diurnal variations have been observed since the beginning of the link. We computed MDEV for each month and checked the amplitudes and found no seasonal variation of the diurnal peak. The mean value of MDEV was 2.0×10^{-14} at an averaging time of half a day, which corresponds to the diurnal amplitude in phase of 860 ps.

So far it was reported in [8] that a time step was observed in a transatlantic TWSTFT link with two-transponder configuration and it is thought that the step was induced by the delay variation on the transponder. Fig. 4 may be an example that the path asymmetry due to the transponder configuration induced the diurnal instabilities.

TABLE II
POSSIBLE INSTABILITY SOURCES.

Instability source	Amplitude [ps]	Site dependency
Instrument delay	~ 500	Yes
Ionosphere	~ 150	Yes
Troposphere	< 4	Yes
Sagnac effect	$50 \sim 650$	Yes
Transponder instability	~ 1000*	No

*This work: estimated to be slightly below 1 ns for Asia-Eu link via IS-4.

2) One transponder: To compare the link performances in the cases of two transponders and one transponder, respectively, inner-Asian time transfer using only one transponder on IS-4 was performed between NICT and KRISS from MJD 53975 and MJD 53982. Both laboratories were connected by another TWSTFT link using JCSAT-1B satellite at that time, which consisted also of a one-transponder configuration like Fig. 1 (b). Fig. 7 (a) shows the time-transfer results by the IS-4 and JCSAT-1B links established using one transponder. Both measurements were performed synchronously and the data were taken every second. The results were averaged for 5 minutes and convenient time offsets were inserted for better visibility in Fig. 7. The green line shows the double difference between them. Its standard deviation around the mean is 135 ps, which proves that the results obtained in both links agree well. Fig. 7 (b) shows their frequency stabilities. The short-term instabilities were lower than those in Fig. 2. Especially any bump cannot be seen in the double difference plot. If a site-dependent instability would exist, it is almost canceled by the subtraction of the results by the different links because of the synchronous measurement. On the other hand, since a site-independent instability is not canceled by the subtraction, the result indicates that such instability seems non-existent or at least negligible. The instability of 3×10^{-15} at half a day corresponds to a diurnal amplitude of 130 ps. This amplitude is much lower than that of about 900 ps shown in the links established by the two-transponder configuration. Thus the link performances showed clear difference between the one- and two-transponder configurations.

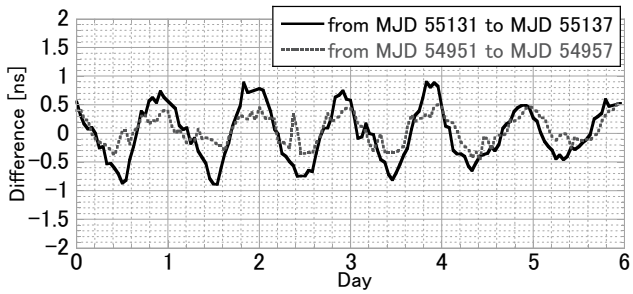

Fig. 6. Diurnal instabilities in the TL-PTB link.

B. via AM-2

The 1-hour averaged time differences and their frequency stabilities between TL and PTB by TWSTFT link via AM-2, GPS PPP and GPS P3AV are shown in Fig. 8. The results by the three methods look consistent. A bump around an averaging time of 40 hours exists in the TWSTFT instability whose reason is unresolved yet. The long-term agreement between TWSTFT and GPS data should be monitored carefully. Since any diurnal instability cannot be seen in GPS PPP and P3AV, the result by the AM-2 link was compared with them. Fig. 9 shows the double differences. Any clear functional variation was not observed. The instability obtained by TWSTFT at the averaging times longer than 2 hours reached the mid-10^{-15} level. It seems that such large diurnal instability as previously observed in the IS-4 link with the two-transponder configuration does not exist.

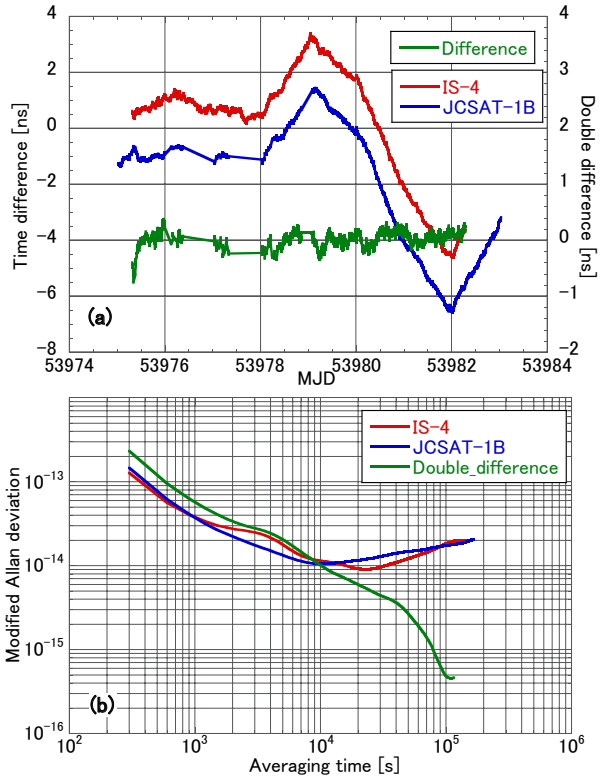

Fig. 7. (a) Time transfer results of NICT-KRISS by the IS-4 and JCSAT-1B links and (b) their frequency stabilities.

V. Conclusion

The Asia-Eu link was established using two transponders of IS-4 and restarted using one transponder of AM-2 after IS-4's malfunction. The diurnal phase variations have been observed since the beginning of the IS-4 link and possible error sources have been discussed so far. Thanks to the participation of the second European station, OP, it became clear that the diurnal instabilities looked site-independent. From the comparison of the one- and two-transponder configurations, such instability seemed existent only in the case when two transponders were involved. The current Asia-Eu link continues by one-transponder configuration on AM-2. Additionally any diurnal variation has not been seen there. It is thought that the on-board path asymmetry caused by two transponders induced such site-independent diurnal variation.

Acknowledgment

The authors would like to thank M. Rost, J. Becker and E. Staliuniene from PTB, and M. Aida from NICT, for their support to keep the regular measurements going.

Slave to Master Clock Synchronization via TCP/IP for Time Distribution and Remote Calibration Applications

Laurent-Guy Bernier, André Stefanov

Time & Frequency Laboratory, METAS Federal Office of Metrology, Lindenweg 50, 3000 Bern-Wabern, Switzerland

***Abstract*—The goal is to distribute UTC(CH) in a remote location via TCP/IP. The MC (Master Clock) is locked to UTC(CH) via a combination of IRIG-B and 1-PPS signals. The SC (Slave Clock) is controlled by a PI control loop that tracks the MC. The SC-MC clock offset and the transmission delay are estimated simultaneously by means of a TW (Two-Way) comparison process similar to NTP but based on TCP/IP.**

I. Introduction

We seek to control a Slave Clock (SC) located in a remote location in order to track a Master Clock (MC) located at METAS. Clock comparison is performed via TCP/IP by means of the classical Two Way (TW) remote comparison technique. Every second, the TW processing yields a measurement of the TCP/IP transmission delay between the MC and the SC and a measurement of the SC-MC clock offset. A PI (Proportional Integral) control loop steers the slave clock by minimizing the low-pass filtered clock offset. The goal here is to use the network in order to synchronize a remote calibrated time reference. This is different from other works such as [2] that use an independent remote calibrated time reference in order to calibrate network controlled time sources such as NTP (Network Time Protocol) servers.

There is an optimum time constant which yields a minimal rms error when applied to the control loop. The better the stability of the oscillator used in the SC, the smaller the time synchronization error for a given amount of transmission delay noise. A typical NTP server steers the local system time generated from the PC microprocessor quartz oscillator, while the MC-SC system reported in this paper steers a hardware clock based on a high quality OCXO (Oven Controlled Quartz Oscillator).

The main limitation of such a MC-SC system is that the estimated clock offset is biased by the lack of symmetry of the send and receive TCP/IP transmission delays. Hence when the control loop steers the SC to minimize the low-pass filtered clock offset signal, the mean value of the resulting true clock offset is a constant different from zero that depends on the degree of asymmetry of the transmission delay.

The reason why we avoid using NTP is a need for flexibility regarding the network security rules. NTP is based on UDP/IP and other protocols that cannot be changed while we want to use TCP/IP and if required some encrypted point to point data link protocol in a taylor made software that complies with the specific network security requirements of the client.

This paper reports the laboratory experiments that we have performed in order to evaluate the performance of such a SC/MC system based on TCP/IP TW measurements. In a laboratory experiment the SC and MC are located in the same room, therefore it is possible to measure the true SC-MC clock offset by means of a time interval counter. In the real application, on the other hand, the performance of the SC control loop can only be estimated by analysis of the TW measurement results and of the the error signal.

II. Experimental Setup

The hardware is identical for the MC and for the SC. The hardware consists of a PC with a Spectracom TSYNC PCIe clock (PCI Express card). The clock is based on a 10-MHz OCXO.

The TSYNC PCIe clock is capable to synchronize automatically to a combination of time code and 1-PPS signal. The time code is used to determine the epoch and the 1-PPS signal is used to synchronize the OCXO as illustrated on Figure 1. This is what we do in the MC system in order to copy UTC(CH). The MC reproduces UTC(CH) with a 1 μs accuracy and generates an IRIG-B time code epoch, a 1-PPS clock signal and a 10-MHz frequency signal.

In the SC system, the OCXO frequency is steered digitally by software. The SC interrogates the MC via TCP/IP and controls itself by means of the PI error signal in order to track the MC as well as possible. The SC, like the MC, generates an IRIG-B time code epoch, a 1-PPS clock signal and a 10-MHz frequency signal.

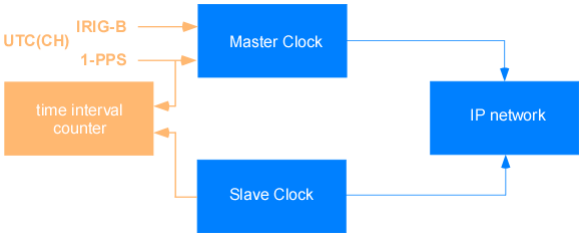

Figure 1. Experimental Setup

III. Two-Way Comparison Technique

The two-way comparison technique is similar to NTP [1]. The TCP/IP telegram exchanged between the SC and the MC

contains four binary time stamps.

The time stamps are defined in Table I. The TW measurements are generated as follows,

$$\theta = \frac{(T_2 - T_1) - (T_4 - T_3)}{2} \tag{1}$$

$$\delta = (T_4 - T_1) - (T_3 - T_2) \tag{2}$$

where θ is the estimated MC-SC clock offset and δ is the estimated TW transmission delay. Worst case clock offset error is half the TW delay (i.e. estimated one-way delay)

$$|\theta_{true} - \theta| < \frac{\delta}{2} \tag{3}$$

Note that, according to definition (1), the SC clock offset versus the MC, noted SC-MC, is given by $-\theta$. This is the sign convention used by Mills in [1].

Table I
DEFINITION OF TIME STAMPS T_1 TO T_4

Symbol	*Time Stamp Description*
T_1	Issued by SC when sending telegram to MC
T_2	Issued by MC when receiving telegram from SC
T_3	Issued by MC when sending telegram back to SC
T_4	Issued by SC when receiving telegram from MC

IV. THEORETICAL EXPECTATIONS

The Allan deviation of the OCXO is better than 1×10^{-10} and the Allan deviation of the TCP/IP delay is 1×10^{-9} for an averaging interval τ of $100ks$ (i.e. about one day) as shown on Figure 2. This means that with a control loop time constant as large as $T = 100ks$, the free OCXO is still more stable than the averaged noise of the TCP/IP half-TW delay. The time deviation of the measured TCP/IP delay is shown on Figure 3. The time deviation actually improves when the averaging interval is increased from $1s$ to $100ks$ but not that much because of the chaotic and non-stationary behaviour of the TCP/IP network. The theoretical expectation for the time stability of the SC-MC offset is about $20\mu s$ for a closed loop time constant of $T = 100ks$. Figure 4 shows a typical recording of the half-TW delay measurements. The chaotic nature of the TCP/IP transmission is visible. Figure 5 shows a typical histogram of the half-TW delay measurements. The histogram is multi-modal (in this example, mean $1.6ms$, standard deviation $74\mu s$). The average transmission delay of the TCP/IP packets across a switch depends on the number of clients connected to the switch and for a given network configuration, the mean value and the standard deviation of the delay between the MC and the SC are stationary. However the configuration of the network changes all the time as TCP/IP sessions are opened and closed by other clients. Hence the non-stationary behaviour of the delay.

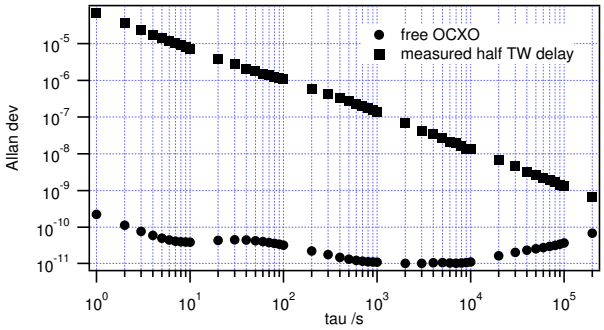

Figure 2. Allan Deviation of Free OCXO and of Half-TW Delay

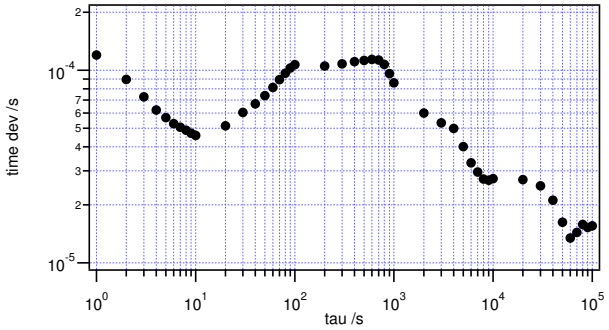

Figure 3. Time Deviation of Half-TW Delay

V. SECOND ORDER CONTROL LOOP

The control loop is similar to a PLL except that the control variable is time instead of phase. The control loop can be modelled as a linear feedback control circuit as illustrated on Figure 6. The DAC (Digital to Analog Converter) varactor frequency control of the SC is used to steer the OCXO. Since the control variable is time $x(t)$ and the error signal fed to the DAC is frequency $y(t)$, we have to model the DAC varactor control as an integrator. In order to have a zero time error in steady state, the loop filter $F(p)$ must include an integrator. Hence there are two integrators in series and the feedback control loop is potentially unstable. This is why we use a PI filter (i.e. the sum of a proportional gain and an integrator) as the loop filter $F(p)$. In closed loop the transfer function is of

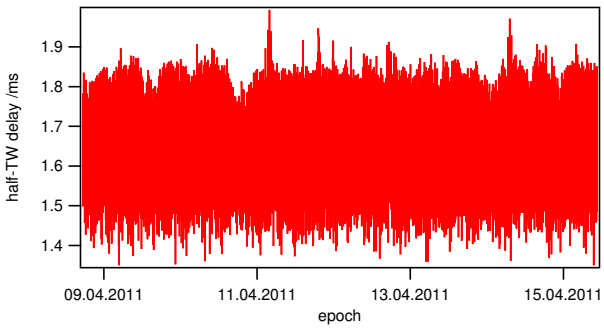

Figure 4. Typical Half-TW Delay Recording

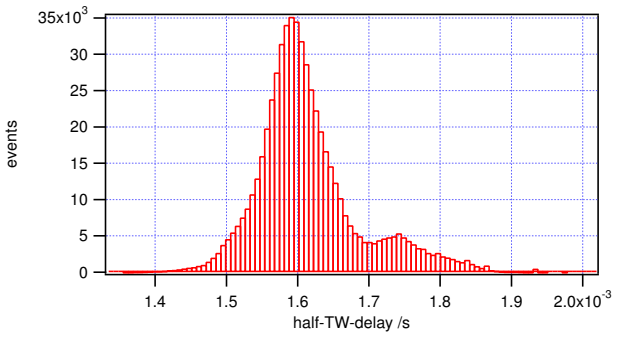

Figure 5. Histogram of Typical Half-TW Delay

the second order type and the two degrees of freedom given by the PI filter enable to set the time constant T as desired while keeping the damping at the critical value.

Calibration of the DAC frequency control of the OCXO yields a maximum rate of $\pm 1 \mu s/s$ (1 ppm) for a normalized maximum error signal of ±1 (DAC is actually16 bit). Figure 7 shows the initial transient when the control loop is started with a time constant of $1ks$. In this example the initial clock offset is $5000\mu s$. Initially the error signal is very large and the control loop works in non linear mode, i.e. the error signal is clipped to the 1 ppm maximum frequency offset of the OCXO which yields a slope of $1\mu s/s$. When the clock offset approaches zero, i.e. after 5000 s, the control loop starts to work in linear mode. Since the control loop parameters are adjusted for critical damping, there is a clean single overshoot, without any ringing visible in the transient.

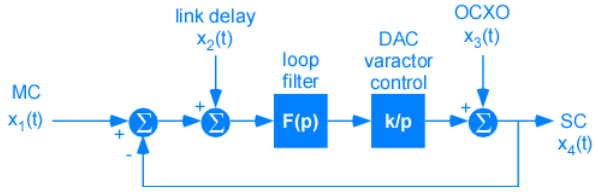

Figure 6. Schematics of PLL control loop

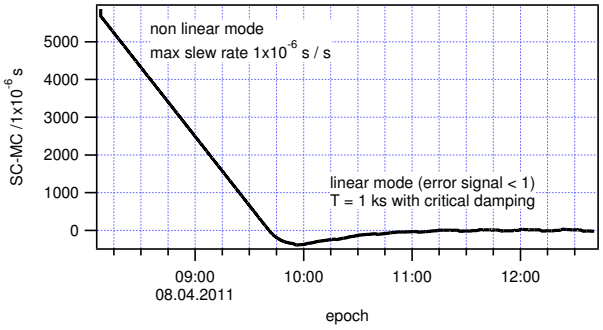

Figure 7. Initial Transient when Starting with Large Offset SC-MC

VI. Adaptative Control Algorithm

The advantage of a very long $T = 100ks$ control loop time constant is a very good noise filtering, but the disadvantage is the duration of transients: several days. An adaptative algorithm sets the SC epoch to the nearest second, when initialised, and then steers the SC frequency, switching between three discrete values of the time constant $T = 1ks$, $10ks$ or $100ks$ depending upon the value of the low-pass filtered SC-MC offset. Of course the goal is to minimize the duration of the transients. The loop is initialized with $T = 1ks$ and the time constant is progressively increased up to $T = 100ks$ in three steps as the low-pass filtered clock offset goes down. In the algorithm, a set of progammable criteria is used to decide when the time constant must be switched up or down.

VII. Estimation of the SC-MC Clock Offset

The measurement of the true SC-MC clock offset by means of a time interval counter is possible only in a lab experiment. In a real application the SC is operated in a remote location and only the TW data is available to the user. The best way to estimate the SC behaviour is by analysis of the error signal. Integrating the error signal using the calibrated DAC sensitivity gives a very good picture of the actual SC-MC time behaviour. Figure 8 shows an example of the true SC-MC clock offset versus the integrated error signal. We observe that the integrated error signal is a perfect image of the true SC-MC clock offset, except for the average value which cannot be determined by integration. By principle, again, it is not possible to deduce the true mean value of the SC-MC offset from the TW data because the asymmetry of the TCP/IP transmission delay is not an observable.

Figure 9 shows how the error signal changes when the control time constant is switched from $1ks$ to $10ks$ after the initial transient. When the time constant is increased by a factor of 10, the noise bandwidth is reduced proportionally. Therefore the rms value of the noise is suddenly reduced by a factor of 10.

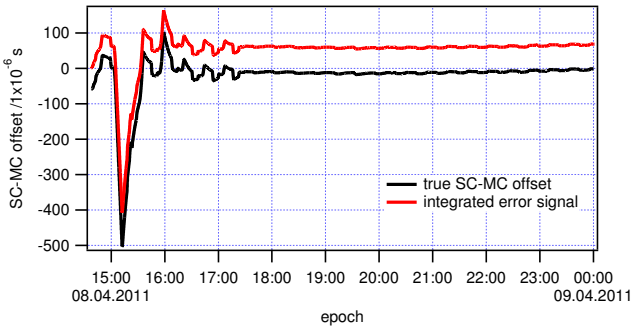

Figure 8. Example of True SC-MC Clock Offset vs Integrated Error Signal

VIII. Experimental Results

The results reported above in Sections IV-VII were taken from a simple single switch experiment, i.e. the MC and SC are located in the same room and connected to the same

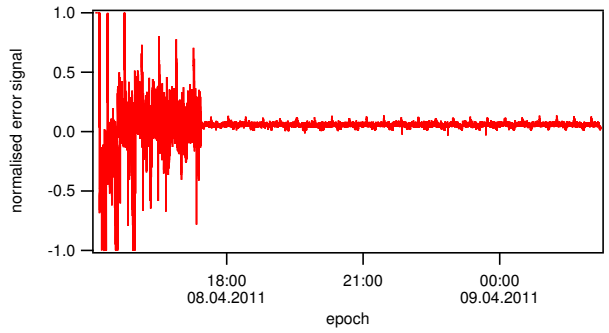

Figure 9. Example of Error Signal when Time Constant is Switched from 1 ks to 10 ks

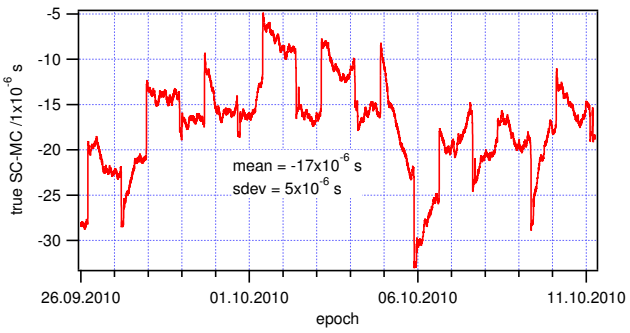

Figure 10. True SC-MC Clock Offset during Relay Experiment

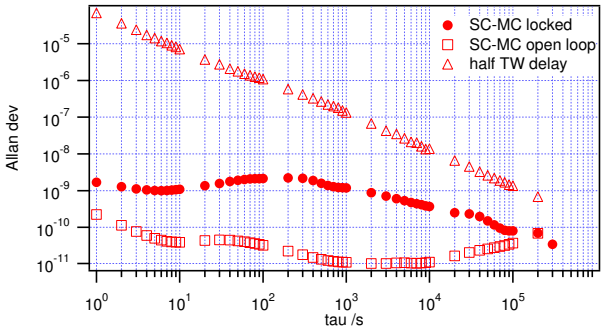

Figure 11. Allan Deviation of SC-MC Clock Offset: Locked vs Open Loop

Ethernet LAN switch. On the other hand the results of Section VIII are taken from a *relay* experiment which is more realistic regarding the everyday life TCP/IP network conditions. In the relay experiment the SC and MC computers are still connected to the same switch. However they do not communicate directly with each other. A third computer, located in another part of the METAS building, is used as a relay, receiving and forwarding all the TCP/IP packets exchanged between the SC and the MC. In the relay experiment several switches and routers are involved as well as the processing delays taking place inside the relay computer.

Figure 10 shows a 15 day recording of the true SC-MC offset as measured in steady state during the relay experiment. The peak-to-peak variation of the true offset over 15 days is only $25\mu s$. The SC-MC offset data shown yields a standard deviation of $5\mu s$ and a mean value of $-17\mu s$. Figure 10 shows three cases of the Allan deviation. Curve one is the SC-MC clock offset with the SC *locked* to the MC. Curve two is the SC-MC clock offset with the SC control *open loop*, i.e. with the OCXO free running. Curve three is the half-TW TCP/IP transmission delay. The linear feedback control loop actually filters out a large part of the TCP/IP delay noise but not all of it. If the delay noise were not filtered at all, then the *locked* SC-MC Allan deviation would be identical to the Allan deviation of the TCP/IP delay noise. On the other hand, if the delay noise were removed completely, then the *locked* SC-MC Allan deviation would be identical to the Allan deviation of the free running OCXO. As expected the *locked* SC-MC Allan deviation is to be found somewhere between these two limit cases. It can be observed that, in terms of Allan deviation, the noise suppression at 1s averaging time is 5 orders of magnitude.

IX. Conclusions

The performance of the prototype SC-MC system reported here, true SC-MC average offset $< 20\mu s$, is more than sufficient for the application we have in mind. Actually we intend to operate a similar SC-MC system with the MC located at METAS in the time & frequency lab and with the SC located at the BIT, the Swiss federal administration IT center. By means of the SC, UTC(CH) will become available to the BIT stratum 1 NTP servers together with other redundant sources of UTC.

Vilnius", Lithuania

***Abstract*—Recent developments in mobile telecommunication networks offer a possibility for synchronization of mobile equipment. The possibility is explored here. To this end, a network operator is synchronized to the Lithuanian national time and frequency standard over internet via NTP (Network Time Protocol). A mobile testing system (MTS) created is synchronized to the operator's network via a radio modem operating in one of the several different modes. The time scale of the MTS synchronized over the mobile telecommunication network is compared to that of the national standard to evaluate the synchronization accuracy and to find out that the most suitable operating mode for the modem is CSD (Circuit Switched Data), which is likely due to its dedicated and symmetrical nature.**

I. INTRODUCTION

Implementation of new services and technologies in mobile telecommunication networks requires more precise timing and synchronization of the network systems as well as user's equipment. Correct timing may be very important for different M2M (Machine To Machine) applications, such as metering (measuring parameters of telecommunication channels), fleet management, mobile commerce, and public key infrastructure (PKI) applications, such as e-health, e-government, e-signature, etc. Some results on time synchronization over the second generation network GSM (Global Standard for Mobile Communications), via the GPRS (General Packet Radio Services) and EDGE (Enhanced Data rates for GSM) channels, are presented in the works [1, 2]. However, the two aspects are not considered – timing over dedicated low bit second generation networks via the CSD (Circuit Switched Data) channel and timing over the third generation network UMTS (Universal Mobile Telecommunications System) via the HSDPA (High-Speed Downlink Packet Access) channel. Networks of the third generation are very popular now. Nevertheless, channels of the third generation networks exhibit propagation characteristics very different from those of the second generation networks, such as GSM. The purpose of our work is a comparative testing of timing and synchronization characteristics of mobile GSM network via the CSD, GPRS, EDGE channels as well as over the UMTS (Release 99) network via the HSDPA channel. Propagation characteristics of different channels have been evaluated by using standard telecommunications testing equipment. Timing characteristics have been evaluated by using the data of NTP communications created during the synchronization of the mobile testing system (MTS) to the NTP servers of the Lithuanian National Time and Frequency Standard Laboratory.

II. TESTING TECHNIQUE

Timing characteristics of mobile telecommunication networks were evaluated by using NTP communications data created during the mobile testing system (MTS) synchronization with NTP servers of Lithuanian National Timing Laboratory (LT). The mobile testing system (MTS) developed consists of Radio modem, Computer (PC) running on LINUX UBUNTU server v.10.10 operating system and second pulses generator (Rb) (Fig. 1). The PC running the Linux Ubuntu Server 10.10 operating system, with operating LinuxPPS Kernel Module (PPS API (Pulse Per Second Application Programming Interface) implemented under RFC 2783) and ntpd (ntp_v4.2.6p3@1.2290 package) program installed, has been connected to the mobile communication network via the "Siemens MC35i" and "Nokia N95 8GB" modems.

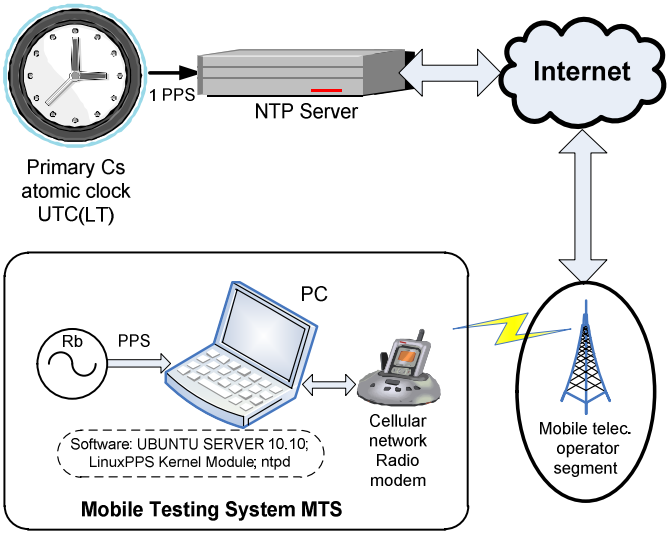

Figure 1. Device setup for investigation of time transfer via the mobile communication network

Such a setup is makes up a complete MTS version ready for measurements. The “Siemens MC35i” has been connected to the computer via the RS232 port and operated in the GSM-CSD and GSM-GPRS regimes. The “Nokia N95 8GB” has been connected to the PC via the USB interface and used to explore the time synchronization possibilities for the EDGE, UMTS, and HSDPA technologies.To estimate the possibilities for time synchronization in a mobile communication network, non-standardized measuring equipment has been used. Therefore, before making any measurements, it was necessary to explore its metrological characteristics. Fig. 2 reveals how the devices have been connected for MTS calibration. The calibration setup includes a primary Cs atomic clock HP5071A reproducing and keeping the UTC(LT) time scale and a “Symmetricom S250“ NTP server. The second pulses from the Rb generator, which during the calibration procedure was synchronized to UTC(LT) with a few nanosecond accuracy, are fed into the RS-232 port of PC. The LinuxPPS Kernel Module, having received a second pulse at the RS-232 port, forms a very accurate time mark, which is possible due to the fact that time marks are formed at the level of the system kernel. PC‘s clock has been synchronized every 16 seconds, using the ntpd daemon operating under the NTP protocol; it has received the time marks at the local (with the propagation time of less than 1 ms) network from the NTP server, which time scale is synchronized with UTC(LT) (Universal Time Coordinated realized by Lithuanian National Time Standard Laboratory) with the accuracy better than ±1 µs.

One can see from Fig. 3 that while synchronizing the computer clock in the local network yields a constant deviation of about 51 µs. It could be influenced by either the LinuxPPS module or the ntpd together with asymmetry of the local area network (LAN). Fig. 4 reveals the stability characteristics of the MTS system clock. From Fig. 4, one can see that at time intervals up to 40 s white phase noise of the LinuxPPS system prevails, while at longer intervals the noise character becomes different. The difference is caused by the fact that although the ntpd daemon is synchronized to the NTP server every 16 seconds, the corrections to the MTS‘ system clock frequency feedback loop are sent upon necessity only,

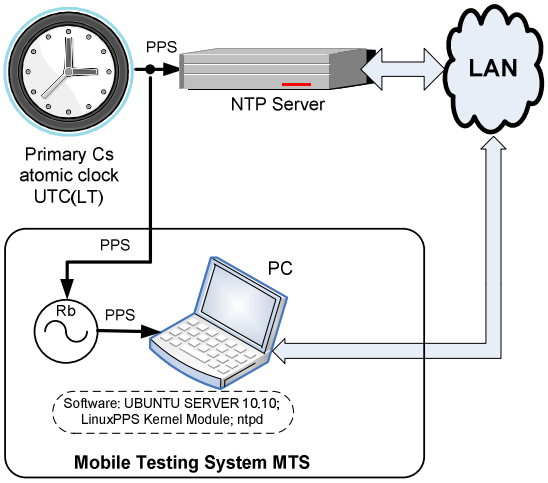

Figure 2. Schematic layout of MTC calibration

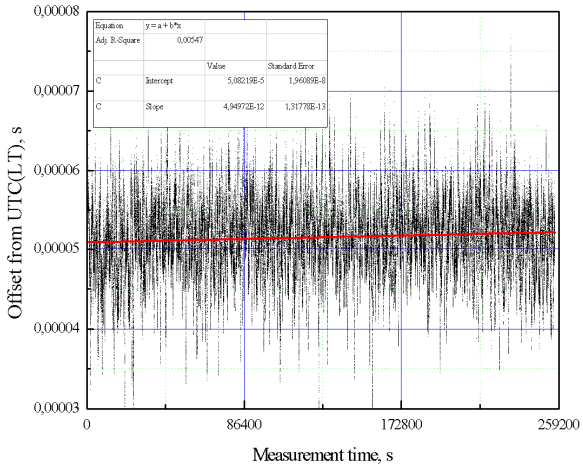

Figure 3. Sattering of the LinuxPPS – formed time marks, while synchronizing the computer clock by the NTP protocol to the server operating in the local network

and, in the most cases, it takes place every 100 s. Starting with intervals of about 1000 s, the white phase noise of the system becomes prevalent. Ntpd program has its algorithms, which automatically adjust the synchronization interval, which enables to improve the stability characteristics at short intervals (100...1000 seconds) and to decrease significantly the number of synchronization events, however, this doesn‘t improve the stability of the clock rate essentially (Fig. 5).

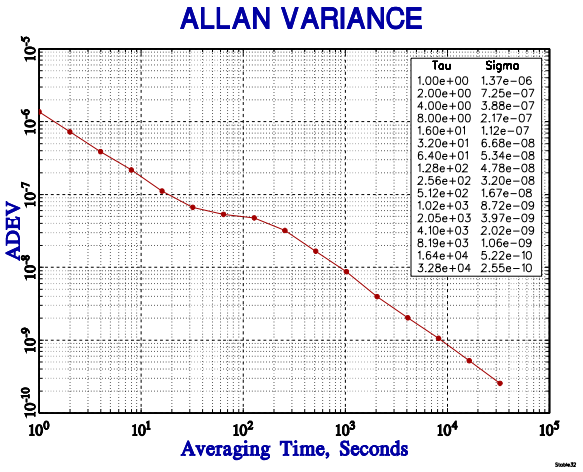

Figure 4. Stability characteristics of the MTS system clock, while synchronization takes place every 16 seconds by the NTP protocol in the local network

From the measurements carried out, one can conclude that MTS has a constant error not worse than 51 µs, while the uncertainty in phase measurement at the intervals starting with 1 s is better than ±1 µs.

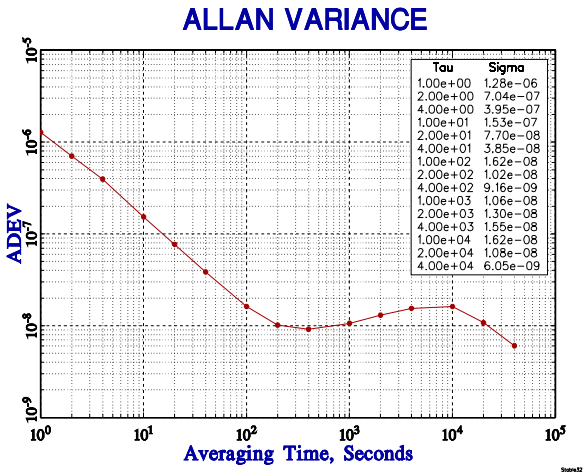

Figure 5. The stability characteristics of the system clock of MTS in the case when the decision concerning the necessity of synchronization is adopted by the ntpd program, and synchronization takes place in the local network by the NTP protocol

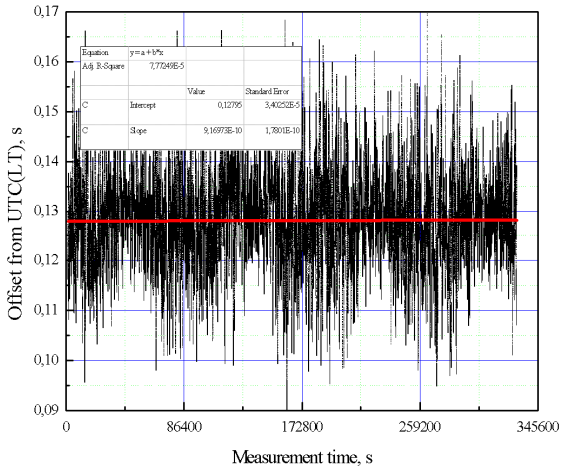

Figure 6. Scattering of the LinuxPPS–formed time marks, while synchronizing the computer clock to the time server by the NTP protocol, by means of the GPRS technology

III. RESULTS

Further, we will review only the results obtained while operating the MTS in the same base station (cell). Statistically, switching to another station is rare, however, such a switching usually causes the packet delay of about 3-5 s due to cell reselection procedure Sometimes, switching is even longer due to few cells reselection in raw. Yet, the investigation of such phenomena requires separate experimental measurements. We don't account for such phenomena here. In order to minimize cell reselection procedures mobile terminal (MTS) was placed close to the base station to have dominant cell all experiment time.

At the beginning, consider the results of the synchronization of the MTS clock while the time scale is transmitted by means of the GPRS technology.

Fig. 6 implies that, despite ntpd's effort to synchronize the system clock by minimizing its deviation from UTC(LT), average deviation of the system clock is about 130 ms. The worst thing is that we cannot see this deviation in the ntpd log files as it is caused by the network asymmetry, which cannot be detected and compensated by the ntpd. Network asymmetry in GPRS is caused by GPRS data scheduling differences in uplink direction (UL) and downlink direction (DL) due to both different algorithms as described in [4] and different cell loads in UL and DL.

Synchronization of the system clock by means of the EDGE technology yields results very similar to those obtained in the GPRS case; network asymmetry is about 150 ms.

The Allan deviation for the clock synchronized every 16 seconds via the GPRS tract has a maximum at 100 seconds because, as mentioned before, the corrections to the frequency feedback loop of the MTS system clock are sent upon necessity only, and, in the most cases, it takes place every 100 seconds (see Fig. 7). The Allan deviation graph implies that it is possible to decrease the overall noise level by means of decreasing the number of synchronization events. In this case, the corrections to the MTS system clock would be sent at longer time intervals because the short-term (100 s, 1000 s)

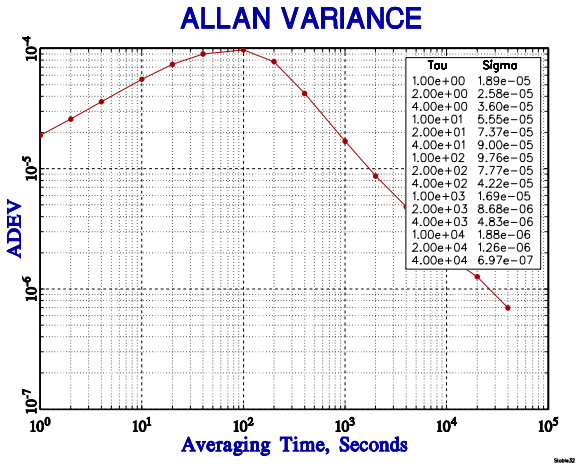

Figure 7. Stability characteristics of the MTS system clock, while synchronization takes place every 16 seconds by the NTP protocol, by means of the GPRS technology (ADEV – Allan Deviation [3])

stability of the clock is good enough. The experiments confirm the inference; Fig. 8 gives the system clock stability with synchronization every 1024 s as an example.

At the beginning of the graph of Fig. 8 (roughly for time intervals of up to 5 s), the measurement noise of the LinuxPPS part of the system is seen, whereas at longer intervals the PLL noise becomes dominant. At long intervals (10^2...10^4 s), its level decreases.

We can see that choosing the synchronization interval of about 1000 s allows obtaining rather good system clock stability. If the objective were to achieve the MTS system clock stability better than 4 µs for any averaging time, it would be reasonable to increase the synchronization interval even more, however, it is necessary to be careful at this point and to ensure that no other process can influence MTS system clock. It is possible to achieve in the laboratory conditions, however, it is more difficult to ensure when the computer works under heavy load.

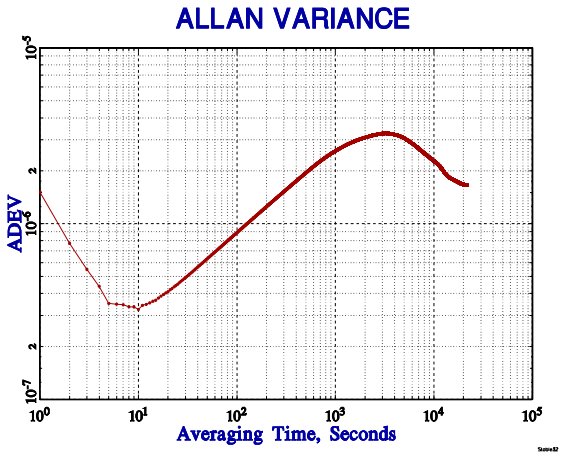

Figure 8. System clock stability with synchronization every 1024 s by the NTP protocol, by means of the GPRS technology

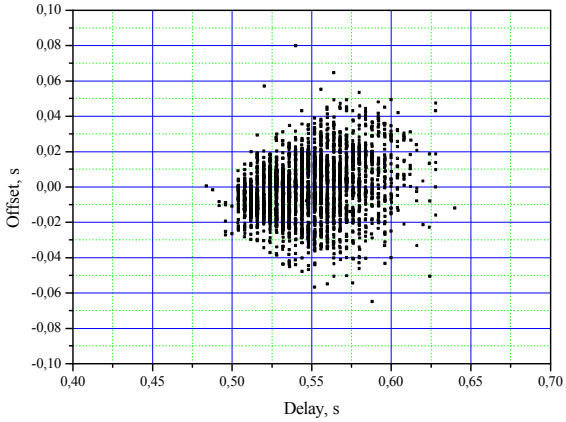

Figure 9. Delay vs.Offset characteristics of the MTS system clock, while synchronization takes place every 16 seconds by the NTP protocol, by means of the GPRS technology

Fig. 9 shows delay versus offset characteristics of the MTS system clock (generated from “peerstats” nptd log file), while synchronization takes place every 16 seconds by the NTP protocol, by means of the GPRS technology; it is seen that the discreteness in delay values is 4 ms. The EDGE technology yields similar results.

Experiments with the UMTS/HSDPA technologies reveal even larger asymmetry of about 230 ms. It is worth noting that this regime gives the worst results. Besides that, it isn‘t possible to evaluate the operation characteristics of UMTS and HSDPA separately. Depending on the network load, the mobile telecommunication operator automatically redirects the phones to use one or another technology. Statistically, in our case about 80% of measurements have been carried out under the UMTS, while the rest – under the HSDPA technology. HSDPA resources with different schedulers and different cell . Generally, the ratio can differ depending on the provider of the mobile communication. Reasons for asymmetry are mostly the same as those in the case of GPRS/EDGE – shared UMTS or loads in UL and DL directions are used for transmission.

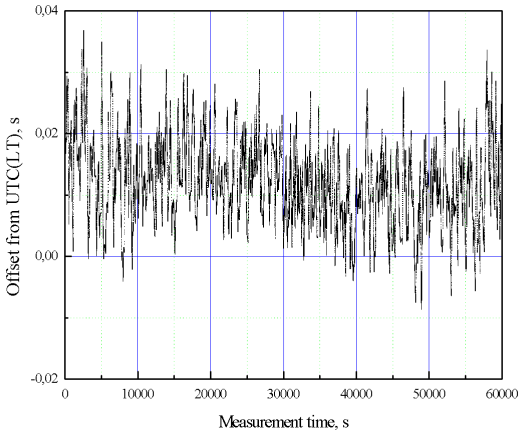

Figure 10. Scattering of the LinuxPPS–formed time marks, while synchronizing the computer clock to the time server by the NTP protocol, by means of the CSD technology

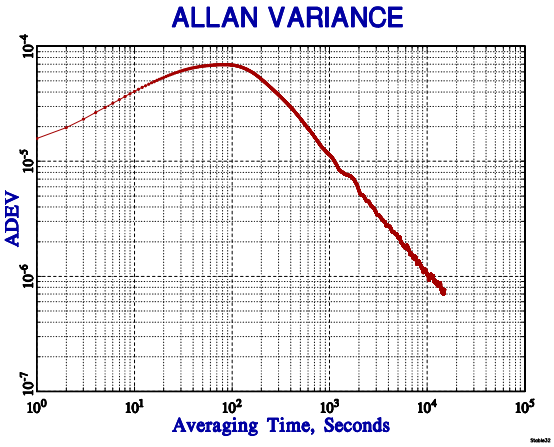

Figure 11. Stability characteristics of the MTS system clock, while synchronization takes place every 16 seconds by the NTP protocol, by means of the CSD technology

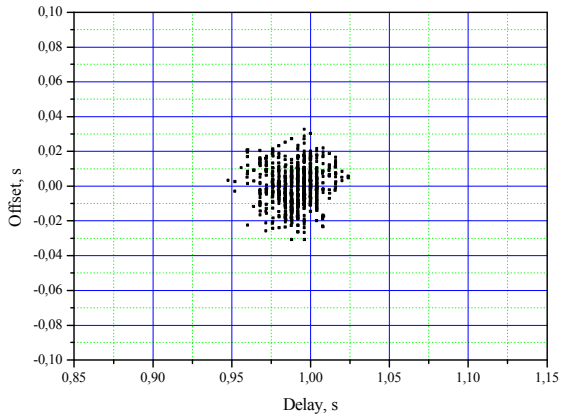

Figure 12. Delay vs.Offset characteristics of the MTS system clock, while synchronization takes place every 16 seconds by the NTP protocol, by means of the CSD technology

In addition, the GSM CSD channel with 9600 bps speed has been investigated. It works only within the GSM-type networks and has the largest possible delay of about 1 s due to bigger interleaving depth, however, asymmetry of the synchronization channel is only 10 ms. Measurement results are shown in Figs. 10 and 11, and can be explained taking into account that the CSD channel is a dedicated resource, therefore, the load doesn't influence channel delay as in the cases of GPRS/EDGE and UMTS R99/HSDPA. Also, the CSD channel processing in GSM is very similar in UL and DL directions, so propagation characteristics are almost the same in both directions.

Fig. 12 shows delay versus offset characteristics of the MTS system clock (generated from "peerstats" nptd log file), while synchronization takes place every 16 seconds by the NTP protocol, by means of the CSD technology.

IV. CONCLUSIONS

1. If the computer clock is synchronized via the mobile communication network by the NTP protocol, the network asymmetry is more important factor than the absolute delay time.
2. The delay time has no impact on the synchronization accuracy at all. While synchronizing by means of the CSD technology, the delay within the system is about 1000 ms, while within the HSDPA network it is about 80 ms, however, the asymmetry within the CSD network is almost 20 times less, whereas the stability of the clock rate synchronizing CSD and HSDPA differ insignificantly. The client doesn't see network asymmetry and can suppose that his clock behaves exactly as it shall do.
3. The stability of the clock rate while synchronizing the computer clock by the NTP protocol via a radio modem little depends on the technology of the signal transmission over the radio channel; it depends to the largest extent on the duration of the synchronization interval.
4. The CSD regime is best suited for time synchronization. It features the smallest asymmetry out of all mobile internet technologies. Besides that, stability characteristics of the MTS system clock in the case the synchronization is carried out by the NTP protocol, by means of the CSD technology, aren't worse than those obtained using other technologies.
5. The GPRS and EDGE technologies are very similar with respect to asymmetry and noise.
6. UMTS and HSDPA feature the worst parameters – the largest asymmetry and noise (although the delays are the smallest out of all the technologies).

Examination of Time and Frequency Control Across Wide Area Networks Using IEEE-1588v2 Unicast Transmissions

***Abstract* - The IEEE 1588-2008 Precision Time Protocol (PTP) version 2 (IEEE 1588v2) can be used to synchronize a slave clock to a grandmaster clock over a wide area network (WAN). However, many of the algorithms the slaves use to steer to the master are optimized for a scenario where both devices are on the same subnet or local area network (LAN). This paper is a study of existing PTP hardware from a number of different manufacturers in unicast mode. We characterize the performance of the equipment, beginning with the timing outputs of the masters that are locked to their built-in Global Positioning System (GPS) receivers. Next, we compare the results of steering unicast clients to their masters through a LAN versus several wider-area network configurations such as virtual-LANs and the public Internet. Analysis of the results will show how clients of different manufacture handle the various network paths. It is our hope that these comparisons will instigate changes to clock steering and synchronization algorithms, which may help improve the overall capabilities of PTP for telecom and other networking environments. As network synchronization techniques improve, the quality of the PTP masters will become more significant. Therefore, the performance and calibration of PTP masters with respect to UTC(NIST) is also discussed.**

I. Introduction

Network timing has become of great interest over the last decade, especially since the implementation of IEEE 1588-2008, where Precision Time Protocol (PTP) was defined to enable precise synchronization of clocks in measurement and control systems through packed based networks [1]. PTP uses a two-way timing method [2] to characterize the delays between two different points across a network. By repeatedly exchanging time-stamped messages between two devices (a master and a slave), the slave clock can be synchronized to, and will 'follow', the master as long as data are being exchanged. The client attempts to determine the delay of the packets through the network and adjusts the timing output to compensate. The use of 1588v2 in a multicast environment is limited primarily to local area networks (LANs) where the client devices (slaves) search the network for masters and begin to exchange time stamps. Network providers may or may not allow multicast on public networks, so the unicast method should be used outside of a LAN [3]. A unicast client can find a master outside the LAN if it has the IP address of the master to look for. We employ the unicast method because we are using the public network in some cases, and we also want to guarantee that we are using a designated PTP master.

The purpose of this paper is to compare the timing synchronization abilities of PTP hardware from several manufacturers in different real-world network settings to show the capabilities and weaknesses of these devices. We were not merely trying to determine which one is the 'best' or to advocate particular hardware. No brand names are used. Also, no boundary clocks or transparent clocks are implemented in the path, only *ordinary clocks* (master and slave) are used, and there is no use of simulations or network traffic generators.

In order to assess the output of a remotely steered client device, the master must first have a reference time source. Typically, the masters synchronize to signals from an internal Global Positioning System (GPS) receiver, a Network Time Protocol (NTP) server or a 1 pulse-per-second (pps) input. Ideally, we would synchronize the master to the NIST timescale, UTC(NIST), and measure the output of the slave compared to UTC(NIST). However, some of the master devices do not allow a 1 pps input as the reference and many facilities may not have an on-time 1 pps available. Therefore, we looked at comparisons using the GPS receiver built in to the master as the reference. Also, the internal receivers were allowed to survey their own positions, as opposed to entering known coordinates. Later in this paper, we will discuss the time offset and stability of the GPS reference inside each master unit and how we calibrated them with UTC(NIST).

II. Experiments

We set up a test bed for multiple PTP masters and clients, including GPS antennas on the roof, time interval counters and multiple network connections, including one outside the NIST firewall on the public network. Figure 1 shows the first measurement setup to compare the 1 pps outputs of the PTP masters to UTC(NIST) by use of a commercial time interval counter (TIC) with an external time base frequency input from UTC(NIST). The results of the measurements were recorded directly into files every second on a desktop computer with a serial connection to the TIC. We calibrated the masters for twenty-four hours and entered the average delays into the units to compensate for their offset from UTC(NIST) due to position errors, cable delays and hardware delays.

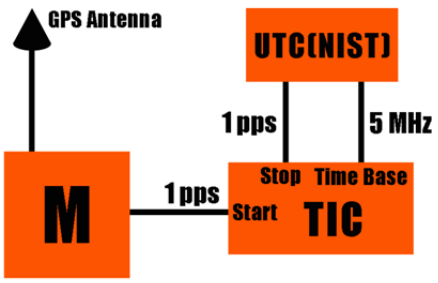

Figure 1. Comparing the PTP master (M) to UTC(NIST)

The PTP masters have internal GPS disciplined oscillators (GPSDOs) that can vary significantly from device to device [4]. Figure 2 shows a comparison of the 1 pps outputs of the four PTP masters, with peak-to-peak variations that range from 30 ns to greater than 110 ns.

Our goal was to compare multiple PTP clients over several different network scenarios, so we began with the simplest setup: a master and slave on the same subnet in the same room (Figure 3). Each client was configured to follow the master of the same manufacture, although subsequent experiments showed cross-operability. The devices were not connected together with a crossover cable but, instead, connected to the LAN via separate jacks in the wall.

The clients were configured to be in unicast mode, with a synchronization rate of 64 packets per second. Also, we allowed the clients ample time to steer to the PTP data before recording any measurements. Our interest was in how well they can do in a steady-state, as opposed to how quickly they can lock to the master. We compared the 1 pps output of each client to UTC(NIST). On the same subnet, the synchronization varied between the different PTP clients, as shown in Figure 4.

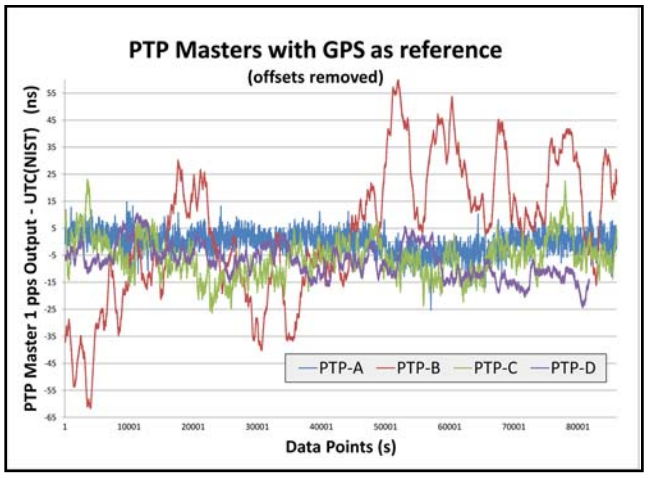

Figure 2. Comparisons of PTP masters to UTC(NIST)

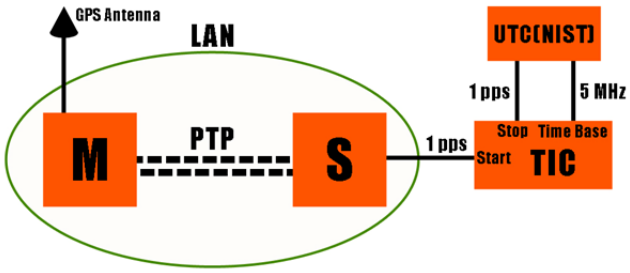

Figure 3. Measuring a slave (S) on the same subnet as the master (M)

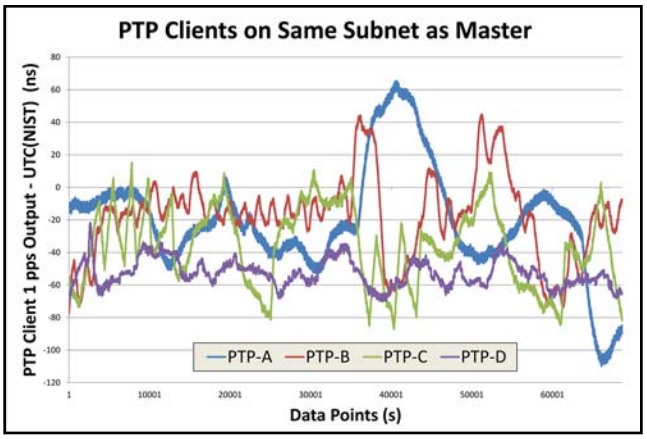

Figure 4. Comparisons of PTP clients on the same subnet

The average time offset for each client was less than 60 ns compared to its master, but the peak-to-peak variations ranged from 45 ns to over 170 ns. It is interesting that the PTP-A master had the tightest range, but the PTP-A client had the largest range. Figure 5 shows how closely each client followed its master. Different steering methods by manufacturers cover a wide range of possibilities for how closely a PTP client follows the master. Following too closely (PTP-B) causes worse stability in the network scenarios we measured, especially when, in this case, the master is the least stable. The PTP-C slave seems to over-react to changes in the master with high gain adjustments.

Next, we put the PTP masters on the public network outside the firewall at the NIST location in Boulder, Colorado, while the clients were still on the internal LAN (see Figure 6). The masters and clients were in the same building, but there were several network elements in between. These elements (referred to as "hops") can cause noise and asymmetries in the timing of the data exchange. In this case there were five hops between the devices.

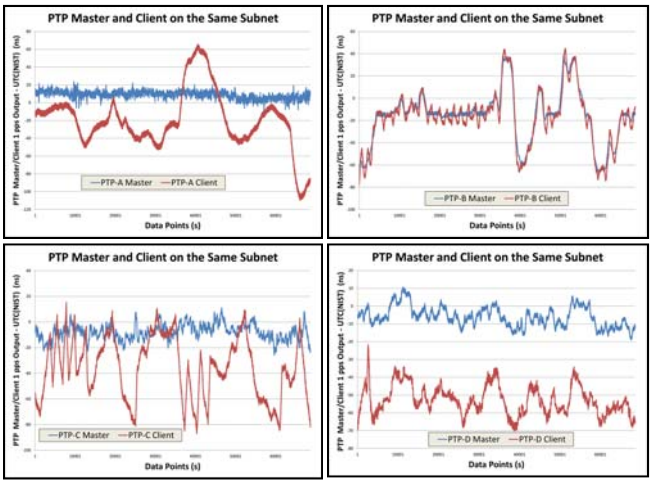

Figure 5. Graphs showing how well each client followed its master

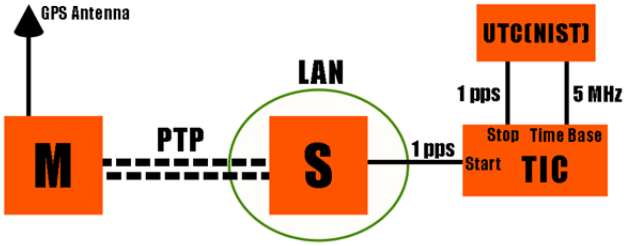

Figure 6. The master is outside the NIST local area network

The differences between the client devices with masters outside the local network are shown in Figure 7. The average time offset of PTP-D was 2.3 µs and the peak-to-peak variation was 4.2 µs. PTP-B had a similar average, but the stability was worse, varying by 9.4 µs. PTP-C had a large average time offset of 22.9 µs, but a good stability, with a peak-to-peak range of 2.0 µs. The timing stabilities are shown in the time deviation (TDEV) plot in Figure 8. The timing requirement for some telecommunication networks is one microsecond [5,6]. None of the devices meet this criterion of accuracy in this case. However, some of the devices remain below one microsecond in stability, so if the network path were calibrated and the delay amount were entered into the client device so its output was advanced by the delay amount, meeting the requirement may be possible. However, much longer data runs would be necessary to see how the network delays change over time. Also, a reference at the client site (like GPS) would be necessary in order to calibrate the PTP client output. We measured an NTP client with a server outside the local network as well. It had an average time offset of 55.4 µs, and $\sigma_x(\tau)$ is shown to be worse than one microsecond for τ >10,000 s (Figure 8). It should be noted that NTP has a considerably slower synchronization rate and a much different intended use than PTP.

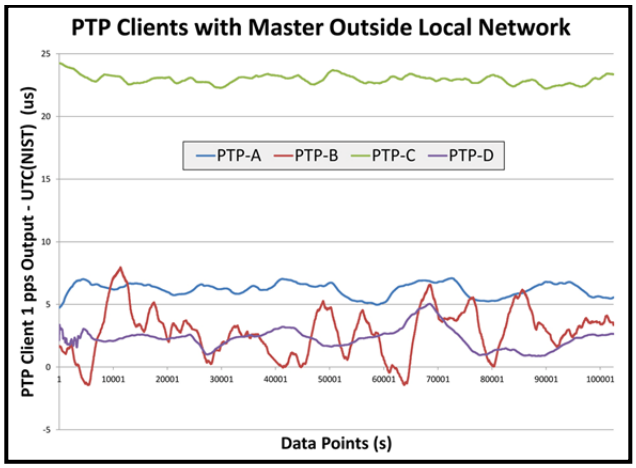

Figure 7. Performance of the clients with the master outside the LAN

The International Telecommunication Union (ITU) Option 2 (less stringent) requirement mask for a locked slave clock in telecommunication networks [7] is shown in Figure 8. The slaves did not stay under this mask for τ > 100 s (best case).

We were also able to compare some of the units at remote NIST sites. Radio stations WWV and WWVB broadcast time signals from a NIST site near Ft. Collins, Colorado, which is about 80 km (direct path) from the NIST location in Boulder. There is a dedicated T1 (1.544 Mbit/s) leased line between the two sites that is considered to be virtual LAN (VLAN) inside the NIST network. We set up the client devices at the remote site (Figure 9) and compared them to 1 pps signals from a backup UTC(NIST) generated at that site, which is typically within 30 ns of the official UTC(NIST) in Boulder. There were four network hops between the master and client in this setup.

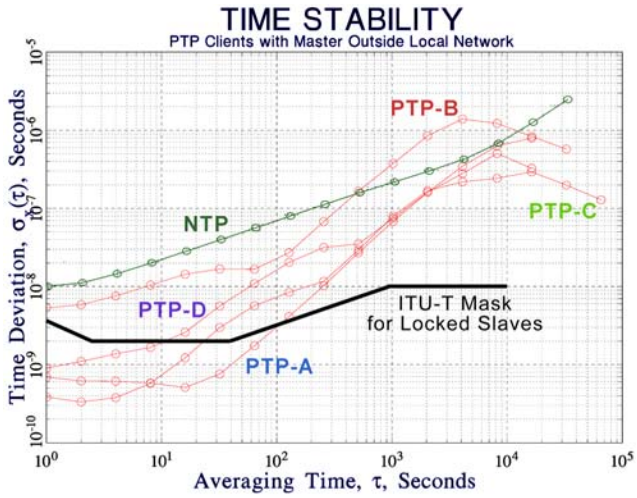

Figure 8. TDEV plot of the clients with the master outside the LAN

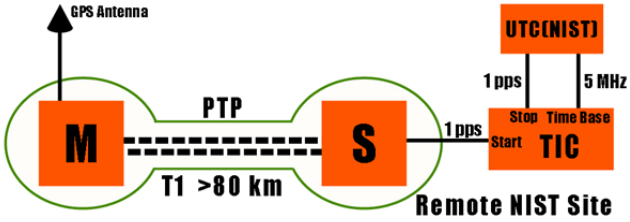

Figure 9. Remote PTP synchronization setup

PTP-A and PTP-D performed the best in this case (Figure 10), but each had an average time offset > 30 µs. PTP-D had the best peak-to-peak variation (< 1.4 µs). As before, if the network path were calibrated, and the outputs of the clients were adjusted to be centered around zero, this still may meet the needs of some applications, *assuming the characteristics of the network do not change*. The TDEV plot in Figure 11 shows the time stability of PTP-D (and maybe PTP-A) remaining below a microsecond, but none of the clients were within the ITU requirements for a locked slave [7] for τ > 250 s.

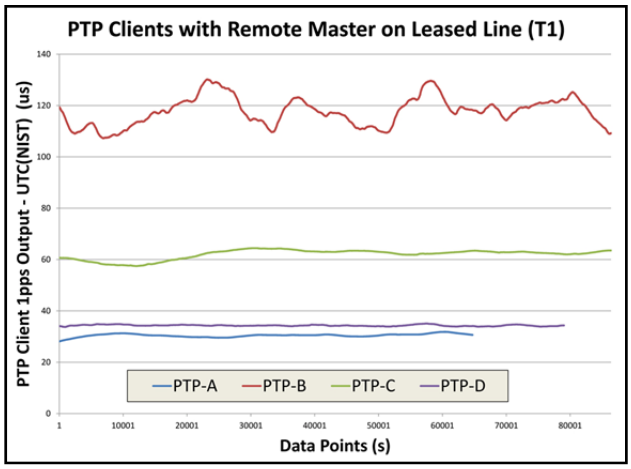

Figure 10. Performance of clients with remote master

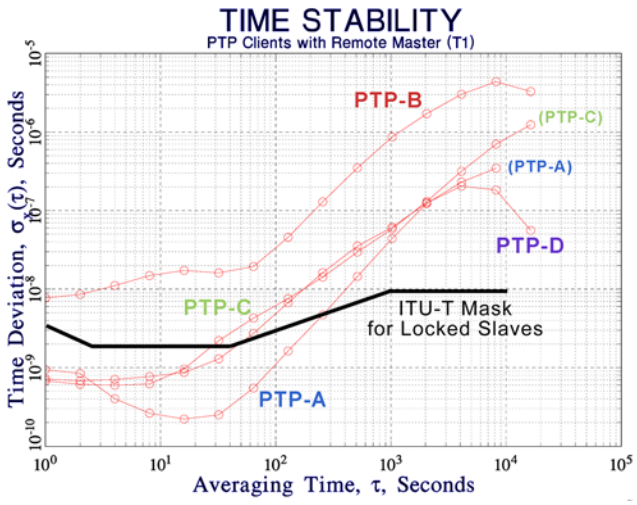

Figure 11. TDEV of clients with remote master

Next, we compared the clients when they were synchronized to the masters by use of the public Internet. The masters were at the NIST Boulder site on the public network, and the clients were at the NIST radio broadcast site, also on the public network (Figure 12). There were nine network hops between the sites.

PTP-D was the "best" with an average time offset of just under 10 ms (Figure 13) and a peak-to-peak variation of 56 µs. The NTP measurement of a remote server using the public Internet was actually better, remaining below 3 ms but varying by more than 2 ms peak to peak. The TDEV plots (not shown) for PTP and NTP clients with a master on the public Internet do not approach the quality of the telecommunication requirements. There may be client settings on some of these PTP devices that would work better in this environment, but from our observations, PTP clients do not work well on the public Internet and should be steered after much more averaging, at least to match the average time offset of NTP. However, not only are the network paths very asymmetric to begin with, but the packets can change course from one synchronization to the next, so calibration of the client output may not improve the timing performance.

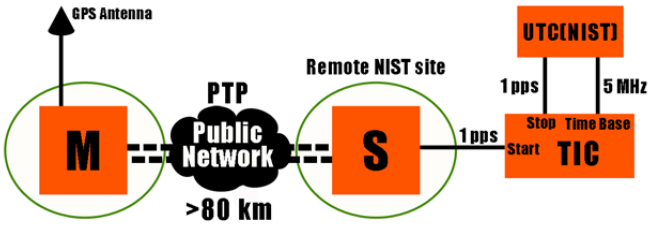

Figure 12. PTP master and slave across the public internet

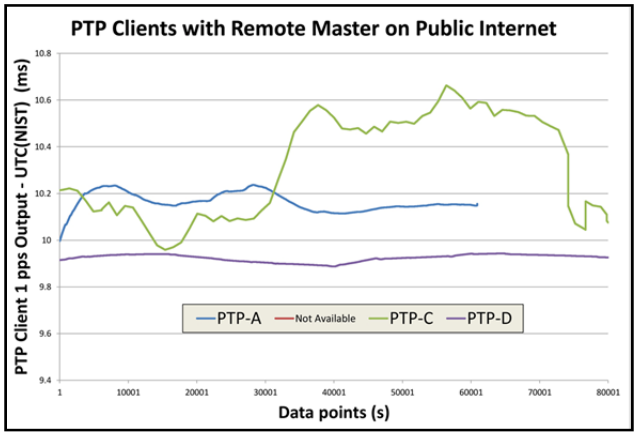

Figure 13. Clients with remote masters the public Internet

The last remote master experiment was conducted between NIST in Boulder, Colorado and NIST in Gaithersburg, Maryland, which is over 2400 km away. There are dual T3 (44.7 Mbit/s) leased lines composing the NIST VLAN, with a significant amount of traffic between the two sites. In this case there were five network hops. Because there is no equivalent to UTC(NIST) generated at the Gaithersburg site, the master there used GPS as the reference. The client was in Boulder, and its output was compared to UTC(NIST). Figure 14 shows that the average time offset was 473.0 µs, with peak-to-peak variations of 128.7 µs. PTP over a leased line may not have large timing steps due to packets taking different paths, but the timing variation is large, possibly caused by variable (and abundant) network traffic.

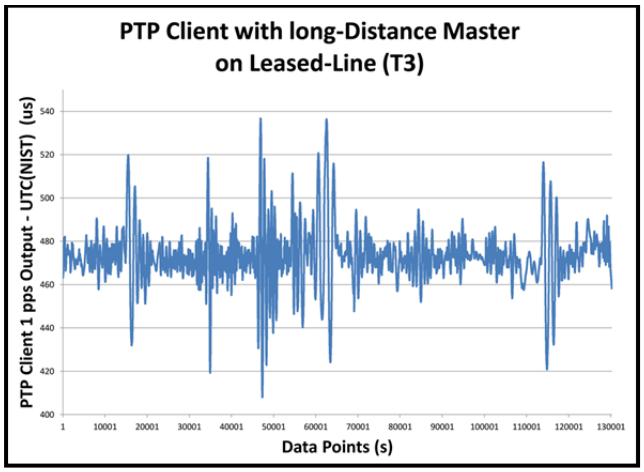

Figure 14. Results with client at a site 2400 km away

III. Calibration of the Masters

Each master's GPS receiver was allowed to survey its own antenna position, but the exact locations of the antennas were well known due to geodetic surveys performed recently. Also, the antenna cable delays were measured. Table I shows the errors in latitude/longitude and height of the surveyed coordinates compared to the geodetic solution. Also, the table shows the measured antenna cable delays and the delays entered into the PTP masters to adjust the output to match UTC(NIST). The difference between these two delays is the resulting master delay, which is affected by the height survey error and the delay through the master itself. It is not known why PTP-D has a negative receiver delay, but it is possible that the manufacturer advances the output of the device to compensate for *presumed* delays. Most important, without calibration of the master, the output can be in error, which will result in client error on the other end.

TABLE I. GPS Errors in the PTP Masters

	Lat/Lon Survey Error	*Height Survey Error*	*Antenna Cable Delay*	*Output Adjustment (based on calibration)*	*Resulting Master Delay*
PTP-A Master	0.4 m	18.2 m	122.1 ns	163 ns	40.9 ns
PTP-B Master	9.0 m	13.3 m	123.3 ns	147 ns	23.7 ns
PTP-C Master	2.7 m	- 0.9 m	108.9 ns	112 ns	3.1 ns
PTP-D Master	1.9 m	19.1 m	101.6	56.0 ns	-45.6 ns

A GPS disciplined oscillator (GPSDO) is sometimes considered a self-calibrating device. However, we have shown that even when the antenna cable delay is entered, position error and receiver delays have caused average time offsets over 40 ns in some cases. Also, even though the mid-term frequency stabilities of the masters (Figure 15) are very good because they are steered to GPS, we noted earlier (Figure 2) that there were short-term peak-to-peak fluctuations of greater than 120 ns in the worst case. Figure 16 shows all of the masters within the ITU specification for time stability of primary reference clocks [8]. At present, there is no ITU requirement for time accuracy. In order to know how well a particular PTP master works with a GPSDO as its reference, it is advisable to have it calibrated by NIST or another National Metrology Institute (NMI) or a calibration laboratory [4]. Ideally, a GPSDO calibration should be performed with the antenna and cable that will be used in the field, leaving only the coordinate error. In order to achieve the best performance with a calibrated GPSDO, precisely surveyed coordinates should be entered into the receiver.

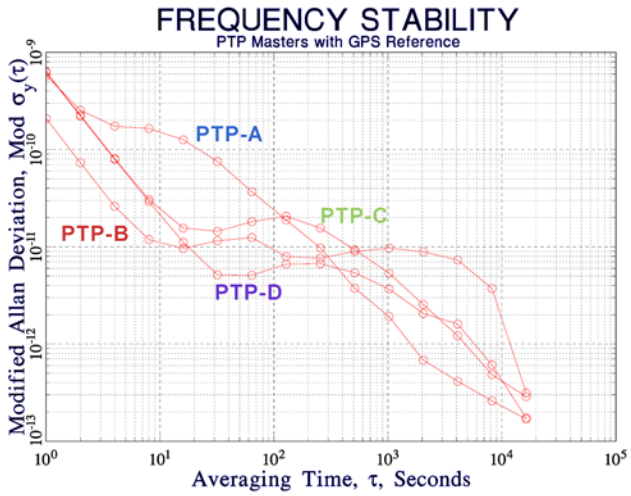

Figure 15. Frequency stability of the PTP masters

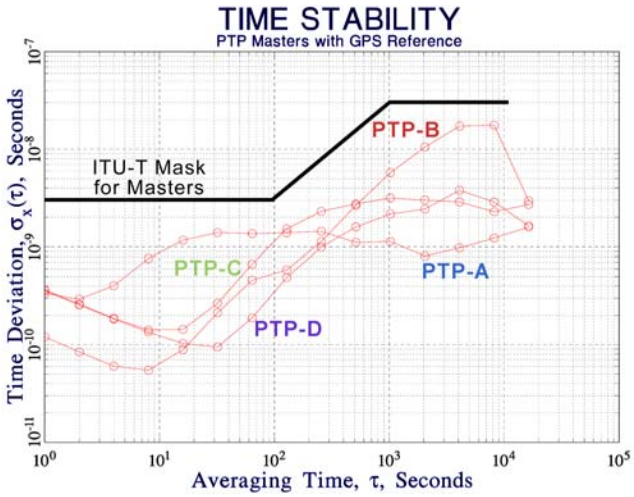

Figure 16. Time stability of the PTP masters

IV. CONCLUSION

These results show several real-world network scenarios and how different commercial PTP hardware reacts in each situation. We see that there is usually one that is worse than the other three, but it is not always the same one. As more distance and network elements are added to the network, the asymmetry of the paths can increase, causing larger time offsets. As PTP continues to grow as a tool for synchronization across networks, and the types of network situations continues to vary, we hope that providers of PTP hardware continue to develop their devices and steering methods to account for this. Also, increasing network infrastructure and opportunities for different levels of service (symmetric paths) from network providers will improve long-distance PTP synchronization. Another possibility of operation is GPS-assisted PTP, where the client would also have an embedded GPS receiver, and the PTP timing would be calibrated continually, so it could be used in a holdover mode if GPS becomes unavailable.

ACKNOWLEDGMENT

We would like to thank Robert Sorensen and Dr. Eugene Song of NIST for their help with these measurements.

***Abstract*—In order to allow the use of GLONASS data from geodetic type receivers providing only raw data in RINEX format, we updated the R2CGGTTS software developed initially at the Royal Observatory of Belgium (ROB) for GPS data. The GLONASS navigation files are used for the determination of satellite clocks and positions, and the computation procedure to get the CGGTTS data from the pseudorange measurements is applied similarly as for the GPS satellites. Using the satellite orbits and clock products provided by the IGS analysis center ESA, we combine GPS and GLONASS in All in view. Adding GLONASS decreases the noise of the clock solution with respect to the GPS-only solution by about 20% thanks to the increased number of satellite observations. We also quantify the added value of using GLONASS data in addition to GPS data for time and frequency transfer based on Precise Point Positioning (PPP). A particular attention is given to the determination of the frequency-dependent hardware delays in both approaches.**

I. INTRODUCTION

Measurements from Global Navigation Satellite Systems (GNSS) are used since the eighties [1] to perform precise and accurate Time and Frequency Transfer (TFT). In its classical version, the GPS time transfer is performed using clock offsets collected in a fixed format, called CGGTTS (Common GPS GLONASS Time Transfer Standard), as described in [2,3]. These clock offsets are obtained from the pseudorange measurements, corrected for the signal travel time (satellite-station), for the troposphere and ionosphere delays, and for the relativistic effects. A smoothing is then performed over 13 minutes observation tracks. Starting with C/A code receivers, the method was then upgraded to take benefice from the dual-frequency receivers measuring codes on both frequencies, which allows to remove the ionosphere delays at the first order (i.e. 99.9 percent of the effect), thanks to the ionosphere-free dual-frequency combination. This led to a factor 2 improvement in the precision of the intercontinental time links (e.g. [4]). Some time receivers directly provides the CGGTTS results, but in order to be able to use classical geodetic receivers driven by an external clock for the time transfer applications with the same standards, a dedicated software named R2CGGTTS was produced to compute the CGGTTS files from the raw observation data provided by the receivers in the RINEX format [5]. This software is presently used by a large portion of the time laboratories for their participation to TAI, through the technique TAIP3 [6]. Thanks to the growing constellation of GLONASS, some time laboratories now upgraded their equipment with receivers capable to observe both GPS and GLONASS. We therefore adapted the R2CGGTTS software to the use of GLONASS observations as will be explained in the first part of the paper.

A more precise version of GNSS TFT consists in using both code and carrier phase observations. The use of PPP, i.e. Precise Point Positioning [7], for time and frequency transfer has been extensively studied and developed in the last years [e.g. 8-11]. Presently several time links in TAI are based on PPP solutions [12]. Only GPS measurements are currently used, while the method should find a significant improvement from the combined use of additional constellations, GLONASS, Galileo, COMPASS, thanks to the increased number of satellites and signals. We propose a first step in this evolution with the combination of GPS and GLONASS data using the Atomium PPP software [9]. This is now possible thanks to the effort of the IGS during the last decade to use the GLONASS data for positioning and providing therefore precise orbits for the GLONASS satellites consistent with the GPS satellite orbits.

A major difference between the GLONASS and GPS constellations is that all the GLONASS satellites do not transmit the same frequency, so that the signal delay in the receiver is different for each satellite group emitting a given frequency. This affects the code measurements, with differential biases up to 25 ns, as already shown by several authors [13-14]. These differential biases must be either determined by calibration or estimated in addition to the clock solution.

The paper will study the added value of GLONASS in CGGTTS and PPP. The PPP results were fully presented in [15], we just here provide a summary.

II. CGGTTS COMBINING GPS AND GLONASS DATA

As explained in the introduction, the CGGTTS files contain clock solutions corresponding to the pseudorange measurements, corrected for the signal travel time (satellite-station) based on broadcast satellite orbits, for the troposphere and ionosphere delays, and for the relativistic effects. The final results provided are the midpoint of a linear fit performed over 13 minutes observation tracks for each visible satellite. Using dual-frequency observations allows to remove the first order ionosphere delay, which will be done here with GLONASS observations.

As the two time scales GPS and GLONASS are differing from an integer number of leap seconds (GPS Time = GLONASS Time + leap seconds) and as the observation files are dated in GPS time, while the broadcast navigation message uses GLONASS time as reference, a first correction for system time must be applied. Secondly, while GPS navigation messages provide parameters of keplerian orbits in WGS84 (very close to the ITRF) each two hour, the broadcast navigation message of the GLONASS constellation is given as a set of positions and velocities in the PZ90 Earth-fixed system at a sampling rate of 30 minutes. As we are computing the CGGTTS from RINEX data in a post-processing, we have the choice between computing the GLONASS satellite positions either by numerical integration, or by polynomial interpolation. A comparison between the CGGTTS results obtained for one day with either interpolation or numerical integration Runge Kutta 4th order was performed [16] using the GLONASS pseudoranges from a RINEX observation file provided by the TTS4 receiver located at the BIPM, and connected to a H-maser. As the noise of the results was larger with the polynomial interpolation, we decided to implement the Runge Kutta 4th order integration in the R2CGGTTS software. Finally, as done by the BIPM for the computation of TAI, we corrected the CGGTTS results computed with broadcast navigation messages by introducing more precise satellite positions and clocks as computed by the ESOC analysis center of the International GNSS Service (IGS). The results so obtained are presented in Fig. 1, with a comparison with similar results for the GPS satellites. We can directly observe a larger dispersion of the GLONASS results with respect to the GPS results, due to the satellite-dependent hardware delays associated with the satellite-dependent carrier frequencies of the GLONASS constellation. This is illustrated in Fig. 2 which presents the differences between the clock solutions obtained with the GLONASS satellites and the GPS All in View (AV) clock solution for the BIPM receiver BP1B. The satellite of the same GLONASS frequency channel have been plotted with a same color; each color represents therefore the biases of one frequency channel. The frequency-dependent biases are clearly visible on the picture. It must be noted that these biases correspond to biases of the P3 combination, i.e. a combination of the frequency-dependent biases of the P1 and the frequency-dependent biases of P2. The variations of the ensemble from day to day are due to the day-to-day changes of reference of the ESA satellite clock solutions. Changing the reference can indeed also change the bias between the GPS pseudoranges and the GLONASS pseudoranges.

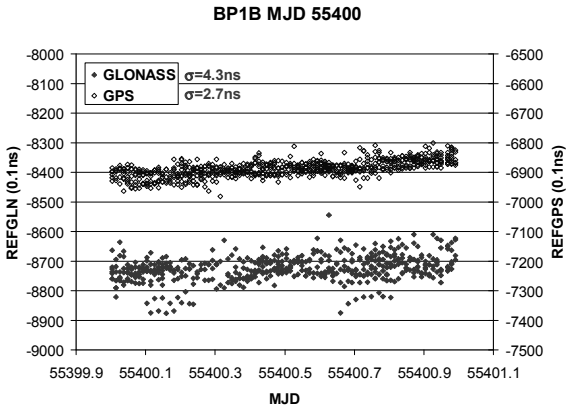

Figure 1. Comparison between the CGGTTS results obtained with either GLONASS satellites or GPS satellites after correction for precise satellite positions and clocks. The ESOC post-processed satellite orbits and clocks are used in both case.

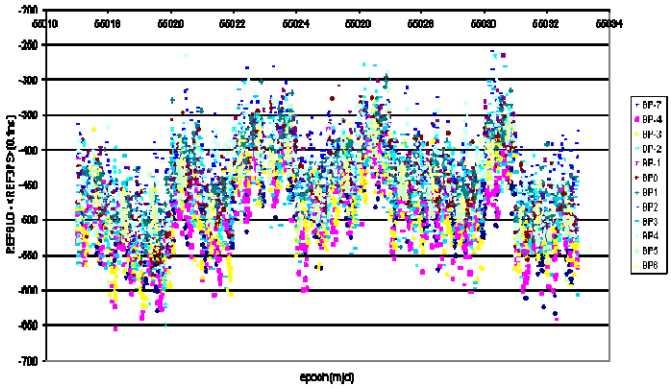

Figure 2. Differences between the clock solutions obtained with the GLONASS satellites and the GPS clock solution for the BIPM receiver BP1B. Each color corresponds to one GLONASS frequency channel.

In order to compute an All in View solution with GLONASS and GPS data, it is therefore necessary to correct the CGGTTS results for the inter-frequency and inter-system biases. As presently no GPS-GLONASS receivers have been calibrated for the GLONASS part, the procedure we propose it to determine for each month (regular basis for the TAI computation) and for each GLONASS frequency channel, one bias with respect to the GPS solution (hopefully calibrated). In order to account for the day-to-day differences due to the changes of reference, the procedure proposed is as follows: first determine for each day j a daily bias *D(j)* between GPS and GLONASS, as the average of the differences between GLONASS results and the GPS AV solution during that day. Then corrects all the frequency-dependent biases of Fig. 2 for *D(j)*, so that for each day they are centered on zero. The monthly bias *B(f)* for each frequency channel *f* is then computed as the average of the biases reported to a zero average. Finally, for each day, the correction for frequency-dependent biases is obtained as the sum of the monthly bias *B(f)* and the daily offset between GPS and GLONASS results *D(j)*.

Figure 3 presents an example of AV solution obtained with GLONASS data, before and after the correction for frequency-dependent biases applied with the procedure just described. The improvement of the stability of the solution is clearly visible.

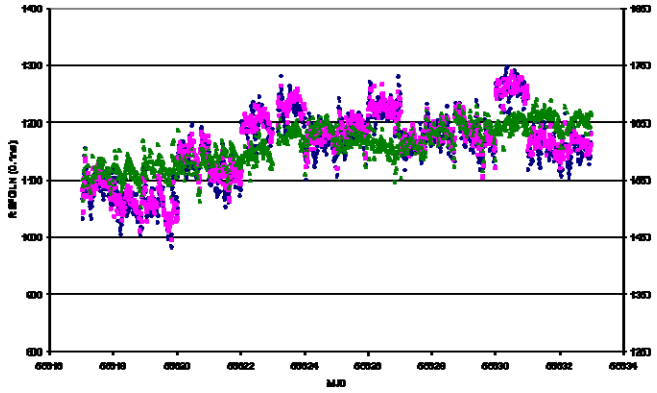

Figure 3. AV clock solution obtained with the GLONASS satellites BIPM receiver BP1B. blue: without correction of inter-frequency biases; pink: using a monthly mean of the biases; green: using a daily mean of the biases.

In order to quantify the added value of GLONASS observations in time transfer links based on CGGTTS results, we computed the link BIPM-IPQ, using the RINEX files from the TTS4 receivers installed in both labs. The time links obtained in All in View with either only GPS or GPS+GLONASS are plotted in Fig. 4, and the stability of both solutions is depicted in Fig. 5. Thanks to the increased number of observations, the noise of the final solution is reduced by about 20% when adding GLONASS data.

III. PPP COMBINING GPS AND GLONASS DATA

The combination of GPS and GLONASS observations for time and frequency transfer was done using the Atomium software [9]. This software is based on a least square analysis of code and carrier phase GPS measurements, using satellite orbits in the format sp3 and clocks in RINEX clock format, to determine the receiver clock synchronization error at each observation epoch, a daily position and the tropospheric zenith path delays each 15 minutes. The precise satellite positions and clocks were also taken from the ESOC products.

The clock solution, obtained from the ensemble of GPS and GLONASS observations, corresponds therefore to the synchronization error between the ground clock and the ESOC reference.

The inter-frequency hardware delays are estimated as additional parameters in the least square inversion, as biases with respect to the GPS pseudoranges. As the data are analysed in daily data batches, one set of frequency-dependent hardware delays is determined for each day analysed.

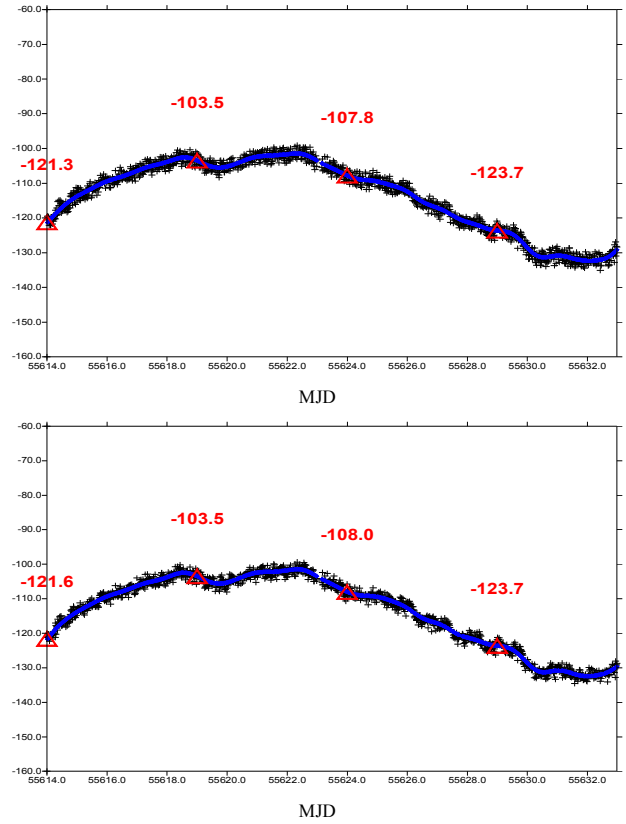

Figure 4. Time link BIPM-IPQ during 18 days, based on All-in-View, up: using only GPS data, down: using GPS+GLONASS data. Units are nanosecond.

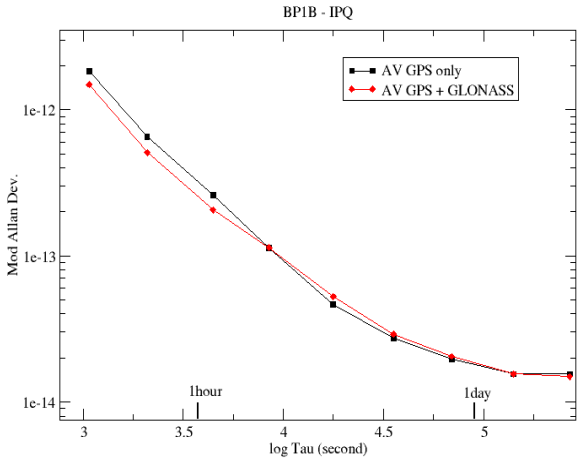

Figure 5. Mod. Allan Deviation of the two curves presented in Fig. 4.

Fig. 6 presents the differences between the PPP clock solutions obtained with GPS data only or using both GPS and GLONASS data for three IGS stations equipped with H-masers: MAR6, ONSA and WTZR. These differences are lower than 200 ps peak to peak. The differences were also computed over a 6 week period for the station WTZR and the same conclusion was drawn concerning the magnitude of the differences.

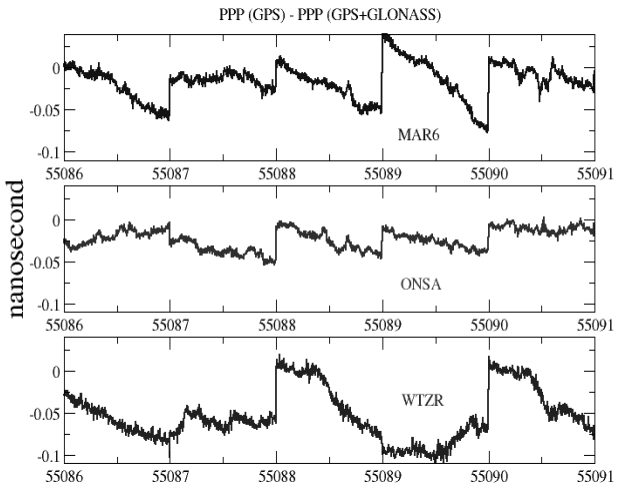

Figure 6. Differences between the PPP clock solutions obtained with GPS data only or using both GPS and GLONASS data for the IGS stations MAR6, ONSA and WTZR.

Figure 7 shows one situation where the addition of GLONASS observations brings an improvement to the global solution. There was a tracking interruption, with a very short data gap in the WTZR observations. This forces the Atomium software to estimate different ambiguities before and after the gap, using approximately two times less pseudorange data in each part. This jump of 200 ps disappears when adding GLONASS code and phase measurements to GPS data within the analysis, thanks to the increased number of data which favors a better determination of the ambiguities in both parts, before and after the data gap in WTZR.

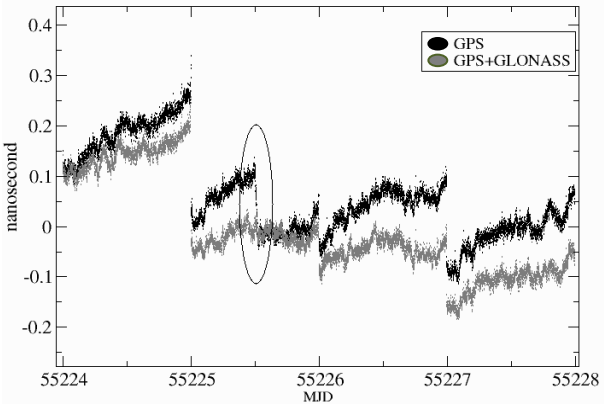

Figure 7. Differences between the Atomium PPP solution and the IGS solution for the time link ONSA-WTZR, with a tracking interruption in WTZR during the MJD 55225.

IV. CONCLUSIONS

The **R2CGGTTS** software has been upgraded and is now able to be applied on GLONASS data. Thanks to the ESA products, it is possible to combine GPS and GLONASS data in AV. The inter-frequency biases of GLONASS data should however firstly been corrected for. These biases are computed on a monthly basis with respect to the GPS solution, further removing the daily average of the differences between GPS and GLONASS solutions due to the daily change of reference of the ESA clock products. For the time link investigated here, i.e. BIPM-IPQ, the addition of GLONASS data to the GPS data in AV reduces the noise level by about 20% thanks to the increased Clock solutions from PPP can now be obtained from an ensemble of GPS + GLONASS observations, thanks to the ESOC products for satellite clocks. Concerning time transfer, i.e. the absolute value of the synchronization errors, the addition of GLONASS observations brings a significant improvement in the case of short data batches, because the higher number of observation allows a better determination of the carrier phase ambiguities This can be important in case of tracking interruption as was the case in the example presented here.

Concerning the frequency transfer with PPP, it was shown that adding GLONASS data modifies the shape of the curve, with a maximum difference of 150 ps peak to peak between the results obtained with and without GLONASS over the 6 week analysis performed.

ACKNOWLEDGMENT

We acknowledge the IGS and ESA/ESOC for making their solutions available.

Time-Code Assisted Low-Power GNSS Single-Shot Receiver for Mobile Devices

Christoph Kandziora and Robert Weigel

Institute for Electronics Engineering, University of Erlangen-Nuremberg,
Cauerstr. 9, 91058 Erlangen, Germany, {kandziora,weigel}@lte.eei.uni-erlangen.de

***Abstract*— The scope of this paper is a new approach to assisted navigation using both signals from a global navigation satellite system (GNSS) and a long-range time code transmitter. The information gathered from the time code signal gives a priori knowledge of signal reception time in the sub-microsecond range. Together with the approximate position of the device and assistance navigation data, both derived from a cellular network, a pre-estimation of code-phases is possible. This leads to a significant reduction in baseband processing effort for the computation of the real code phases for the navigation solution.**

The structure of the time code signal gives the opportunity to reuse the core of the baseband signal processing of the GNSS single-shot receiver with only minor modifications to determine the reception time. Therefore the number of cross correlation channels in the baseband processing hardware can be reduced by at least a factor of two.

I. Introduction

The market for mobile devices is increasingly dominated by smartphones, which incorporate a lot of different functions such as camera, FM-radio receiver or GNSS receivers. Therefore each of these functions has to be optimized regarding power consumption and speed. Looking at GNSS receivers, the introduction of the assisted GNSS principle provides a major advantage in the performance of the GNSS receivers. These concepts strongly rely on a cellular network connection which feed the GNSS receiver with the appropriate information about the satellite constellation and errors in the navigation solution due to atmospheric effects, hence the navigation message. The baseband signal processing can then be arranged in a massive parallel structure to scan the whole code-phase-Doppler search space for all satellites in view in parallel. This leads to a very small time-to-first-fix (TTFF). The main disadvantage of this concept is that the massive parallel structure consumes a lot of hardware.

The proposed concept overcomes the problem of extensive hardware usage by adding information about the reception time of the satellite signal to the navigation solution. The time information is gathered by a time code receiver for the German DCF77 transmitter. Compared to a common Single-Shot receiver concept the architecture has to be expanded by only an analog RF front-end for the reception of the DCF77 signal. Since the DCF77 transmitter emits a 512 bit long PRN sequence modulated on a 77.5 kHz sine wave carrier, the baseband signal processing hardware of the common single-shot receiver can be reused with minor changes to the concept but major changes to the amount of applied cross correlation channels.

II. DCF77 Signal in Space

The DCF77 transmitter is located near Frankfurt, Germany, and emits a 77.5 kHz sine wave which is amplitude modulated in the way that at the beginning of each second the amplitude is reduced by 75% for 100 ms or 200 ms whether a '0' or '1' is transmitted. To set the minute mark the amplitude at the beginning of the 59th second is not reduced but held at 100% level [1]. Additionally the phase of the sine wave is modulated with a 512-bit long PRN-sequence in the segment of the second when the amplitude is at 100% level, hence from 200 ms after the second mark until the next second mark [2]. The PRN sequence is generated from a 9 stage linear feedback shift register which is reset every second. The generation of the DCF77 PRN sequence follows equation(1):

$$y = x^9 + x^5 \tag{1}$$

The PRN sequence also carriers the information encoded in the amplitude modulation [2]. Dependent on whether the PRN sequence is transmitted directly or with inverted phase a binary '0' or '1' is transmitted. Fig.1 shows the behavior of the DCF77 signal.

III. RF Front-end

The demands to the GNSS RF front-end are similar to those of common GNSS receivers. Therefore its characteristics will not be described here. For further information the reader is refered to the literature [3] [4] [5].

The demands to the RF front-end for the presented architecture of the time-code receiver are on the one hand an extremly narrow band receiver design (around 10-20 Hz) for the generation of a reference frequency and a design

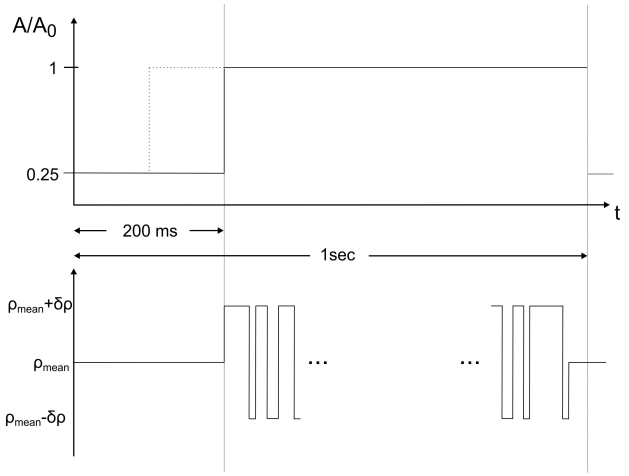

Fig. 1. Behavior of DCF77 signal in amplitude and phase. [2]

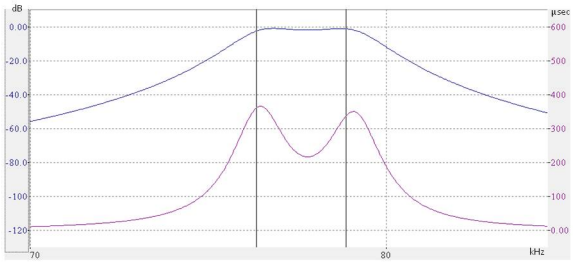

Fig. 3. Attenuation and group delay characteristic of band pass filter

with a wider bandwidth of around 2.6 kHz in order to allow demodulation of the information.

These two, at first glance, contrary demands can be overcome by the architecture shown in Fig. 2.

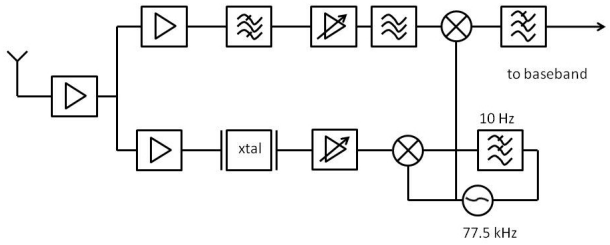

Fig. 2. Block diagram of the RF front-end architecture

Similar to the well know receiver chipsets, the proposed architecture uses a ferrite antenna to receive the DCF77 signal. After a first amplification stage, which again also decouples the antenna from the rest of the circuit, the signal is fed into two parallel branches of the circuit. The lower branch in Fig.2 filters the signal, after further amplification, by a high-Q crystal filter. The bandwidth of this filter is around 10-20 Hz. This eliminates all kind of distortions and even affects the rising edge of the amplitude modulation. After filtering the signal is again amplified and then fed as reference frequency into a PLL. The VCO output signal is by that tightly coupled to the received highly precise 77.5 kHz sine wave and therfore serves as the demodulating reference frequency.

The second branch of the RF front-end amplifies the signal, too, and filters it with a bandpass filter with a 3 dB-bandwidth of around 2.6 kHz. The filter is realized by a four-pole multiple-feedback (MFB) configuration. A screenshot of the simulated filter characteristic regarding attenuation and group delay is shown in Fig 3. After filtering the signal is again amplified by an automatic gain control (AGC) amplifier to compensate losses from the filter stage and prevent the signal from clipping.

The next block in the demodulating branch of the RF front-end represents an allpass filter which is used to compensate differences in the signal delays of the two branches. The phase rotation introduced by this allpass filter is necessary to generate a DC-offset free output of the following phase detector (PD). This is important for proper operation of the digital baseband processing engine. The phase rotation introduced by the allpass filter is compensated in the digital baseband.

The following phase detector is fed by the output of the allpass and the frequency generated in the other branch of the circuit. The phase difference at the inputs of the phase detector is constant and can easily be measured to calulate the characteristic of the precedent allpass.

The demodulated signal is then digitized by a 2 bit flash ADC for further signal processing.

IV. Digital Baseband

The digital baseband processing engine is based on that of the common single-shot receiver. It is used for the computation of the cross correlation function between the received time-code or the GNSS satellite signals and their local replica. As mentioned before both are a pseudo-random-noise (PRN) codes of different length. All possible code-phases for one signal are processed in a massive parallel approach. The structure of one cross correlation channel is shown in Fig. 4. The correlation function is performed in two steps. The first step is a coherent correlation which must be performed for at least one complete code epoch, namely 1 s for the time code signal or 1 ms for GPS signals.

Depending on the received power level and distortions it can be necessary to correlate over more than one epoch to determine the actual code phase of the received signal. Since the actual data bit of the time or navigation message are coded into the PRN sequence by transmitting either non-inverted

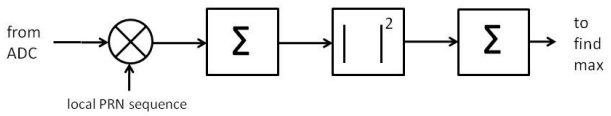

Fig. 4. Block diagram of baseband processing channel.

or inverted PRN-sequences [6] coherent integration lead to false results if correlated over data bit boundaries [7]. That is why it is essential to perform the subsequent non-coherent integration.

The proposed architecture, incorporating 1024 channels shown in Fig. 4, is shown in Fig. 5. The channels are arranged in parallel each fed with the same digitized demodulated signal (either time-code or GNSS signals) and the local generated replica of the appropriate PRN sequence. The PRN replica is half chip-wise shifted regarding adjacent channels. The position of the maximum result of the parallel cross correlation functions correspond to either the actual error of the local RTC with respect to UTC or the actual code phase for the actual space vehicle (SV).

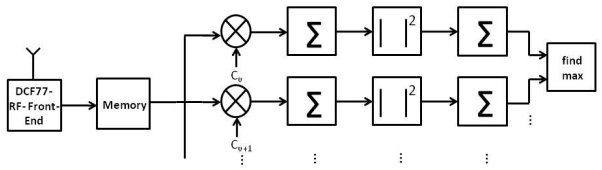

Fig. 5. Block diagram of baseband processing engine.

Regarding the result for corellating the time code signal, the resulting clock offset has to be corrected from two main errors. First of all the offset introduced by the allpass filter in the RF front-end. This error is an offset which is constant for a particular receiver and varies from receiver to receiver due to component tolerances. As already mentioned it can be measured once for each receiver and then be hard-coded in the baseband processing engine or the software of the receiver, e.g. by an initial shift of the local PRN replica. Second the distance between the transmitter and the receiver has to be taken into account.

V. Positioning Algorithm

The algorithm to determine the actual user position is controlled by a host platform based on an OMAP3530 embbeded processor running Google Android.

The first step is to collect the GNSS navigation message over a cellular network connection. As already mentioned this connection is essential for the single-shot operation mode of the proposed architecture, due to the fact that the navigation message does not have to be extracted from the satellite signal. Together with an approximate position and time information which again can be derived from the cellular network two essential pieces of information can be extracted. First of all the time of flight of the time-code signal is now known. The error because of the error in the inital position approximation is negligible. The host then initiates the reception of both the time-code and the GNSS signals. The received samples are stored in memory for offline processing and both front-ends can be shut down for power saving.

The host then instructs the baseband processing engine to cross correlate the DCF77 signal. The code-phase computed directly relates to the offset between the local RTC and UTC. With the known reception time the actual satellite constellation can be computed and the SVs with the best GDOP can be selected.

Together with their position at the calculated time and the estimated position of the user an estimation of the code phases for the selected SVs can be calculated by the baseband processing engine either. Since the error of the inital user position approximation and the error in the reception time calculated are together smaller than 500 μs the search window for the real code phase for the appropriate SV can be cut down to 512 chips. Therefore again the 1024 cross correlation channels available in the baseband processing engine are sufficent to calculate the real code phase.

After four code phases are computed the well known algorithms [8] for calculating the position from code-phases can be applied.

VI. Conclusion

A new low-power approach to assisted navigation is proposed. Incorporating a long-range time-code receiver gives a priori knowledge of the reception time of the satellite signal. With the already know constellation a estimation of the code phases for the appropriate SVs at the estimated position of the user can be calculated. Since the resulting search window is much smaller compared to the search window for common receiver architectures the 1024 parallel cross-correlation channels for the determination of the reception time are sufficient even for the determination of the code phases of the GNSS satellite signals. This directly correlates to a cut in hardware effort by a factor of two regarding GPS satellite signals and a factor of 8 for Galileo satellite signals. Since active hardware strongly correlates to power consumption the cut in active hardware prooves the low-power approach mentioned at the beginning.

Towards an All-digital Time Scale

Stefania Römisch, Steven R. Jefferts, Thomas E. Parker
Time and Frequency Division
NIST
Boulder, CO USA
romisch@boulder.nist.gov

***Abstract* — The implementation of an all-digital time scale is under way at NIST, by use of a novel 8-channel, all-digital phase measurement system based on subsampling techniques. The phase measurement system is used to compare output signals from several commercial atomic frequency standards; the phase differences between these signals, at different measurement times, will then be input to the algorithm used to generate the digital time scale. The subsampling technique allows the elimination of analog mixers in the system's front end, with their noise contributions, and yields performance that is comparable to or better than the present state of the art. Long-term (up to 80 days) comparisons of both common-clock performance and fractional frequency measurements between the latest generation of the digital measurement system and the commercially available system used in the implementation of UTC(NIST) are presented.**

I. Introduction

The implementation of a time scale requires the ability to compare the time evolution of several clock signals. The instantaneous absolute phase of each clock is expressed in seconds to account for the accumulation of more than one cycle (2π radians) of phase difference between two signals. The quantity used in the computation of time scales is still commonly called *phase* but is in fact indicated with x and defined according to (1) below:

$$x(t)=\frac{\varphi(t)}{2\pi\nu_0}, \tag{1}$$

where $\varphi(t)$ is the instantaneous phase of the signal in radians and ν_0 is the nominal frequency of the same signal.

The differences between the instantaneous phase of n different clocks with respect to a clock r, elected to be the reference for the time scale, are indicated as $x_i(t)$-$x_r(t)$ and are then used by a weighting algorithm that computes the instantaneous phase of a virtual clock, the *ensemble clock*.

The ensemble clock, calculated by use of the algorithm *at1e* at NIST, is the representation of a local time scale, $TA(t)$. At NIST there are two real-time time scales, called AT1 and TSC, computed separately (but using the same algorithm) from distinct measurements of the same set of commercial atomic standards comprising both hydrogen masers and cesium thermal-beam clocks.

A third time scale, called DIG, will be computed, using the same algorithm, from the phase measurements on the same set of commercial atomic standards as executed by the novel, all-digital measurement system developed at NIST in the past few years.

The addition of a third time scale will provide increased redundancy for the entire time-scale operation, and the fundamentally different technology at the core of the digital measurement system (with respect to the ones presently used to provide the data for AT1 and TSC) will serve as a discriminating tool for the occasional aberrant behavior of the measurement systems. In fact, different technologies usually have different shortcomings that are often triggered by different occurrences.

II. The Measurement of Phase Differences

The high stability of the clocks involved in time-scale operations requires high-resolution measurement systems, making it impossible to use currently available time-interval or frequency counters without the use of sensitivity-enhancing techniques. The traditional and our all-digital sensitivity-enhancing techniques are briefly described below.

A. The dual-mixer technique

The technique traditionally used to compare the phase of two (or more) atomic frequency standards is referred to as dual-mixer measurement technique [1], [2] and is illustrated in its basic conception in Fig. 1.

The mixers in Fig. 1(a) simply down-convert each of the clocks' signals (generally at 5 MHz) to a much lower frequency (generally at 10 Hz) to increase the effective resolution of the time-interval counter. In fact, the phase difference in radians between the two 5 MHz waveforms amounts to the same number of radians for the 10 Hz waveforms, resulting in a time difference which is $5\cdot10^5$ times larger. A time-interval counter with a resolution of 10 ps used in this manner will therefore yield an effective resolution of about $2\pi\cdot10^{-9}$ rad for the phase measurement of the 5 MHz signal.

To first order the quality of the synthesized intermediate frequency (4.999990 MHz in this case) is irrelevant, because its noise contributions are common to both down-converting

processes and therefore cancel out, resulting in easier implementation of this measurement scheme.

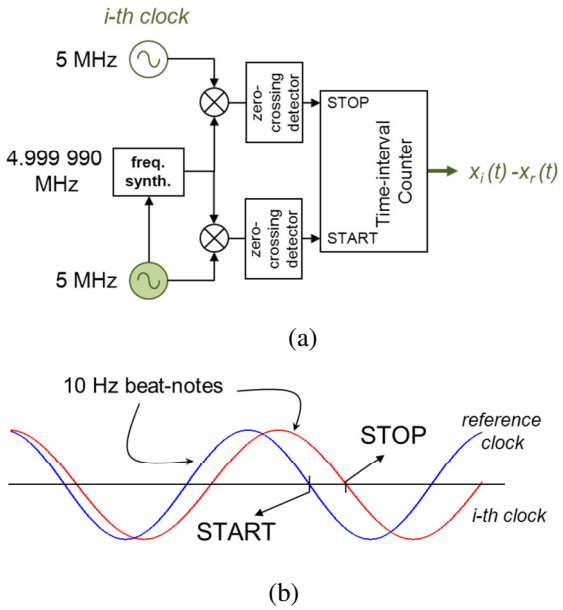

Figure 1. The dual-mixer technique for measuring phase differences between two signals. (a) The down-converting mixers produce two beat-note signals used to measure the time (phase) difference. (b) The two down-converted signals and their relation with the start and stop of the time-interval measurement.

The basic concept depicted in Fig. 1 can be expanded to simultaneously measure phase differences between *n* clocks and a common reference.

B. The All-digital technique

The all-digital technique for measuring phase differences between clocks can be summarized in one basic concept: the down-conversion performed by the analog mixers in Fig. 1 is replaced by digital sub-sampling of the clock signals [3]. The result of this operation is a digitized signal that is fitted by a sinusoidal waveform at a much lower frequency than that of the original clock signal.

The sub-sampling operation, like frequency mixing, preserves the signal's phase at the beginning of each measurement instance, allowing the measurement of the phase of a 5 MHz clock signal with a sensitivity gain similar to the one described for the dual-mixer technique.

In Fig. 2 is shown a graphical representation (not to scale) of the sub-sampling process used in the all-digital phase measurement system. The nominal 5 MHz clock signal is sampled at the rate set by the sampling time base square-wave for the duration of the measurement window, providing a set of samples that will be fitted by a sinusoidal waveform that is at a much lower frequency than both the sampling rate and the clock's frequency.

The frequency of the "beat-note" is determined by the residual of the ratio between the clock's frequency (5 MHz) and the sampling rate, which in fact must not be an integer fraction of 5 MHz.

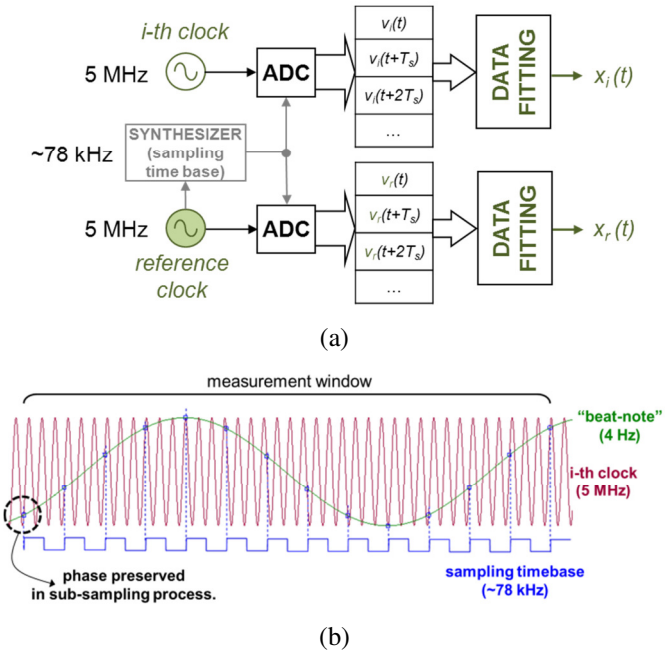

Figure 2. (a) Phase measurements using the all-digital technique. A synthesized sampling time base drives the subsampling process and the resulting samples are then fitted by a sinuoisdal waveform. The initial phase of this waveform is the final result of the measurement. (b) Not-to-scale representation of the sub-sampling process. The 5 MHz signal (in red) is sampled at the rate set by the sampling timebase square-wave (which must not be an integer fraction of the nominal 5 MHz) producing a set of samples indicated by the blue squares. These samples are then fitted by a sinusoidal waveform whose frequency is much lower that 5 MHz. The phase of the 5 MHz signal at the beginning of the measurement window is preserved by the sub-sampling process.

The length of the measurement window is a free parameter that can be chosen together with the sampling rate to determine the number of samples acquired for each measurement instance. The sampling rate and the length of the measurement window are parameters that should be chosen with some care. In fact, if a higher number of samples available for the "beat-note" fitting generally means a higher accuracy in the waveform's initial phase, a longer measurement window may result in a set of samples whose statistical properties are no longer stationary, introducing a bias in the determination of the waveform initial phase.

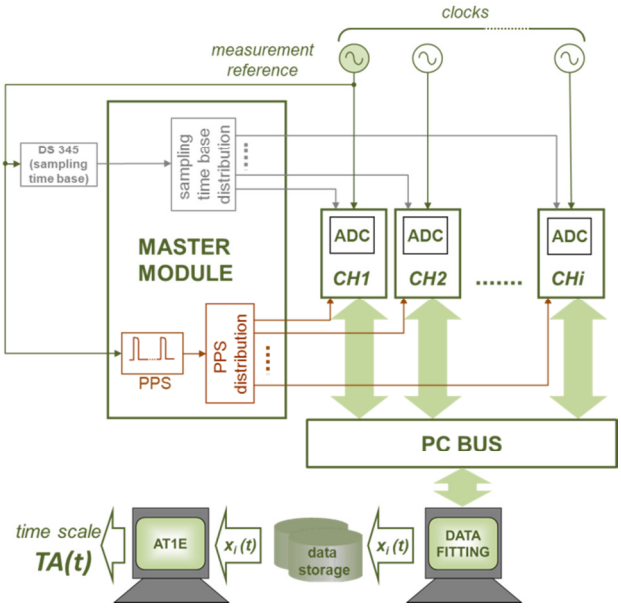
III. THE ALL-DIGITAL MEASUREMENS SYSTEM

The all-digital measurement system presently implemented at NIST is a re-engineered version (V1.5) of the prototype (V1) described in [3] and it can be seen in the photograph shown in Fig. 3(a).

The three main system components are a Master Module (top enclosure), a PC Bus (second enclosure from the top) and the crate housing the six active acquisition modules. The same three components are also indicated in the functional block diagram in Fig. 3(b). One of the clocks under measurement is used to synthesize both the sampling time-base and the pulse-per-second (PPS) signal used to trigger the measurement instances of the system, making that clock the reference for the measurement system. The sampling time-base is not an integer fraction of the nominal 5 MHz frequency of all clocks'

signals, so as an intermediate step towards full Master Module implementation with a Digital Direct Synthesizer (DDS) a commercial synthesizer was used. Both the sampling time-base and the PPS signals are distributed by the Master Module to all acquisition modules indicated as CH1, CH2 and CHi in the diagram.

(a)



(b)

Figure 3. (a) Photograph showing the re-engineered measurement system V1.5. The top enclosure is the Master Module, the second enclosure from the top is the PC Bus, and the crate below them houses the six active acquisition modules. (b) Functional block diagram of the same sytem. The sampling time base and the PPS signal are synthesized from one of the available clocks, which is then the reference clock for the measurement system.

The PC Bus allows the PC dedicated to data fitting to poll in turn each acquisition module, reading the acquired samples from the flash memory chip where they were stored by the microcontroller managing the acquisition process. At the end of the fitting process the phase of each 5 MHz signal at the beginning of each measurement instance, $x_i(t)$, is stored to be processed at a later time by the time-scale algorithm of choice.

Because any time-scale algorithm is substantially a prediction algorithm for clock *differences*, one of the ensemble's clocks is chosen to be the reference clock for the time-scale calculations. This reference clock must not be confused with the clock that is used as the *measurement reference* as indicated in fig. 3(b): while the two may be chosen to be the same physical clock, their functions are separate and different. Although some measurement systems may not allow a complete freedom of choice in this regard, and despite the setup chosen for the measurements shown in this paper, the conceptually optimal choice should use UTC(NIST) as the *measurement* reference clock. The effect of using, instead, one of the clocks as the *measurement* reference has the effect of introducing a skew in the measured data, due to the drift of that clock with respect to the ensemble clock representing the local UTC. As it turns out, the effect of such drift is of no consequence, as discussed in the next section.

IV. System Characterization

The names of the frequency sources (clocks) used in the measurements described in this paper are summarized in Table I, where the channel numbers are indicated for both all-digital (DIG) and dual-mixer-based (AT1, TSC) measurement systems.

TABLE I. Summary of Measured Clocks

DIG Channel number	AT1 Channel number	TSC Channel number	Clock name and description
1	30	30	ST004 – Hydrogen maser
2	5	5, 25, 26	ST003 – Hydrogen maser
3	7	7	AOG03 – Auxiliary Offset Generator (ST006 steered by UTC(NIST))
4, 5	13	13	ST0022 – Hydrogen maser (reference for sampling time-base, PPS)
7	18	18	ST006 – Hydrogen maser
-	17, 24	17, 24	HP1074 –Cs thermal-beam clock

There are several ways to characterize this measurement system, each one of them providing different and complementary information about its overall performance in the domain of time-scale applications.

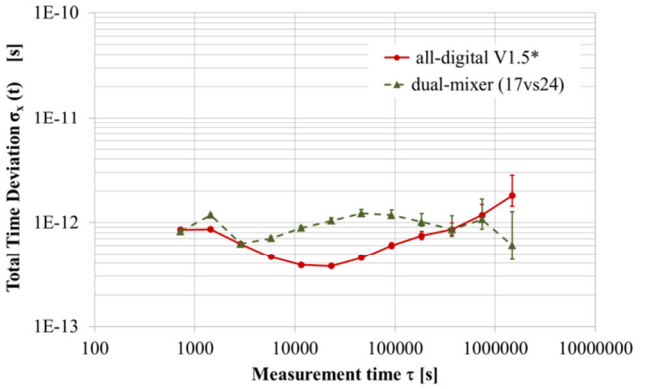
A. Common-clock Measurements

In a common-clock measurement, two distinct channels (acquisition modules) measure the same clock, thereby offering as a result the residual noise of each channel, summed in quadrature. Presuming the two measuring channels are virtually identical, the resulting "noise floor" for each of them is assumed to have a total time deviation (or a total fractional frequency deviation) that is 0.7 times better than the one computed from the measured noise levels.

Several results for this configuration are shown and compared for different measurement systems in Fig. 4, where the quantity depicted is the total time deviation (total TDEV)

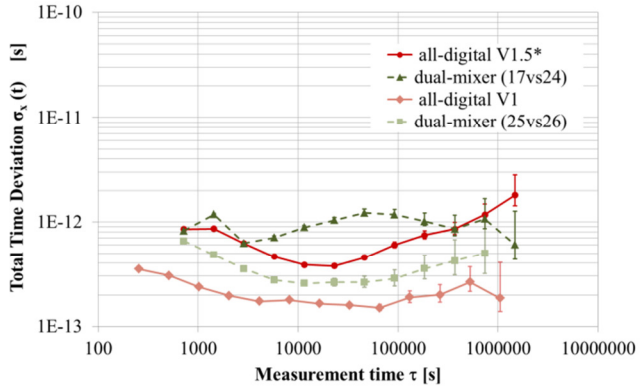
computed from the measured noise, without the 0.7 factor reduction.

Fig. 4(a) shows the time instability of channels 4 and 5 for the all-digital measurement system (V1.5), as compared with the results of similar measurement for channels 17 and 24 of the dual-mixer-based system that is the core of UTC(NIST). The all-digital system exibits a time instability below 1 ps for measurement periods up to approximately 10 days, and it is comparable with, or better than, the dual-mixer system. The measurements were conducted between MJD 55560 and 55680.



* Glitches removed are > 5 s and amount to less than 3·10-3 of total data points

(a)



* Glitches removed are > 5 s and amount to less than 3•10-3 of total data points

(b)

Figure 4. (a) Total time deviation calculated for channels 4 and 5 for the all-digital measurement system (V1.5), as compared with the results of similar measurement for channels 17 and 24 of the dual-mixer-based system that is the core of UTC(NIST). (b) Total time deviation calculated for common clock measurements using the prototype all-digital system prior to its re-engineering and a different pair of channels of the dual-mixer system, compared with the data in (a).

In Fig. 4(b) the same data are shown together with the results from common clock measurements using the prototype all-digital system (V1) prior to its re-engineering. Data from a better-performing pair of channels for the dual-mixer measurement system (for the same period spanning approximately MJD 55350-55400) are also shown.

The discrepancy between the two sets of measurements illustrates the dual-mixer system channel-to-channel performance variability and the unwanted effect of the re-engineering process of the all-digital system, which significantly raised its noise floor, albeit without invalidating its viability for time-scale applications. In fact, even the worse performance is still within the spread of performance of the dual-mixer system generating UTC(NIST).

Finally, a comparison of the projected effect of using a specific clock as measurement reference clock, instead of UTC(NIST), is compared with the noise floor of the system and determined to be inconsequential, at least for the measurement periods described in this paper. In fact, if the measured drift of ST006 (used as the measurement reference clock) is approximately $-1.27 \cdot 10^{-21}$, after 100 days of measurements the 720 s measurement interval will have an error of approximately 10 fs. This would be the timing error of the measurement system if it were otherwise noiseless: in reality it is well below even the best noise floor of the all-digital measurement system. The measurement reference clock drift with respect to UTC(NIST) is a negligible contribution to the all-digital system for measurement periods up to 2000 days.

B. *Frequency Offset and Double-difference Measurements*

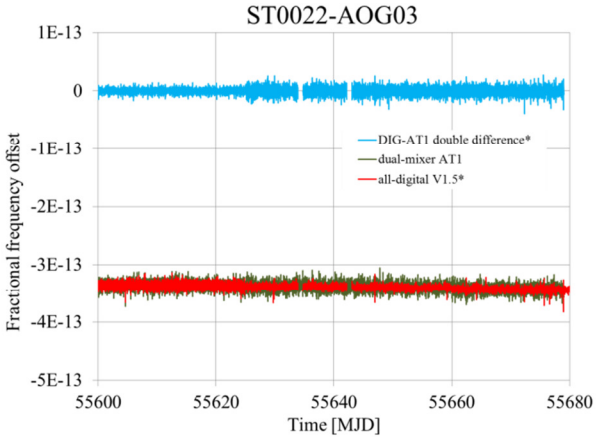
Although the common-clock measurements are very important in determining the capabilities of the measurement system, its typical operating conditions require the simultaneous measurement of *n* different clocks' phases.

Apart from channels 4 and 5, all other active channels in the all-digital measurement system are measuring different clocks (see Table I). The measurement of the absolute frequency of a clock happens only through its comparison with a primary frequency standard. The clocks that constitute a time scale are all secondary standards, so any time scale algorithm is essentially a predictor for clock *differences*. In Fig. 5, therefore, is shown one example of the frequency offset (difference) between maser ST0022 and the output of the AOG03, as measured by the all-digital measurement system and the dual-mixer-based one, AT1 in this case. The blue curve (around zero) is the difference between the same frequency offset, as measured by the two systems: it represents the combined residual noise of the two measurement systems and is obtained by calculating the difference between the red and the green curve of Fig. 5:

$$\text{double diff.} = (\text{ST0022-AOG03})_{\text{DIG}} - (\text{ST0022-AOG03})_{\text{AT1}}$$

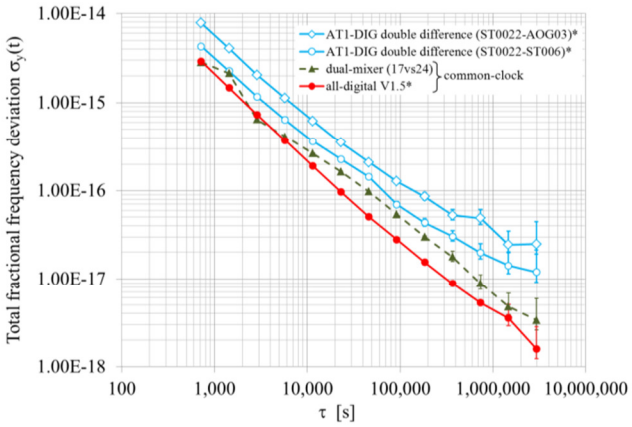
The data in Fig. 5 are representative of the frequency offsets measured between all other clocks listed in Table I: they confirm the ability of the measurement system to accurately measure phase differences evolving with time.

An evaluation of this accuracy is shown by the total fractional frequency deviations shown in Fig. 6, where the combined residual noise of both measurement systems is compared with the common-clock measurements for each one of the measurement systems. The total fractional frequency deviation for the common-clock measurements is computed from the same sets of data used to compute the TDEV shown in Fig. 4.



* Glitches removed are > 5 s and amount to less than 3•10-3 of total data points

Figure 5. Measurement results for the frequency offset (difference) between maser ST0022 and AOG03, as measured by the all-digital system (red curve) and the dual-mixer-based one (green curve). The blue curve is the difference between the red and the green curves, and it represents the combined residual noise of the two measurement systems.



* Glitches removed are > 5 s and amount to less than 3•10-3 of total data points

Figure 6. Total fractional frequency deviation computed for the common-clock measurements (same data sets used for the TDEV shown in Fig. 4, red and green curves) and for the combined residual noise of the two measuremetn systems, for two different frequency offsets: ST0022-AOG03 and ST0022-ST006. The combined residual noise is obtained by subtracting the frequency offset of each clock pair as measured by each measurement system.

In particular, two double differences are shown in Fig. 6, for two different pairs of clocks: (ST0022-AOG03) and (ST0022-ST006). The residual noise calculated through double differences is expected to be $\sqrt{2}$ above the noise of a common-clock measurement, because the noise of each pair of channels is summed in quadrature. The differences between the two double difference curves in Fig. 6 (empty circles and empty diamonds) is due to the variability between the each channel's noise floor, as shown by the difference between the results of common-clock measurements between different pairs of channels of the same dual-mixer-based measurement system.

The interesting feature of Fig. 6 is in the flicker-type behavior shown by both the double difference curves, but not by the curves based on common-clock measurements. At this time it is not clear what the cause of it is, and it is currently under investigation.

V. Conclusions and Future Work

The performance of the re-engineered, multi-channel, all-digital measurement system presently active at NIST is presented, and compared, for both common-clock performance and operational (difference clocks) performance with the dual-mixer-based system that is at the core of UTC(NIST).

Apart from validating the all-digital system as fit to be used as part of an operational time scale, the comparison between the measurements obtained from both systems offers the possibility to investigate long-term behaviors not seen previously, as shown in Fig. 6.

Future work includes reducing the residual noise for the all-digital system in order to reach the levels warranted by the prototype V1, implementing ancillary systems allowing for automated processing of the data into a time-scale algorithm, and investigating the long-term trends of both measurement systems.

Aknowledgemnts

The authors thank Judah Levine for extremely helpful discussions, regarding both the system's design and the subsequent data analysis.

***Abstract*—This paper presents a time synchronization method based on the COMPASS code measurements in combination with two-way transfer ranging, which results the clock offset between COMPASS GEO satellite and the ground station. The clock offset of COMPASS G3 satellite on board is computed by using the data observed on October 2010. In order to verify the accuracy of this method, the results are compared with the results, which are determined only by pseudo-range observation. By comparison and analysis, the following facts can be drawn. ①The precision of navigation satellite clock bias is better than 10 ns, when the clock bias is calculated by the new method .There is no systematic error between our results and clock bias deduced from precise satellite orbit. ②The new method can separate satellite orbit and clock bias, it is beneficial to researching satellite clock bias.**

I. INTRODUCTION

Time synchronization is a basic key technology and performance of a satellite navigation system, directly affecting the navigation, positioning and timing accuracy. GPS system in order to improve accuracy for time synchronization, the first request the satellite clocks are atomic clocks with high stability, also require the satellite and ground system clock on a regular basis compared with the standard clock to give the clock parameters of the satellites clocks than the relative standard clock .In GPS control and operation, or IGS system, the satellite clock correction determined using the method "orbital inversion", this method is applied to GPS, it works well. Characteristics of this method is dependent on the satellite orbit, there will be a problem in COMPASS geostationary satellites. The high-level precise orbit determination for geostationary satellites is difficult to achieve, because the tracking geometry for GEO is almost unchanged due to the geostationary feature of the GEO satellite, resulting in weak dynamical constraints.GEO satellites are often in the orbit maneuver, this time it also will be difficulties in determining the orbit of the satellite. So clock correction determined based on the satellite orbit will be a problem. This paper presents a time synchronization method with the combination pseudo-range and two-way transfer ranging data, free from influence of the orbital maneuvering to determine the satellite clock correction.

Two conventional GEO tracking techniques are the pseudo-ranging and the transfer ranging. The L-band downlink navigation signal is received by the receiver and the pseudo-range is observed with clock corrections of both the satellite and the receiver. The transfer ranging is a two-way ranging mode. The C-band ranging signal from a ground station is transmitted by a transfer onboard GEO satellites designed for communication, and is also received by the station, without clock corrections in the ranging data.

This paper proposes a new method which directly combines the two-way transfer ranging data and code pseudo-range data to determine clock correction of the satellite and the ground station. This combined solution haves the advantages, i.e. a high accuracy clock correction free from satellite orbit. Section 2 of this paper will describe the algorithm and methodology used for the combination. In section 3, this direct method will be applied to COMPASS G3 in order to quantify its efficiency, advantages and limitations.

II. COMBINATION STRATEGY

The C-band transfer ranging is a two-way ranging mode. Ranging signals are emitted by a transfer tracking station, transmitted by the transponders onboard a GEO satellite and the transmitted signals are received by the original tracking station to realize the distance measurement between GEO satellite and tracking station. Ignoring the delay correction, can be written as

$$\rho = \frac{\tau}{2} c$$

where c is the speed of light.

For the L-band pseudo-range, the signal propagation time between a satellite and a receiver is determined by correlation processing between the local receiver code and the pseudo-range code of the satellite. To accurately determine the distance from the satellite to station, the satellite clock and the receiver clock must maintain a strict synchronization, which is difficult to achieve in practice. As the satellite clock and receiver clock are not synchronized, so the pseudo-range is observed with clock corrections of both the satellite and the receiver, which is equal to the measured distance from the satellite to the receiver plus two clocks correction, omitted delay correction, can be written as

$$\rho^{'} = \rho + c\left(\Delta t_r - \Delta t_S\right)$$

Where $\rho^{'}$ is the pseudo-range, Δt_r the receiver clock offset, Δt_s satellite clock offset.

Since the two-way transfer range directly determine the distance between the satellite and the station, and without clock error information. If the two-way transfer ranging tracking station and the COMPASS tracking receiver using the same clock, at the same time and the same site to tracking the same satellite to attain distances between satellite and stations. So

$$c\left(\Delta t_r - \Delta t_s\right) = \rho^{'} - \rho$$

It can be seen from the above equation as long as there are transfer ranging and pseudo-range at the same ground station, it can directly be access the clock correction of satellite and ground station.

Combine two-way transfer ranging with pseudo-range to achieve time synchronization must be processing on transfer ranging and pseudo-range data, including synchronized record timestamp of two observational data, error correction, and the antenna of the L-band receiver and C-band transfer ranging system convert to the same center corrected.

A. Error correction

The pseudo-range measurement model is

$$\rho^{'} = \rho + c\left(\Delta t_r - \Delta t_s\right) + \Delta^{ion} + \Delta^{trop} + \Delta^{sagnac} + \varepsilon$$

where Δt_r is the clock correction of a station and Δt_s is the clock correction of a satellite, Δ^{trop} is tropospheric delay, which has nothing to do with the signal frequency , and the values of troposheric delay of two-way ranging are canceled out each other. Δ^{ion} is ionospheric delay, and here the dual-frequency ionosphere-free combination of pseudo-range observations is used. Δ^{sagnac} is the sagnac effect correction，which is directly corrected by the formula from the reference[1]. ε is the observing noise.

The two-way transfer range measurement model is

$$\tau c = 2\rho + \Delta_{up}^{ion} + \Delta_{down}^{ion} + \Delta_{up}^{trop} + \Delta_{down}^{trop} + \left(I^e + I^r\right)c + \tau_s c + \varepsilon$$

where R_{up} is the uplink geometric distance between the satellite and the station, R_{down} is the downlink geometric distance between the satellite and the station, we suppose $R_{up} = R_{down} = \rho$, τ_s is the instrumental delay of the satellite transponder , I^e and I^r are the signal instrumental delays for transmitter and receiver, which can be determined by a special survey. Δ_{up}^{trop} , Δ_{down}^{trop} , Δ_{up}^{ion} and Δ_{down}^{ion} are the uplink and downlink tropospheric delay and ionospheric delay respectively, the ionospheric errors are corrected by using global precise ionosphere delay model provided by CODE. The tropospheric delay has nothing to do with the signal frequency, then uplink and downlink can be approximately considered equal， when combination with pseudo-range, the tropospheric delay can be cancelled out， and ε is the observing noise. The upward and downward sagnac effects for two-way transfer range are the same with opposite signs, so they can be canceled out each other.

B. Timestamp synchronization of observation records

The recorded timestamp of two-way transfer range is the time for UTC (converted into GPST) of ranging signal emitted from the MODEM, marked as t_{tw}^{0}, while the recorded timestamp of pseudo-range is the received time for BDT (also converted into GPST) of the signal by COMPASS receiver, marked as t_{sw} ,and such recorded timestamps of two observations must be translated into the same basis. Two-way ranging signal transmission time is converted to the signal reception time $t_{tw} = t_{tw} + \tau$, where τ includes instrumental delays, and the errors are negligible if the accuracy of time synchronization is 1 nanosecond. The time scale only effects the observing time. Typically, t_{tw} and t_{sw} are not synchronized. In order to solve the integration of two-way transfer range and pseudo-range, synchronization correction must be done. As a basis of t_{sw}, the two-way range is interpolated into t_{sw} to form virtual two-way range as a reference timestamp using t_{sw}, and two observing data in the same timestamp are attained, where a 6-order Lagrange interpolation formula is used.

C. Correction for centering between transfer ranging tracking station and COMPASS receiver

Although the geometry distance of the satellite and the ground transfer station ρ and pseudo-range only including clock corrections of both satellite and the receiver ρ' above has been calculated, transfer station and the receiver are not at the same absolute position on the ground. Correction for centering between transfer ranging tracking station and COMPASS receiver must be carried out. The formula to correct for centering is

$$\Delta\rho = \frac{\rho_x \Delta E + \rho_y \Delta N + \rho_z \Delta H}{\sqrt{\rho_x^2 + \rho_y^2 + \rho_z^2}}$$

Where (ρ_x, ρ_y, ρ_z) is the satellite position vector in the station's coordinate system, $\Delta E, \Delta N, \Delta H$ are ,respectively, relative to the center of the receiver east, north, and up deviation of the transfer station center.

In the calculation, the satellite coordinates calculated using broadcast ephemeris; $\Delta E, \Delta N, \Delta H$ can be calculated

$$\begin{bmatrix} \Delta E \\ \Delta N \\ \Delta H \end{bmatrix} = \begin{bmatrix} X_{compass} - X_{tw} \\ Y_{compass} - Y_{tw} \\ Z_{compass} - Z_{tw} \end{bmatrix}$$

where $(X_{compass}, Y_{compass}, Z_{compass}), (X_{tw}, Y_{tw}, Z_{tw})$ are the coordinates of COMPASS receiver and coordinates of transfer tracking station in the ITRF 2000 coordinate system, respectively. M is transformation matrix from ECEF to station coordinate system, the specific expression see reference [2].

Due to the geostationary feature of the GEO satellite, the change of correction for centering is up to 2 ns, broadcast ephemeris is not used to correct for centering, only elevation and the distance between transfer station and pseudo-range receiver are used to correct for centering. This helps separation of the satellite orbit and clock errors. From this perspective, the integration solution does not rely on the satellite orbit, and the error of the orbit of the satellite will not be introduced into the satellite clock error.

III. COMPUTATION AND ANALYSIS

A. Experimental device configuration

Relying on transfer ranging tracking network in National Time Service Center, Chinese Academy of Science, the domestic tracking network of the COMPASS satellite navigation system are established. In addition to each tracking station equipped with geodesic receiver, high-performance atomic clocks and a two-way satellite time transfer (TWSTFT) system are equipped. Test system configuration as shown in Figure 1.

In tracking stations, the output of cesium atomic clock, a 10MHz signal of high stability performance, is send to the receiver.

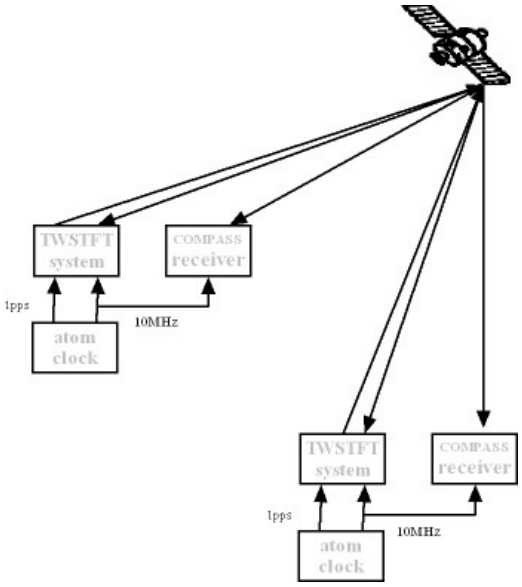

figure1. Test system configuration

B. *Experimental results and analysis*

The experimental data were from the Lintong tracking station from 2nd to 7th October, 2010. The clock error of satellite G3 and the Lintong ground station is calculated with the following two strategies. Solution ①: our new combined method; Solution②: deduced from the precise satellite orbit, which is determined by pseudo-range observations. At this time interval to evaluate the orbit accuracy based on the pseudo-range data, we used the SLR data of Changchun station to evaluate the orbit radial error. The maximum was less than 1m. So the error of clock bias between satellite and ground computed by solution ② is relatively small as a standard of comparison reference. Finally, the clock errors calculated by two solutions were directly compared.

During the test calculations, first the clock error was computed using solution①, then the clock error corresponding to timestamp was calculated by solution②, and the last two results were compared directly. Table 1 shows the comparison of the two results. Fig2-4 shows the results of October 5th -7th, the upper are the results using two solutions, the lower are the two solutions comparison residuals.

The compared results show that: from October 2nd to 4th, there are big systematic errors, taking into account that the compared results contain not only clock offset error of solution ①, but also the clock bias error of solution ②. We need further analyze whether the GEO satellite maneuvers occur these days or the change of the instrument delays and so on.

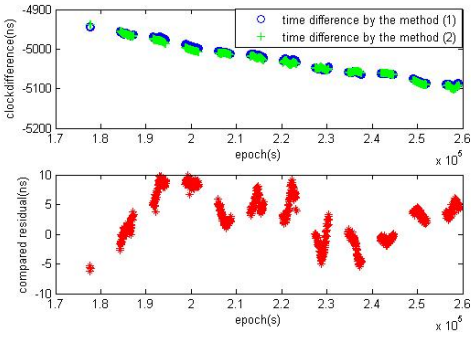

Fig2. the results on October 5th

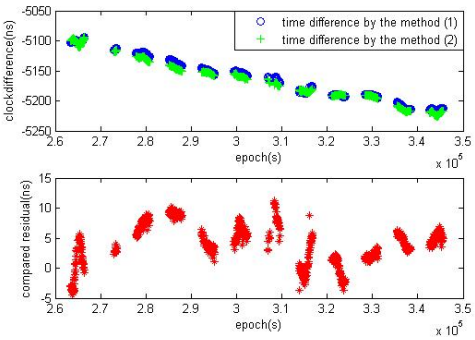

Fig3. the results on October 6th

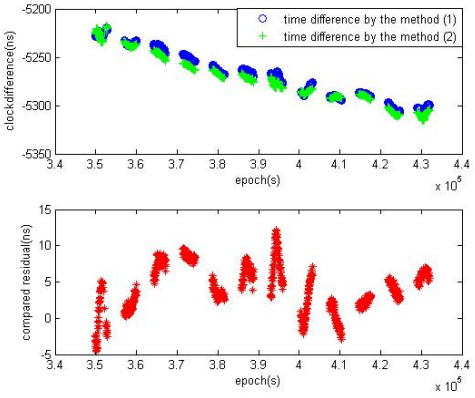

Fig4. the results on October 7th

From October 5th to 7th, the comparison shows that there are some systematic errors, which have not been corrected completely, such as the ionospheric delay. we need further analysis.

IV. CONCLUSIONS

From the analysis and comparison above the following conclusions can be drawn:

1. Combination of two-way transfer range and pseudo-range data can be directly measured the clock errors of satellite and ground station;

2. Time comparison between the navigation satellite-borne clock and the ground system standard clock can be achieved by integration of

two-way transfer range data and pseudo-range. As the GEO satellite needs maintain its position relative to the equator in some time intervals, it must be adjusted regularly. Solution ② is not reliable during and after an orbital maneuver, because the orbital errors determined affect the satellite-borne clock bias measured, it could harm the separation of the satellite coordinates and on-board clock errors. The use of integrated solver ④ to determine the satellite clock error reflects the actual satellite clock error. This can be based on navigation satellite clock error prediction to improve the real-time navigation and positioning accuracy.

This paper presents the measurement method of clock errors of satellites and ground stations based on combination two-way transfer range with pseudo-range observations. The preliminary test results show that the method can weaken the interaction of GEO navigation satellite coordinates and clock offsets, determining the satellite clock errors using a single tracking station. Taking into account the carrier phase measurement accuracy is far higher than the pseudo-range observation accuracy, in future work, we will further develop integration of two-way ranging and carrier phase observations to measure clock errors of the GEO navigation satellite.

***Abstract*— The signal-to-noise ratio in the detection of a single ion is one of the determining factors in the speed of the detection of the ion's internal states. Its value defines the necessary interrogation time to distinguish between an ion in the "on" and an ion in the "off" state. The improvement of the detection signal by means of active optics is a new approach in single-ion experiments. They accompany further progress in the stabilization of the clock laser for the single ion interrogation.**

I. Introduction

The frequency stability of an optical frequency standard can be quantified by the evaluation of the Allan deviation [1], where the stability value depends on the interrogation time, the cycle time of the measurement as well as the signal-to-noise ratio (SNR) which can be realized throughout the probing of the clock transition.

Single ion detection is always carried out on the cooling laser's wavelength as it scatters a maximum of photons. Today, trap structures are getting smaller and smaller and even with tightly focused laser beams, scattered light from the metallic electrodes contributes to the background light level. A high quality detection objective [2] as well as spatial filtering in the imaging process are among the stringent requirements for the detection of a single trapped ion.

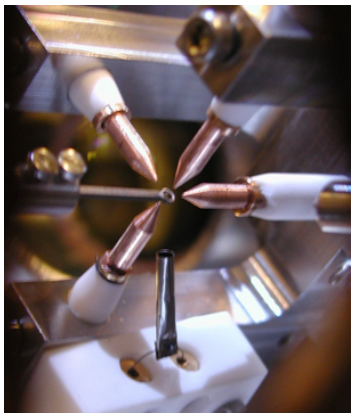

Fig. 1. Miniature ion trap

A perfect Gaussian beam of 100 μW focused to a waist diameter of 20 μm in the centre of a trap (even if it is a miniature trap) should give a scattered light level of less than one photon per second collected by the optical detection solid angle. However, it can be observed in essentially all single ion trap experiments ([3], and references therein) that the background level is typically larger than the photomultiplier's dark count rate (10 photons per second). Even with high-quality UV optics (a large majority of single-ion experiments has a cooling laser in the blue or near UV) in many experiments a deformation of the laser-beam can be observed, as well as an additional halo due to scattering in the optics.

Aberrations in a beam have been corrected with active (or adaptive) optics (AO) elements at multiple occasions since seminal works in high-intensity lasers [4] and of course in astronomy [5]. Moreover, it has been shown that strong scattering in optics can be corrected by an AO element [6].

We propose the use of an AO element to optimize the SNR in the detection of a single trapped ion. In this manuscript we will develop the necessary requirements and envisaged solutions. We suppose that aberrations in our system do not show temporal fluctuations, we will thus concentrate on means of active optics rather than adaptive.

II. Cooling and detection of a single ion

The interrogation of a single ion as a frequency standard is made with the help of the electron-shelving technique [7], the interrogation statistics is built by sequential probing of the fluorescence state of the ion which indicates whether the ion is in the "on" (scattering photons) $4S_{1/2}$-$4P_{1/2}$-$3D_{3/2}$ - cycle or shelved in the dark ("off") $3D_{5/2}$-state (cf. energy level scheme in Figure 2).

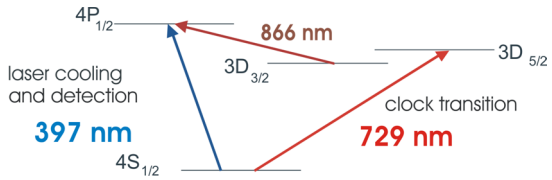

Fig. 2. Scheme of the first energy levels of $^{40}Ca^{+}$

Quantum jump statistics are presented in Figure 3, the right part of this figure shows the distinction between "on" and "off" state. The higher the SNR the faster the interrogation procedure can be. This value conditions the cycle time in the interrogation of the single ion for all types of high-resolution experiments.

In our experiment, a frequency-doubled titanium-sapphire laser at 397 nm is used for laser-cooling the ion on the $4S_{1/2}$-$4P_{1/2}$ electric dipole transition. This laser is transported onto

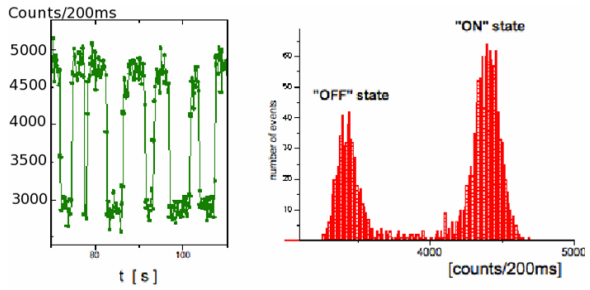

Fig. 3. Quantum jump statistics in the interrogation of a single trapped ion

the ion experiment by a single-mode optical fiber, which also spatially cleans the laser beam. The laser is then split in three beams in order to dispose of different probing axis. This separation is done by half-wave plates in conjunction with polarization beam splitter cubes. Each beam is then focused by a 50 mm-diameter achromat lens into the vacuum vessel to a waist of about 20 μm radius.

A. Preliminary characterization of the cooling laser

In order to obtain a quasi-perfect beam in the plane of the single ion, i.e. a Gaussian beam focused on a waist of 20 μm, it is necessary to measure the deformations of this beam as well as to estimate the scattering of this beam by the optical elements of the system, before applying eventual corrections. Scattering in optics has been suppressed by spatially filtering with a pinhole in the image plane of the laser waist and is considered to be negligible in the final background detected.

In order to identify the origin of the unusually high background of scattered light in our detection system, a realistic description of the beam profile is required, which considers the beam not only as a perfect Gaussian envelope but as a Gaussian field amplitude with an aberrated wavefront. This approach has to be made experimentally as well as theoretically. The corner stone of the description of an aberrated beam is the decomposition of the wavefront surface on the orthonormal basis of the Zernike polynomials.

Hence, a beam characterization was carried out on our set-up by different means. Analysis were made with two types of wave-front sensors based on different technologies (Shack-Hartmann and phase-shearing), and imaging with a camera is under way. The presence of aberrations in the laser beam can be quantitatively described with the Strehl ratio, or in terms of encircled energy, which is the intensity deposited in a given area. Indeed, the fiber output shows an almost perfect Gaussian

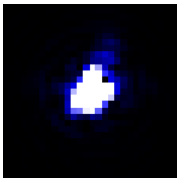

Fig. 4. Deformed laser beam as measured with all optical elements inserted in the beam-line

beam, with a Strehl ratio higher than 95%. Travelling through the optical system, the beam is then deformed, and the Strehl ratio drops below 80% at the site of its focus on the ion, as can be seen in Figure 4. Monitoring the beam by a CCD camera is a complementary method of waist characterization. For reasons of acquisition dynamics, the center of the beam has to be masked in order to reveal residuals in the wings.

Correction of the observed distortions in the beam profile can be carried out by different means, actually, several types of AO corrective elements are available : deformable mirrors (DM), spatial light modulators (SLM) and optical valves (OV). While DM have a number of actuators typically limited to a few hundreds, and therefore present a limited spatial resolution, they show a modulation depth of typically a few micrometer. On the other hand, spatial light modulators are LCD devices with an important number of pixels (on the order of 10^5), their main drawback is the important diffraction patterns they produce. Finally, OV probably present the best spatial resolution, but the amplitude dynamics of the correction is rather weak.

Only the precise characterization of the laser-beam with the identification of the induced perturbations allows to determine the spatial resolution and amplitude dynamics necessary for the choice of the AO element adapted to his application.

The influence of aberrations in the beam on the noise level in the single-ion detection has been evaluated with the use of a deformable mirror. This 97-actuator device with a mirror diameter of 13.5 mm was set-up in normal incidence at the entrance of the vacuum vessel. Preliminary measurements have demonstrated the link between the SNR and wavefront modifications. The measured noise level is represented on the graph in Figure 5 as a function of induced aberrations in the beam.

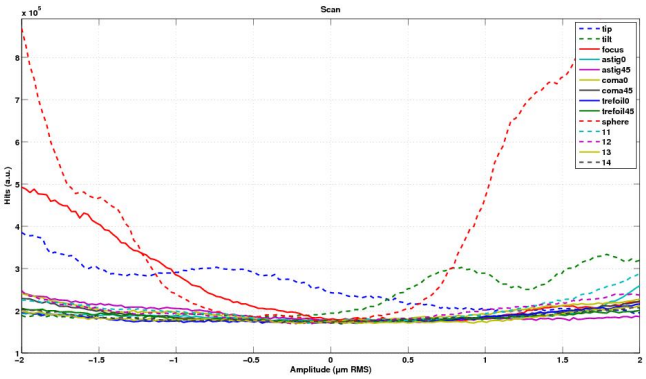

Fig. 5. Noise level in the optical detection line as a function of the amplitude of aberration, decomposed for the different Zernike polynomials

B. Simulation of the cooling laser beam

In parallel to the experimental characterization of the optical set-up, a quantitative analysis of its defects based on simulations of the full optical system up to the trap is carried out. Using an optical design software (Zemax), we can precisely reproduce each optical element (plane mirrors of finite size,

achromatic lenses, pinholes and the entrance viewport of the vacuum chamber) and predict the amount of aberrations that affects the beam in the end, considering the consequences of chromaticity, tilting and off-centering of the optics. The results of this study consist of a qualification and a quantification of the optical defects of the system decomposed on the basis of Zernike polynomials. For each polynomial of this basis, the depth value of the deformation in units of λ is obtained and this computer assisted study, validating the experimental observations, provides us with a versatile tool to precisely understand and even predict the effects of the modifications introduced in the set-up (especially modifications of the angle of incidence).

A second type of simulation is based on the measurement of the Zernike coefficients in the pupil plane of the system. With the input of the measured coefficients in a numerical program and the propagation of the aberrated field using the Fresnel formalism, it is possible to deduce the intensity profile (point-spread function) of the beam, at the site of its focus inside the trap. Figure 6 shows the simulated profile of the focused aberrated Gaussian beam with 0.4 μm of coma in x and y directions and -0.2 μm of 3rd order spherical aberration. This work directly allows to quantify the percentage of light that can be intercepted and diffused by the trap structure and to understand the consequence of each aberration on the detection noise we observe.

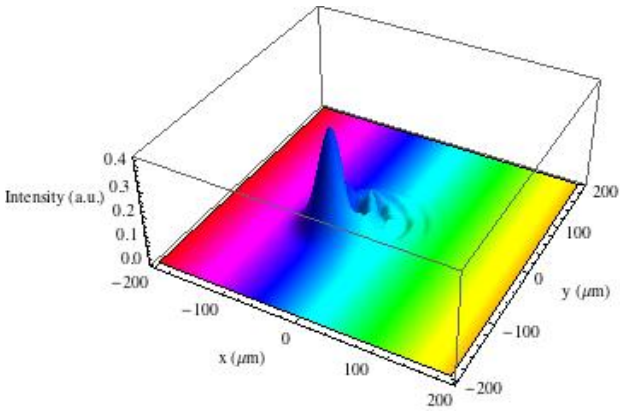

Fig. 6. Simulated point-spread function of the aberrated Gaussian beam with 0.4 μm of coma and -0.2 μm of 3rd order spherical aberration. Note that the beam waist is approx. 20 μm and the trap's inner diameter is 190 μm.

C. Feedback algorithm on the AO element

In astronomy the feedback on the active optics element is made by a two-dimensional signal either from a wavefront analyser or from a CCD camera, located at a reference position. The presented laser-ion interaction experiment could allow to test correction algorithms based on the only signal and noise values. Using these two 1D signals for correction falls into the category of the novel approach of wavefront sensorless adaptive optics [8].

An intermediate approach would be to use a classical type of correction, for instance a pre-registered correction map, for a first rough adjustment, and to apply corrections based on 1D signals only around this pre-optimized solution. The main interest of such a method is that it could widely increase the correction bandwidth. Moreover, in case of success, this would also reduce the requirement of a permanently installed wavefront analyser on the experiment.

III. Clock laser stabilisation

To probe the narrow, electric quadrupole transition $4S_{1/2}$ - $3D_{5/2}$ of the Ca^+-ion at 729 nm, the spectral linewidth and the frequency stability on a 1-second time-scale of the clock laser have to be of the same order of magnitude as the clock transition's natural linewidth (below 1 Hz, [9]).

Our home-built titanium-sapphire laser at 729 nm is pre-stabilized onto a low-finesse (≈ 1000) Invar-cavity in a 10^{-6}-vacuum by the Pound-Drever-Hall technique resulting in a linewidth of the order of a few kHz. Further reduction of the linewidth and in particular frequency stabilisation is made by locking to a vertically mounted, high-finesse ULE cavity of 150 mm length. This cavity has been numerically and mechanically optimized [10], to render it vibration-insensitive to a maximum extent. Fused silica mirrors are optically contacted to the ULE-spacer, the finesse of this cavity has been measured to be 140 000.

The cavity is surrounded by three thermal screens of polished aluminum, mounted in a vacuum-vessel. This set-up is enclosed in a box, with an active thermal control and mounted on a passive vibration isolation platform (see Figure 7). Locking of the clock laser on this cavity is made by a commercial locking electronics (Toptica).

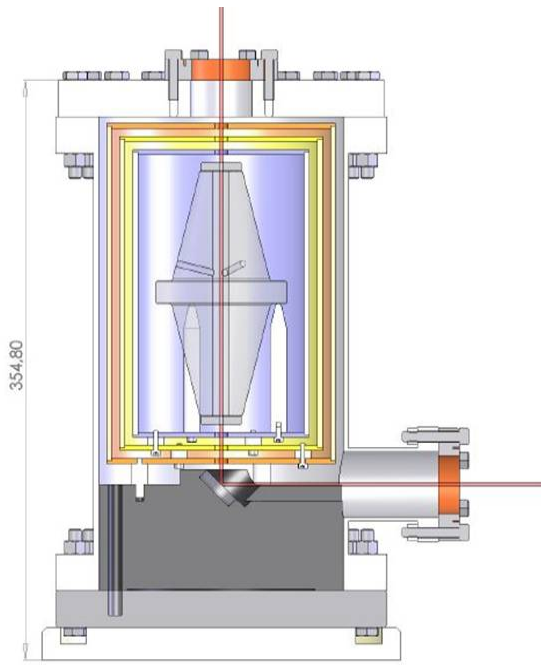

Fig. 7. The high-finesse cavity is thermally and vibrationally stabilized by different means, see detailed description in the text

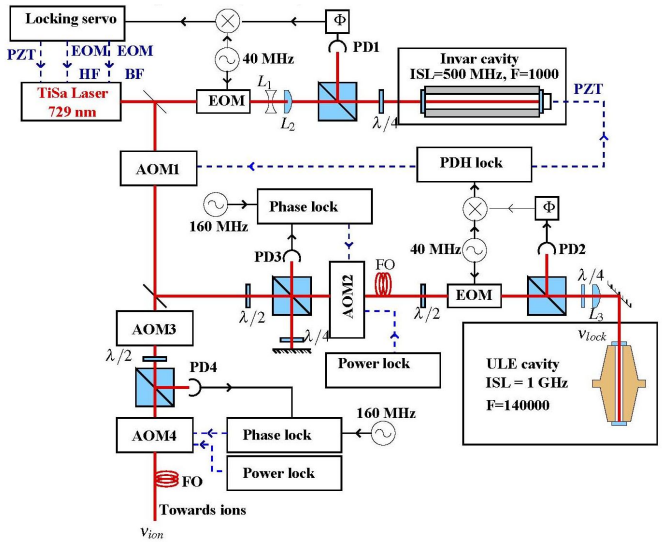

Fig. 8. Clock laser stabilisation scheme

IV. Conclusion

The use of an active optics device to control the wavefront and intensity profile of a cw laser interrogating single atoms in a trap opens the way to a tailored interaction of the electromagnetic wave with the atom. This approach will help to increase the SNR and thus optimize the frequency stability of an atomic clock.

Additional advantages are expected for the implementation of a similar device for the probing of single ions in micro- and surface traps, which have even smaller dimensions, and which are extremely sensible to the illumination by ultraviolet light. Addressing of individual ions in ion chains [11] is a supplementary application of the use of AO devices, allowing a 'real-time' correction of laser beams probing ions at different sites.

***Abstract*— We present the setup of a cryogenic single-crystal silicon optical cavity with a potential thermal noise floor below 10^{-16}. The system comprises a vibration-free cryostat based on gaseous nitrogen as coolant.**

Thomas Kessler
May 30, 2011

I. Introduction

The stability of optical clocks is currently limited by the performance of the interrogating laser system. The reference cavities used to stabilize the laser suffer from thermal noise on a level of fractional instability of $10^{-16} - 10^{-15}$ at one second [1]–[3]. To overcome these limits a sub-Hz laser system based on a monocrystalline silicon resonator is being developed with expected instability below 10^{-16}. To avoid a large sensitivity to temperature fluctuations, state-of-the art cavities are typically operated close to the zero-crossing of the coefficient of thermal expansion of the cavity material. For silicon, the zero-crossing lies at approximately 124 K [4], therefore requiring construction of a dedicated cryostat. As an additional requirement the maximum accelerations induced by the cryostat should not exceed 1 μg.

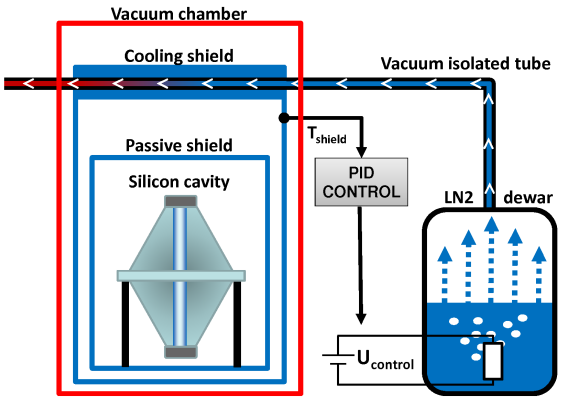

Fig. 1. Schematic sketch of the cryostat. The outer shield is cooled by nitrogen gas evaporated from a dewar.

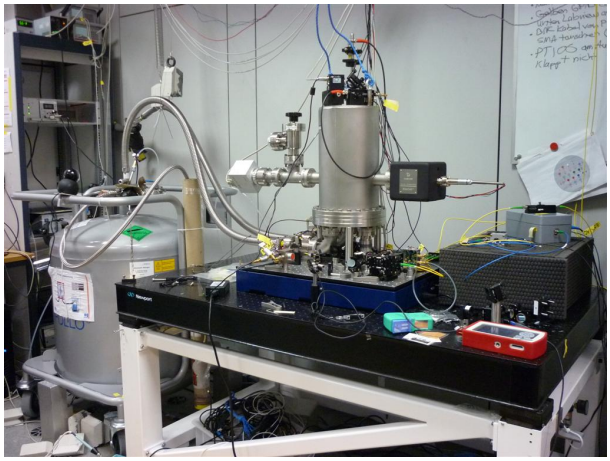

Fig. 2. Photograph of the cryostat.

II. Experimental Setup

The cryostat has been developed in a collaboration between PTB and JILA. A sketch of the setup is shown in figure 1. The cavity is held by three rods which are made of Teflon to suppress heat exchange with the base. To avoid refractive index fluctuations and for thermal insulation, the cavity is placed in a vacuum chamber. The vacuum chamber is set up on a vibration isolation table. The outer shield of the cryostat is actively cooled by a flow of nitrogen gas evaporated from a dewar. The temperature of the shield is obtained by a Platinum sensor and fed into computer-controlled feed-back system. Additional thermal insulation of the cavity from its surroundings is reached by a gold-plated passive copper shield placed between the cavity and the outer shield.

Figure 2 shows a photograph of the complete setup. The gas is evaporated from a 200 liter liquid nitrogen dewar and guided by superinsulated vacuum tubing to the cryostat. The tubes are suspended by additional weights for improved vibration isolation. A fiber laser operated at a wavelength of 1.5 μm is locked onto the cavity. All free-space optics are placed on the vibration-isolation platform to minimize optical paths. In thermal equilibrium a consumption of 1 liter of liquid nitrogen per hour is achieved with residual vibrations well below the

978-1-61284-110-6/11/$26.00 ©2011 IEEE

required specification. The thermal shield suppresses residual Temperature fluctuations of a few mK at the cryostat down to μK level for the cavity.

III. Conclusion and Outlook

A vibration-free cryostat has been built for operation of a single-crystal silicon cavity at a temperature of 124 K. First tests indicate that the performance of the cavity will not be limited by the cryogenic enviroment and therefore a stability below 10^{-16} seems feasible. After the completion of the characterization of the cryostat we will focus on a direct frequency comparison with state-of-the-art room-temperature stable cavities to explore the potential of the silicon cavity.

***Abstract*—A method to measure the absolute frequencies of molecular transitions in the mid-infrared region is presented. The method is based on a mid-infrared cw optical parametric oscillator, which can be used for sub-Doppler molecular spectroscopy at ~ 3.4 μm while being phase-coherently linked to an optical frequency comb in the visible/near-infrared.**

I. Introduction

Absolute optical frequency measurements can be done relatively easily in the visible and near-infrared using self-referenced, octave-spanning optical frequency combs (OFCs) based on mode-locked femtosecond lasers [1, 2]. The task is significantly more difficult in the mid-infrared. Despite the recent remarkable progress in the development of mid-infrared frequency comb generators based on femtosecond optical parametric oscillators [3, 4], most optical absolute frequency measurements reported so far at wavelengths longer than 2.5 μm have been done using continuous-wave techniques. The advantage of the cw techniques is that they allow spectroscopic measurements to be done with sub-Doppler resolution without spectral filtering, and in some cases also without an optical power enhancement cavity. As an example, Takahata et al. measured the absolute frequencies of several tetrahedral fine structure components of the P(6) and P(7) lines of the ν_3 band of methane using a narrow-linewidth mid-infrared beam that was produced by difference frequency generation (DFG) from two near-infrared laser beams [5]. The absolute frequencies of the mid-infrared transitions were obtained by referencing the two near-infrared beams to an OFC based on an Er-doped fiber laser. The measurement can alternatively be referenced to a mid-infrared OFC that has been generated by DFG from a near-infrared OFC [6, 7]. Also in this case, a cw mid-infrared source is required to probe the molecular transition, owing to the low power of the mid-infrared OFC obtained by DFG. Another technique reported earlier is to use a mid-infrared quantum cascade laser for spectroscopy and to link it to a visible/near-infrared OFC by sum-frequency mixing with a near-infrared laser [8].

Here we present a new technique for the measurement of absolute frequencies of molecular transitions in the mid-infrared. The technique is based on a cw optical parametric oscillator (OPO), which can be used for sub-Doppler mid-infrared spectroscopy. A phase-coherent link between the OPO and a visible/near-infrared OFC is established through the pump and signal beams of the OPO. This method resembles another one previously reported by Kovalchuk et al., in which a frequency comparison between a 3.39-μm CH_4-stabilized HeNe laser and a 532-nm I_2/Nd:YAG laser was demonstrated using a combination of pump-enhanced cw OPO and Ti:sapphire OFC [9]. Unlike any of the previously reported methods, our solution is based on a singly-resonant cw OPO, which produces high output power and easy wavelength tuning in the mid-infrared. This makes the experimental setup for frequency-comb referenced sub-Doppler spectroscopy simple. A particular advantage of our method is that the carrier-envelope offset frequency of the OFC does not need to be known or stabilized. This, and other characteristics of the method are described in more detail in the following section. The experimental setup is presented in Section III, and the results in Section IV.

II. Method

The basic principle of the method is to use a continuous-wave optical parametric oscillator (cw OPO) to phase-coherently link the mid-infrared and the visible/near-infrared regions of the optical spectrum. The OPO is

978-1-61284-110-6/11/$26.00 ©2011 IEEE

pumped by a near-infrared laser at frequency ν_p. Through a parametric nonlinear frequency conversion process it produces two output beams: a near-infrared beam called signal (ν_s), and a mid-infrared beam called idler (ν_i). The frequencies of the three optical beams involved in the parametric process are linked to each other by the law of energy conservation,

$$\nu_i = \nu_p - \nu_s. \quad (1)$$

According to (1), the absolute frequency ν_i of the mid-infrared beam can be determined by measuring frequencies ν_p and ν_s. This can be done using a femtosecond frequency comb generator. A typical mid-infrared cw OPO emitting at $\lambda_i \sim 3$ μm is pumped with a 1-μm laser, which sets the signal wavelength to $\lambda_s \sim 1.5$ μm [10]. Both λ_p and λ_s are therefore within the range of a typical near-infrared OFC based on an Er-fiber laser (0.95-2.1 μm) and can easily be measured. Another approach, which is the one we have used in this work, is to frequency double the pump and signal frequencies so that they can be measured with a Ti:sapphire-laser OFC that typically extends from 0.5 to 1.1 μm. The measurements can be done with a very high accuracy if the OFC is phase-locked to a microwave frequency standard. If that is the case, then also the mid-infrared frequency becomes referenced to the same standard, and a phase-coherent link between the mid-infrared and microwave regions is established (in addition to that between the mid-infrared and visible/near-infrared).

To have a closer look at the method we first assume an OFC generator (such as the Er-fiber comb) that can be used to directly measure the pump and signal frequencies of the OPO. The OFC consists of equidistant peaks, whose frequencies are

$$f_m = f_{ceo} + mf_{rep}, \quad (2)$$

where m is an integer, f_{rep} is the laser repetition rate, and f_{ceo} is the (carrier-envelope) offset frequency. The beat frequency f_p between the OPO pump frequency and the nearest comb peak m_p is then

$$f_p = f_{ceo} + m_p f_{rep} - \nu_p. \quad (3)$$

For the sake of clarity, we assume that the pump frequency is measured against the comb peak that is on its high-frequency side (so that $f_p > 0$). In a similar manner, beat frequency f_s between the OPO signal frequency and the nearest comb peak m_s (again on the high-frequency side) is

$$f_s = f_{ceo} + m_s f_{rep} - \nu_s. \quad (4)$$

Using (1)-(4), we get the absolute frequency of the mid-infrared idler beam as

$$\nu_i = (f_s - f_p) + (m_p - m_s) f_{rep}. \quad (5a)$$

In practice, the two beat frequencies can be counted with frequency counters referenced to a stable frequency standard. The difference $m_p - m_s$ of the comb mode numbers can be determined by measuring the pump and signal frequencies with an accurate wavelength meter. The repetition rate f_{rep} is phase-locked to a microwave frequency standard and hence known with high accuracy. It is important to note that the measurement is independent of the offset frequency f_{ceo}. This simplifies the experimental setup, since f_{ceo} does not have to be stabilized or measured. (In a typical octave-spanning OFC, in which the spectrum is broadened using a microstructured fiber, slow degradation and misalignment of the fiber makes long-term stabilization of f_{ceo} more difficult than stabilization of f_{rep}. Long-term operation of the comb is therefore easier if the offset frequency does not require stabilization).

If the OFC used in the experiment is based on a Ti:sapphire laser instead of an Er-fiber laser, the measurement procedure remains the same but all optical frequencies are replaced by their frequency-doubled counterparts. That is, instead of (4a) we get

$$\nu_i = \tfrac{1}{2}[(f_{2s} - f_{2p}) + (m_{2p} - m_{2s}) f_{rep}], \quad (5b)$$

where f_{2p} and f_{2s} now refer to the beat frequencies between the comb and the second harmonic frequencies of the OPO pump and signal, respectively. The absolute frequency ν_i can be unambiguously determined also in this case. Although the pump laser frequency is already within the spectral coverage of the Ti:sapphire OFC, frequency doubling of both the pump and the signal is done in order to cancel out f_{ceo}.

III. Experimental Setup

A. Optical Frequency Comb

The MIKES frequency comb generator used in this work is described in detail in a previous publication [11]. A 15-THz wide comb centered at ~800 nm is generated in a mode-locked femtosecond Ti:sapphire laser. The ~1 GHz repetition rate of the laser is referenced to an active hydrogen maser (Kvarz CH1-75A). The offset frequency f_{ceo} does not have to be stabilized or monitored, since the measurement of ν_i is independent of it.

The maximum output power of the Ti:sapphire laser is 0.7 W when pumped with 5.5 W of 532-nm cw light from a frequency-doubled Nd:YVO_4 laser. For the experiments discussed here, the output power was divided into two

branches. Most (85%) of the power was coupled through a 1-m long microstructured fiber that broadens the comb over a full octave. This comb was optimized for 532 nm in order to measure the second harmonic frequency of the OPO pump laser. The remaining 15% of the total power of the Ti:sapphire laser was coupled into another microstructured fiber, which was selected so that the original comb produced by the laser was broadened to cover the wavelengths from approximately 760 nm to 860 nm. This branch was used to measure the second harmonic of the signal frequency.

B. Optical Parametric Oscillator

The cw optical parametric oscillator used in this work is schematically shown in Fig. 1. It is based on our previous design, which is described in detail in a previous publication [10]. The OPO is pumped at $\lambda_p = 1064$ nm with an Yb fiber laser system, which produces a maximum output power of 15 W. The output beam of the pump laser is linearly polarized and has an instantaneous linewidth of ~ 100 kHz. The pump beam is focused into a nonlinear crystal, which is placed within the OPO cavity. The size of the pump beam waist in the crystal is 42 μm, which corresponds to a focusing parameter of $\xi_p \sim 2.3$ [10]. The crystal is 5% MgO-doped periodically poled lithium niobate (MgO:PPLN). The poling period used in this work was 30.5 μm. Both ends of the crystal are antireflection coated for the pump, signal, and idler wavelengths. The crystal is 1 mm thick and 50 mm long, and it is placed in a copper oven. The oven temperature can be stabilized to any value between 15 and 200°C with 10 mK precision using Peltier elements.

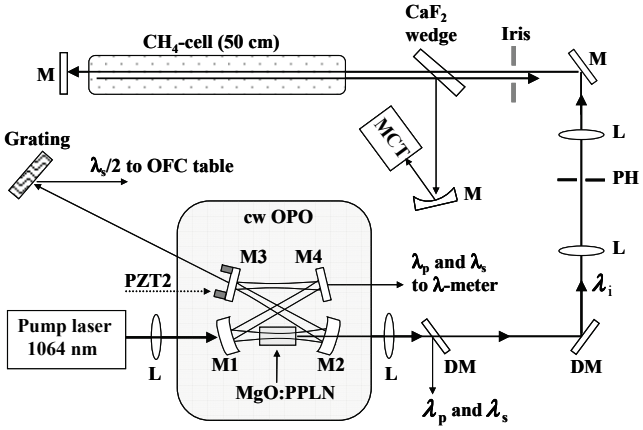

Figure 1. Schematic of the cw OPO (on gray background) and of the CH_4 spectrometer, which is described in Section III.C. The abbreviations are: DM – dichroic mirror, L – lens, M – (gold) mirror, and PH – pinhole (diameter 200 μm).

The OPO cavity is formed by 4 mirrors that are highly reflective for the signal wavelength, and transparent for the pump and idler wavelengths. The cavity is therefore singly resonant at the signal wavelength. A bow-tie ring geometry is used, and the dimensions of the cavity have been chosen so that the focusing parameter of the signal beam is matched with that of the pump beam ($\xi_s \sim \xi_p \sim 2.3$). The length of the cavity corresponds to a free-spectral range (FSR) of 580 MHz.

The first version of our experimental setup was designed for accurate spectroscopy at wavelengths between 3.2 and 3.4 μm (ν_3 band of methane). The OPO wavelength can be tuned within this range by adjusting the MgO:PPLN temperature. Gaps in the tuning range are unavoidable when using the temperature tuning method, but they can be easily covered with pump laser tuning [10]. Fast and mode-hop-free tuning of the pump laser by more than 90 GHz can be done by applying a voltage to a piezoelectric actuator that controls its cavity length. Fine tuning of the idler frequency can also be done through the signal beam by scanning the OPO cavity length using a piezoelectric actuator (PZT2 in Fig. 1), which is glued on one of the cavity mirrors. This method provides a maximum tuning range of approximately one FSR.

The single-mode output power of the OPO is > 0.5 W. Within the single-mode regime, the long-term frequency stability of the free-running OPO is typically better than 500 MHz [10]. The linewidth of the mid-infrared idler beam is of the order of 1 MHz, and therefore sufficient for sub-Doppler spectroscopy.

C. CH_4 Spectrometer

The output power of the OPO is one to three orders of magnitude higher than what can be achieved with pump-enhanced mid-infrared OPOs [9] or by DFG [5, 7]. The high output power simplifies the use of the OPO in high-resolution molecular spectroscopy. Several molecular transitions, even rather weak ones, can be measured with sub-Doppler resolution using a simple setup for saturated absorption spectroscopy. There is no need to use a power enhancement cavity. In this work, we have studied the ν_3 band of methane, which is centered at 3.3 μm. The saturation spectrometer used in the measurements is schematically depicted in Fig. 1. The mid-infrared output beam of the OPO is first separated from the residual pump and signal beams using dichroic mirrors, and subsequently spatially filtered using a pinhole. After the pinhole, the beam is collimated and passed through a 50-cm long sample cell that has Suprasil windows (ISI ASCR). The sample cell is filled with $^{12}CH_4$ to a pressure of ~1 mTorr. After the cell, the beam is reflected back and a fraction of it is directed to a MCT detector using an uncoated CaF_2 wedge. A rotatable polarizer is used to attenuate the power below the saturation level of the MCT detector. The focus of the beam is at the gold mirror that reflects the beam back. The $1/e^2$ diameter of the beam at the mirror was measured to be 2.7 mm.

D. Coherent Link Between the OPO and OFC

Doubled frequencies of the OPO pump and signal are needed in order to establish a phase-coherent link between the OPO and the Ti:sapphire OFC. To get the first one of these, a fraction of the output beam of the OPO pump laser is picked up before the OPO and frequency-doubled in a 3-mm long potassium titanyl phosphate (KTP) crystal. The crystal is cut for type II (eo-e) phase matching at room temperature; the cut angles are $\theta = 90^{o}$ and $\phi = 23.5^{o}$. The phase-matching bandwidth of the crystal is so large that no temperature control or tuning is required. With 2 W of pump power incident on the KTP, we get more than 1 mW of green 532-nm light using a simple single-pass doubling scheme. A single-mode optical fiber is used to transfer the frequency-doubled light beam to another optical table that accommodates the OFC. The beam is then combined with the green part of the OFC spectrum in a non-polarizing beam splitter. The overlapped beams are spectrally filtered with a grating and focused into a fast Si-photodiode to measure their beat frequency f_{2p}. A signal-to-noise ratio (SNR) of >35 dB was achieved in a 300-kHz resolution bandwidth (RBW) by using a long (1 m) distance between the grating and the photodiode [12].

Generation of the frequency-doubled beam of the OPO signal does not require an additional doubling crystal. A sufficient amount of optical power at $2\nu_s$ is produced in the OPO crystal as a result of a residual non-phasematched mixing process. Depending on the OPO wavelength, and with idler output powers of >0.3 W, the frequency-doubled power emitted through mirror M3 of the OPO is between 30 and 700 μW. This was measured from the -1^{st} order diffraction from a gold-coated grating, which was used to separate $\lambda_s/2$ from the other wavelengths, such as λ_p, also emitted through the mirror. After the grating, the beam was coupled into a single-mode fiber, and combined with the near-infrared part of the OFC in a 2×1 fiber coupler. The beams were then filtered using a grating before focusing them into a fast Si-photodiode for the detection of beat frequency f_{2s}. The SNR of the beat signal is 20 to 25 dB (300-kHz RBW), depending on the power of the frequency-doubled signal beam.

Both beat frequencies f_{2p} and f_{2s} can be simultaneously counted using two separate frequency counters. Alternatively, they can be mixed in an RF-mixer, in which case only one counter is required. A calibrated wavelength meter is, in general, needed to determine the integers m_{2p} and m_{2s} (Eq. 5b), i.e. the mode numbers of the OFC peaks used to measure f_{2p} and f_{2s}, respectively. Pump and signal beams leaking out through mirror M4 of the OPO are used for this purpose – they are coupled into the wavelength meter through a single-mode fiber, and optical band-pass/reject filters are used to select the wavelengths to be measured.

IV. Results

The setup described here can be used to measure the absolute frequency of the OPO idler beam anywhere between 3.2 and 3.4 μm. The long-wavelength side of the region is currently limited by the spectral coverage of the OFC´s near-infrared part. Even with the free-running OPO the setup can be used for mid-infrared spectroscopy referenced to the OFC. The resolution and accuracy of the spectroscopic measurements are, however, limited by the frequency stability of the OPO. These can be greatly improved by taking advantage of the high output power of the OPO. The OPO outputs enough power so that it can be used for saturation spectroscopy of several molecular transitions without a power enhancement cavity. The OPO idler frequency can therefore be stabilized on a Doppler-free absorption line (Lamb dip), after which it can be precisely measured with the OFC. As a first test we decided to study the P(7) transition of the ν_3 band of $^{12}CH_4$, located at 3.39 μm. This is a good test transition, since its frequency and other parameters are known from previous studies. Especially the P(7) $F_2^{(2)}$ line is well known, since it has been used for frequency stabilization of the HeNe laser. The 3.39-μm CH_4/HeNe laser is a common mid-infrared optical frequency standard, whose frequency has been determined with high accuracy. It provides a CPIM recommended radiation for the realization of the definition of the meter [13].

A scan over six tetrahedral fine structure components of the P(7) line of $^{12}CH_4$ is shown in Fig. 2. The spectrum was recorded using the spectrometer described in Section III.C, and the scan was done by tuning the frequency of the OPO pump laser. The etalon fringes in the spectrum are mainly caused by the OPO pump laser [14]. We have previously used a balanced-detection scheme to get rid of the fringes but decided not to use it here for simplicity. Instead, we are planning to solve the problem by replacing the seed laser (a fiber laser) of the pump system with a DFB diode laser.

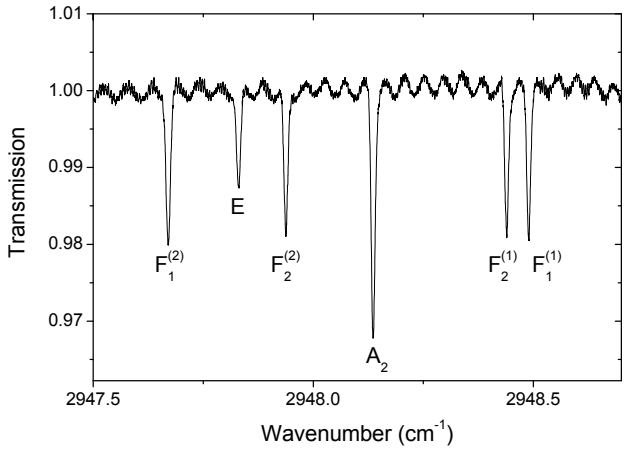

Figure 2. Absorption spectrum of the P(7) transition of $^{12}CH_4$.

Figure 3a shows a detail of the recorded spectrum, revealing the Lamb dip of the A_2 component of the transition. The observed linewidth of 4.3 MHz (full-width at half-maximum) is mainly due to the OPO linewidth and due to power broadening, which results from the high intensity used in the experiment (~ 10 times the saturation intensity). In addition to direct recording of the sub-Doppler spectrum, we used wavelength modulation spectroscopy with 3*f* detection. The frequency of the wavelength modulation was 1249 Hz, and it was done by dithering the OPO cavity length using PZT2. The modulation depth was ~2.5 MHz peak-to-peak. The third harmonic of the lock-in detected Lamb dip is shown in Fig. 3b. The time constant of the lock-in amplifier was 1 ms (24 dB) and the scan speed over the Lamb dip was 440 MHz/s.

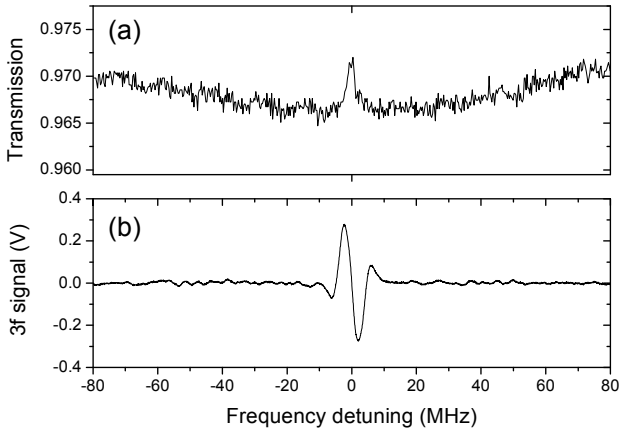

Figure 3. (a) Detail of Fig. 2, showing the Lamb dip of the A_2 component of the P(7) transition. (b) The third harmonic signal of the Lamb dip, as obtained from the output of a lock-in amplifier using wavelength modulation spectroscopy.

The 3*f* signal from the lock-in amplifier provides an error signal that can be used to lock the idler frequency to the center of a Lamb dip. We are currently carrying out the first absolute frequency measurements of the OPO idler frequency locked to a Lamb dip of the P(7) transition. The results of these measurements will be reported elsewhere.

V. Conclusion

We have presented a new method and instrumentation that can be used to measure the absolute frequencies of molecular transitions in the mid-infrared region. The method is based on the use of a high-power cw optical parametric oscillator, which can be applied to sub-Doppler molecular spectroscopy as a part of a simple saturated-absorption spectrometer. As an example, we have demonstrated sub-Doppler spectroscopy of the ν_3 band of methane at 3.4 μm. The optical parametric oscillator is linked to a Ti:sapphire optical frequency comb through its pump and signal beams. As the frequency comb is referenced to a microwave frequency standard, a phase-coherent link between the mid-infrared and the microwaves is established as well.

Optical-optical double-resonance (OODR) Spectra for the $5^2P_{1/2}$ –$6^2S_{1/2}$ and the $5^2P_{3/2}$ –$4^2D_{3/2,5/2}$ transition of ^{87}Rb have been used for frequency stabilization in near-infrared region for many years. Though the method works well, it calls for locked 780nm lasers to pump Rb atoms into $5^2P_{3/2}$. We are trying to use an electrodeless discharge Rb vapor lamp to replace the complex locked pumping laser. The lamp's spectra show us that there are two spectral signals, 780nm and 795nm, are much larger than others. We are trying to make $5^2P_{3/2}$ level populated by shining the lamp light into a Rb vapor cell. Meantime, the lamp could absorb 1529 nm laser most seriously when operating in red mode. The absorption signal with high SNR but with several hundred megahertz line-width is hopefully to be used to lock the 1529 nm laser directly without 780 nm laser. The advantage of the lamp used in the frequency stabilized system is to reduce the size and cost of 1.5 μm wavelength standard for optical communication application.

I. INTRODUCTION

Frequency stabilized 1.5 μm laser is a necessary wavelength standard in optical communication [1-2]. Nowadays the frequency of 1.5 μm laser source can be stabilized by using saturated absorption spectroscopy of molecule[3-4] and double resonance spectroscopy[5-6]. The transition wavelengths between $5^2P_{3/2}$ –$4^2D_{3/2, 5/2}$ of rubidium atoms are 1529 nm. For $5P_{3/2}$ and $5P_{1/2}$ are the first excited states, double resonance optical pumping (DROP) and optical-optical double resonance (OODR)[7] are two useful ways to make these states populated. These methods work well, however they call for complex and expensive frequency stabilized 780 nm lasers.

We are trying to use an electrodeless discharge Rb vapor lamp in DROP and OODR methods to simplify the complex 1529 nm frequency locking system. The lamp's spectra show us that there are two spectra signal, 780nm and 795nm, are much larger than others[8]. So we consider that the lamp could replace the pumping laser in DROP system. Besides, for the lamp is pumped by radio frequency source, almost all the excited states of Rb atom are populated with different populations. So the lamp can absorb 1529 nm laser directly without 780 nm pumping laser. The absorption signal of 1529 nm laser could be used to stabilize the frequency of 1529 nm laser, which can be used as a wavelength standard for optical communication.

II. ELECTRODELESS DISCHARGE RB VAPOR LAMP

The Rb vapor cell in our lamp is a cylindrical glass cell winded with copper wire and can output light from the both (ends) sides of it. Details of the bulb are listed in Table 1.

Near-infrared region spectra (780 nm-1550 nm) of the lamp are measured when the lamp is working in red mode. The optical power of one side of the lamp has been measured by a pyroelectric power meter as 46 mW. The spectra of $5^2S_{1/2}$ –$5^2P_{3/2}$ and $5^2S_{1/2}$ –$5^2P_{1/2}$ transitions are much stronger than that between higher excited states. The results show that there are much more atoms in the first excited states than that in the higher ones[8].

TABLE I. PARAMETERS OF THE RUBIDIUM VAPOR LAMP

Parameters	Vapor Cell in the Lamp
Shape	Cylindrical
Diameter	3 cm
Length	3 cm
Filling	Nature Rb, 2 torr Xe
Rf signal frequency	178 MHz
Max temperature	200 ℃

III. EXPERIMENTS, RESULTS AND DISCUSSION

Firstly our experimental scheme for investigation is shown in Fig. 1. A low pass filter was used in front of the lamp trying to prevent atoms to be pumped into higher excited states. However, no obvious change of 1529 nm absorption signal was observed. The cylindrical shape of the bulb perhaps caused low pumping efficiency for the atoms on the path of light.

Project supported by National Natural Science Foundation of China (Grant No 10874009 and No 11074011)

In order to improve the pumping efficiency, the experimental scheme is changed as shown in Fig 2. Laser passed through the lamp and the nature Rb vapor cell orderly to let atoms on the light pass to touch lamp light closely. Besides, we could compare the result induced by the lamp with the traditional DROP spectra.

Laser at 780 nm is locked on the $5^2S_{1/2}$ (F=2)–$5^2P_{3/2}$ (F'=3) transition in an ^{87}Rb D2 line. Transmitted signal of 780 nm is detected when the frequency of 1529 nm laser is scanned. As shown in Fig 3, red line corresponds to the transmission signal of 780 nm laser obtained when the lamp is absence, and the blue line is measured when the lamp is working in ring mode. Actually, the traditional DROP spectra of the transition $5^2P_{3/2}$ (F=2)-$4^2D_{3/2}$(F'=2, 3) have 2 transition signals, and that of $5^2P_{3/2}$(F=2)-$4^2D_{5/2}$(F'=2, 3, 4) have 3 signals. The red line here fails to distinguish the hyperfine transition signals apart partially due to the copropagating beams of the two lasers. Thought the signal obtained corresponds to which transition is still not clear, due to the lamp, the magnitude of DROP signal is increased by 4 times with a line-width which doesn't changed so much. When the radio frequency source power supplied to the lamp is turned low and let the lamp operates in red mode, the transmitted signal of 780 nm laser disappears but the absorption signal of 1529 nm laser reaches the maximum value. In red mode, the first excited state of Rb in the lamp can gather most atoms and then make serious absorption of 1529 nm laser[9]. So the laser pass through the nature Rb vapor is too low to induce obvious DROP process. Until now, we are not very clear to what degree that the vapor is pumped by the lamp. More experiment should be done to research the underlying phenomenon.

On the other hand, since the lamp in red mode could generate an absorption signal of 1529 nm laser with big magnitude and big signal-to-noise ratio (Absorption process corresponds to transitions between higher excited state is generally weak, because that the intermediate state is not easily populated[7]), the lamp is useful to be used to lock the 1529 nm laser by the absorption signal directly. However, because of the buffer gas in the lamp, the hyperfine structures in the absorption signal are mixed together, and then induce the line-width of the signal widen to several hundred megahertz. The final stability of the laser depends on the balance of SNR and line-width. So the lamp is still hopefully can be used to reduce the size and cost of the stabilized 1.5 μm laser source for optical communication.

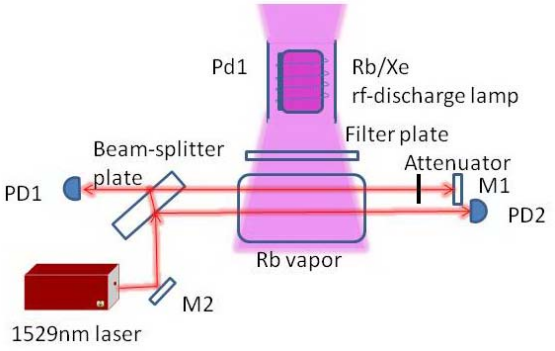

Fig 1. Experimental scheme for the first time. M1 and M2 are two reflection mirrors for 1.5 μm region. PD1 and PD2 are two Ge photodiodes, and PD1 obtains SAS signal, PD2 gets Doppler background signal. The filter plate lets only 780 nm region light pass.

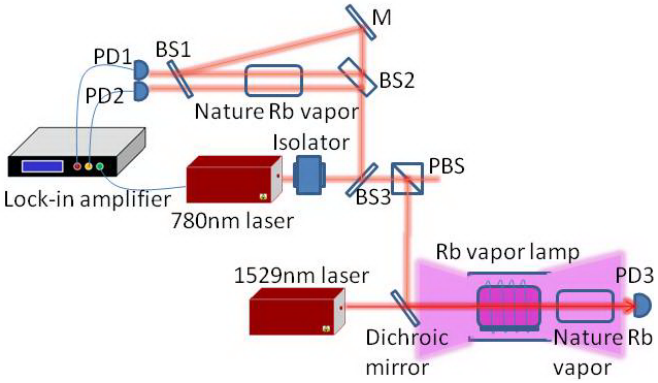

Fig 2. BS is beam-splitter mirror; PBS is polarized beam-splitter mirror; Dichroic mirror: reflection at 1529 nm, transmission at 780 nm; Filter is a high-pass mirror which cutoff frequency is 800 nm; PD1 and PD2 are Si photodiodes; PD3 is photo-detector, Thorlabs.Inc, PDA10A. At point A, the power of 1529 nm laser is 7.76 mW and, 780 nm, 1.7 mW.

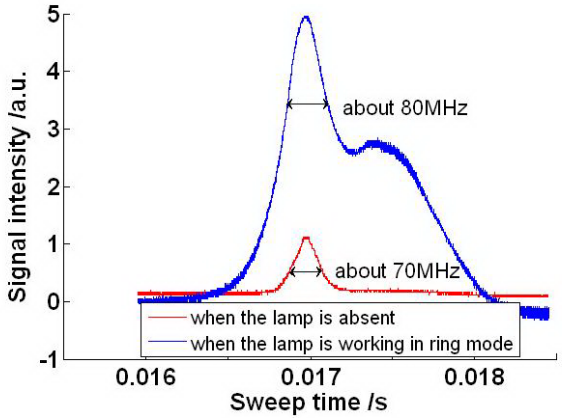

Fig 3. Detected transmitted signal of 780 nm laser

IV. Conclusion

We explored the potential applications of electrodeless discharged Rb vapor lamp in simplifying the frequency locking system for 1529 nm laser. Firstly, we checked the possibility of the lamp to replace the frequency stabilized 780 nm pumping laser, and there are still a lot of research we should do in the future. Moreover, we presented the possibility of locking the 1529 nm laser on the lamp simply by detect the absorption signal which passed through the lamp. Without the complex frequency locking 780 nm laser, the Rb vapor lamp could reduce the size and cost of a frequency stabilized 1529 nm laser as wavelength standard for optical communication application.

Use of AOM-RN as a Phase Modulator in FM Sideband Heterodyne Technique in the Atomic Frequency Standards

Viacheslav Baryshev, Viacheslav Epikhin, Sergey Slyusarev

FGUP VNIIFTRI, Moscow Region , Mendeleevo, Russian Federation
E-mail: baryshev@vniiftri.ru

Abstract – **AOM-RN, an acousto-optic modulator designed to operate in the pure Raman-Nath diffraction regime, was applied as an optical phase modulator in FM spectroscopy of saturated absorption resonances, coherent population trapping resonances, sub-natural magneto-optical resonances in Cs vapor, i.e. such kind of optical resonances which are currently employed as the frequency references in metrology of the microwave and optical frequency standards and in magnetometry. We show experimentally that the spatial divergence of the AOM-RN frequency modulated output spectrum, the only seeming disadvantage of AOM-RN, is not an obstacle, as well, to obtain the error signals by means of Pound-Drever-Hall heterodyne technique with the use of high-finesse (up to tens of thousands) Fabry-Perot cavities as the frequency discriminators.**

I. INTRODUCTION

It has been shown in [1, 2] for the first time that phase-sensitive detection of the sub-Doppler saturated absorption resonances within D_2 line of Cs atom can be carried out by means of the conventional FM sideband heterodyne spectroscopy [3, 4] with an acousto-optic modulator operating in the Raman-Nath diffraction regime as an external phase modulator. This technique has been used to obtain the error signals for wide bandwidth, high-speed servo-loop for frequency control of the external cavity diode lasers (ECDLs), as well. Then, it has been reported in [5] on the production of AOM-RN (see fig. 1), a compact acousto-optic modulator operating purely in the Raman-Nath diffraction regime. The application of AOM-RN as a phase modulator in FM spectroscopy appeared to be reasonable, since in the case of weak AOM excitation, due to the phase modulation, its output spectrum consists of a strong carrier and two weak sidebands corresponding to the ±1st diffraction orders. It has been confirmed that FM spectroscopy with the use of AOM-RN is capable of measuring both the absorption and dispersion associated with the spectral features.

It has been shown in [5] that AOM-RN as an external phase modulator in FM spectroscopy has some features advantageous in comparison with the electro-optic modulators (EOMs) which are conventionally used for the same purposes. The important advantage is the possibility of obtaining error signal with a desired slope sign of its linear central part in a wide frequency range, which is easily achieved by varying the frequency of the amplified local oscillator signal without changing its power. This feature of AOM-RN has been utilized in a fast and wideband (about 10 MHz) ECDL locking system, developed for using in Cs fountain frequency standard at VNIIFTRI. It provides on-line tuning the ECDL frequency and optimization of the detection signals by varying the local oscillator frequency in a few tens of kHz range with corresponding shift of the saturated absorption error signal lock point in a few MHz range. Next, driving AOM-RN local oscillator signal power that is necessary to ensure a few-percent ratio of powers of each ±1st diffraction order sidebands to the carrier power did not exceed 100 mW. Actually, the existing EOMs do not produce a pure FM spectrum. Hence, one has to control the polarization of the input and output beams to remove the residual amplitude noise. When using AOM-RN, such control is not required, and the experimental setup is simplified. Also, the accurate spatial adjustment of AOM-RN is not required since, for sufficiently short acousto-optical interaction length, the Raman-Nath diffraction takes place at any incidence angle of the light on the acoustic beam. That distinguishes the Raman-Nath diffraction from Bragg diffraction which happens and is optimized at certain incidence angle satisfying Bragg condition.

FM spectroscopy in that sense as it was introduced by Bjorklund [1], when the AOM-RN modulation frequency is larger than the linewidth of the investigated transitions, enabled to get the error signals corresponding to the narrow coherent population trapping (CPT) resonances [5, 6]. It has been experimentally demonstrated [7, 8] in Cs vapor that the detection of sub-natural magneto-optical resonances in the Hanle configuration by means of FM spectroscopy with AOM-RN as an external phase modulator is possible. The electromagnetically induced absorption (EIA) error signal superimposed on the saturated absorption error signal becomes apparent when the last one corresponds to the dispersion component of

Fig. 1. Photographs of the "ISOMET" 1205-C2 AOM and couple of the "VNIIFTRI" AOM - RN.

the photo-detector beat signal formed by the frequency modulated probe radiation.

A closely related to the FM spectroscopy method the Pound-Drever-Hall method [9] is a most powerful technique for frequency stabilization of the existing lasers. Pound-Drever-Hall method introduced in practice a highly effective optical frequency discriminator: Fabry-Perot interferometer and based on that laser stabilization scheme. In our work, the Pound-Drever-Hall method with AOM-RN as an optical phase modulator has been used for frequency stabilization of the diode lasers. The only seeming disadvantage of AOM-RN is the spatial divergence of its frequency modulated output spectrum. In this paper, we will show experimentally that this divergence, as in the case of saturated absorption spectroscopy in the atomic vapor, is not an obstacle to obtain the error signals by means of FM sideband heterodyne technique with the use of high-finesse (up to tens of thousands) Fabry-Perot cavities as frequency discriminators.

II. EXPERIMENTAL SETUP AND RESULTS

The experimental setup which has been used for obtaining the error signals via Pound-Drever-Hall method is shown in Fig. 2. Developed and designed in VNIIFTRI AOM-RN provides fm spectrum of a single-mode ECDL radiation at λ=689 nm. This modulator has a center working frequency of 30 MHz and a modulation bandwidth of 20 MHz. Its acousto-optic interaction length is 2 mm. AOM-RN frequency modulated output spectrum consists of a strong carrier at frequency ω_{ECDL} and two weak sidebands at $\omega_{ECDL} \pm \Omega$ corresponding to the ±1st diffraction orders. Ω is the AOM-RN modulation frequency. The laser radiation at λ=689 nm is used in the second stage cooling of ^{87}Sr , ^{88}Sr atoms in the Sr atom optical lattice clock developed, at present, in VNIIFTRI. The second stage laser cooling of Sr atom in a optical lattice on 689 nm $^1S_0 - {}^3P_1$ transition requires an ECDL whose short-term linewidth is comparable with the 7.5 kHz transition natural width [10]. The spectrum width of the ECDL can be first narrowed by locking the laser to a stable optical cavity via the Pound-Drever-Hall technique. To ensure long-term stability, the ECDL should be next locked to the $^1S_0 - {}^3P_1$ resonance via saturated absorption spectroscopy. Again, this can be done by means of FM spectroscopy of saturated absorption resonances in the Sr atomic beam with the same AOM-RN as a phase modulator.

So, AOM-RN frequency modulated output spectrum consists of a strong carrier at frequency ω_{ECDL} and two weak sidebands at $\omega_{ECDL} \pm \Omega$ corresponding to the ±1st diffraction orders. Lenses L1 and L2 form a telescope system with AOM-RN in between. The Fabry-Perot input radiation represents three collimated and parallel light beams with size of 2 mm in the plane where all three beams lie. First, we used "Thorlabs" model SA200-5B confocal Fabry-Perot cavity with finesse about 200 and FSR=1.5 GHz. The total incident radiation power was 1.25mW. The zero background level error signal (curve *1*) and FP-cavity transmission (curve *2*) signals recorded

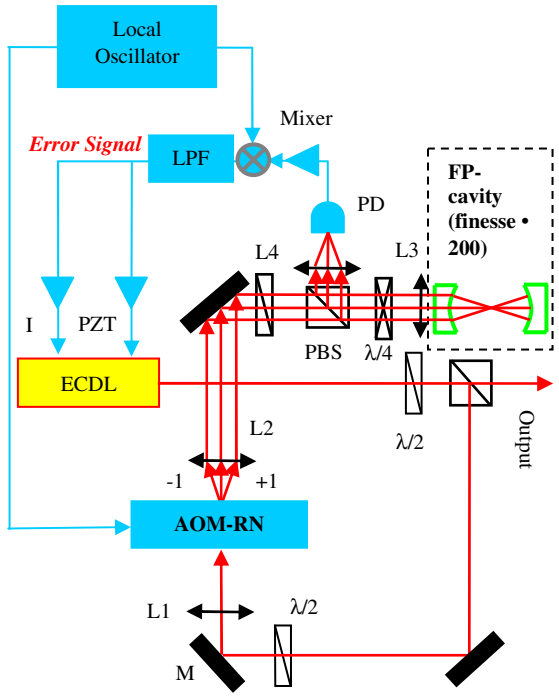

Fig. 2. The experimental setup. ECDL – external cavity diode laser; L – lens; M – mirror; LPF – low-pass filter; PZT – piezo-electric transducer; PBS – polarizing beam splitter; λ/2 and λ/4 – halve and quarter waveplates; PD – photo-detector.

simultaneously are shown in fig. 3. The AOM-RN modulation frequency was Ω = 20.25 MHz. The same signals are given in fig. 4 at Ω = 47.09 MHz. At continuous varying of the local oscillator output frequency Ω from 20 to 50 MHz, the error signal slope periodically changes its sign several times, as it can be seen in fig. 3 and 4.

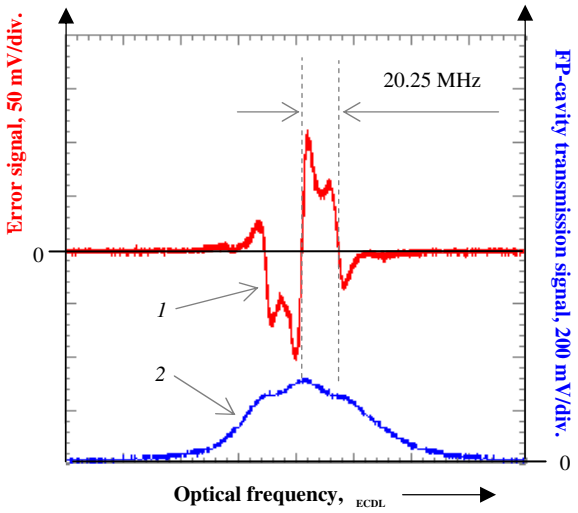

Fig. 3. The error (curve *1*) and SA200-5B confocal Fabry-Perot cavity transmission (curve 2) signals recorded simultaneously. Ω=20..25 MHz.

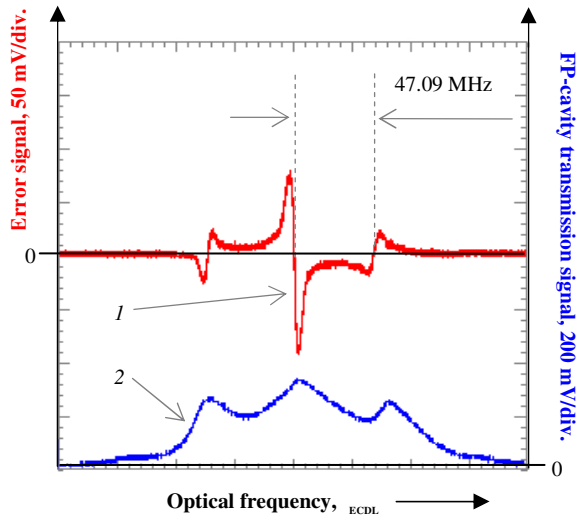

Fig. 4. The error (curve *1*) and SA200-5B confocal Fabry-Perot cavity transmission (curve 2) signals recorded simultaneously. Ω=47.09 MHz.

Since the photo-detector beat signal amplitude is proportional to the geometrical mean of the carrier intensity P_c and the intensity of some sideband P_s, the optimizing of the error signal and increase of its slope can be provided by varying the power of the driving AOM-RN local oscillator signal. Taking into account only sidebands of the ±1st diffraction orders, i.e. when the total laser power is $P_0 = P_c + 2P_s$, then the value $(P_c P_s)^{1/2}$ is maximum for $P_s / P_c = 1/2$ and $P_s = 1/4\ P_0$. Such a ratio of the power deflected into first diffraction order and carrier power several times larger than that ratio of a few percent which is sufficient to conduct the saturated absorption spectroscopy. However, it is not critical for operation AOM-RN in the Raman-Nath diffraction regime.

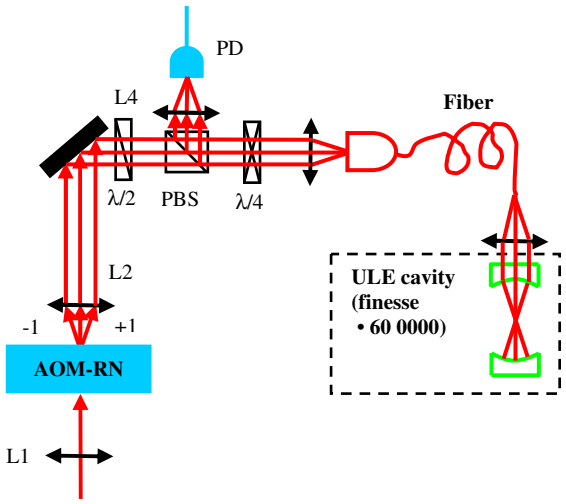

Fig. 5. Experimental setup with ULE-cavity.

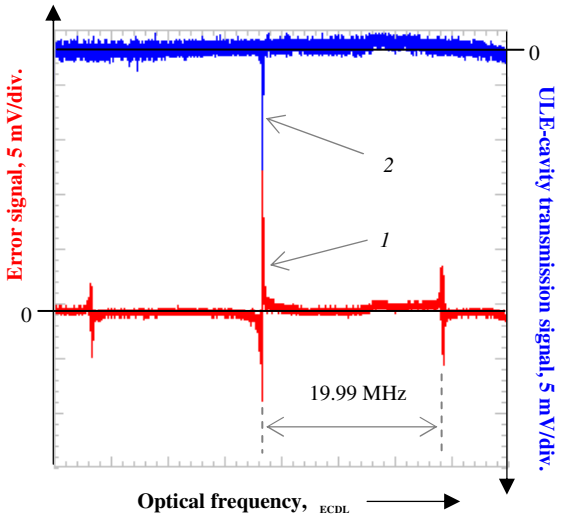

Fig. 6. The error (curve *1*) and ULE-cavity transmission (curve 2) signals recorded simultaneously. Ω=19.99 MHz.

In the same experimental arrangement, the ultra-low expansion (ULE) Fabry-Perot cavity with finesse about 60000 and FSR=1.92 GHz has been used as a frequency discriminator. A part of collimated AOM-RN output consisted, as before, of a carrier and two sidebands was fed via polarization maintaining fiber to the ULE-cavity as it is shown in fig. 5. The AOM-RN modulation frequency was Ω= 19.99 MHz. The total radiation power at the fiber output was P=0.34 mW. Three dispersion-like error signals can be observed on curve *1* in fig. 6 when the ECDL frequency ω_{ECDL} is scanned. Each of them arises when the frequencies of the upper, carrier and lower sidebands match consecutively the ULE-cavity resonance frequency.

III. CONCLUSION

AOM-RN, an acousto-optic modulator designed to operate in the pure Raman-Nath diffraction regime, was applied as an optical phase modulator in FM spectroscopy of saturated absorption resonances, coherent population trapping resonances, sub-natural magneto-optical resonances in Cs vapor, i.e. such kind of optical resonances, which are currently employed as the frequency references in metrology of the microwave and optical frequency standards. We showed experimentally that the spatial divergence of the AOM-RN frequency modulated output spectrum, the only seeming disadvantage of AOM-RN, is not an obstacle, as well, to obtain the error signals by means of Pound-Drever-Hall heterodyne technique with the use of high-finesse (up to tens of thousands) Fabry-Perot cavities as the frequency discriminators.

***Abstract*—Based on an extended-cavity diode laser locked to a high-finesse ultra-low thermal expansion Fabry-Perot cavity using the Pound-Drever-Hall (PDH) technique, we are developing an ultra-stable laser at 1.55 µm for the generation of low phase noise microwave. Our target short-term frequency instability is 10^{-15} at 1 s. The horizontally-mounted cavity has a resonance width of 8.1 kHz, experimentally determined from the cavity ring-down time. The analysis of the in-loop error signal of the laser stabilization to the cavity shows that the residual servo loop noise contributes only $<10^{-15}$ (@ 1 s) to the laser instability and no additional contribution to the laser linewidth is induced by the PDH stabilization. Consequently, the laser linewidth will be ultimately limited by the cavity noise only. The cavity will be stabilized at its zero coefficient of thermal expansion temperature, which has been experimentally determined to be 22.6°C.**

I. Introduction

In the development of an all-optical microwave oscillator based on an optical frequency comb (OFC), the transfer of the relative stability of an ultra-stable laser to a microwave signal is studied. The most critical component in this scheme is the ultra-low thermal expansion (ULE) reference cavity used for laser stabilization. Our target relative frequency stability in the low 10^{-15} at 1 s requires the same challenging stability in the cavity length, which must be made as little sensitive as possible to any external perturbation, such as temperature, pressure or vibration. We have designed and manufactured a 2-layer enclosure to hold the ULE cavity and minimize its temperature sensitivity. This enclosure, made of an internal copper "cradle" and an external aluminum thermal screen with gold-coated surfaces, placed in a vacuum chamber, aims at simultaneously achieving a high temperature stability (by efficiently attenuating external temperature fluctuations) and a high temperature homogeneity of the cavity. However, a much simpler 1-layer prototype enclosure made of an uncoated aluminum cradle without any temperature stabilization and little long-term temperature fluctuations filtering has been used so far to hold the cavity. Laser stabilization to a cavity resonance has been implemented and studied using this prototype enclosure.

II. Cavity-Stabilized Laser

A. Laser Frequency Noise

Our 1.55-µm extended cavity diode laser (ECDL) is stabilized to a 10-cm long, horizontally-mounted ULE cavity by the PDH stabilization technique [1]. The frequency noise properties of the free-running ECDL were first analyzed using a scanning Fabry-Perot interferometer with a resonance width of ~2 MHz. In order to use the linear side of the Fabry-Perot resonance as an optical frequency discriminator, the cavity was weakly locked to the laser by a side-of-fringe stabilization technique with a low servo-loop bandwidth of ~2 Hz.

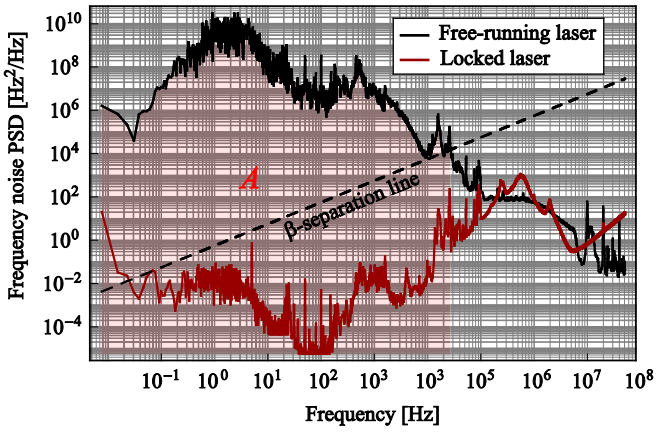

Figure 1. Frequency noise spectrum of the ECDL (free-running and locked to the ULE cavity). The free-running laser was measured using the resonance of a scanning Fabry-Perot interferometer as a frequency discriminator. Below 2 Hz, the measured frequency noise is reduced by the weak lock of the cavity to the laser. The noise of the locked laser is determined from the in-loop error signal. The β-separation line that is relevant for the determination of the laser linewidth [2] is also shown.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

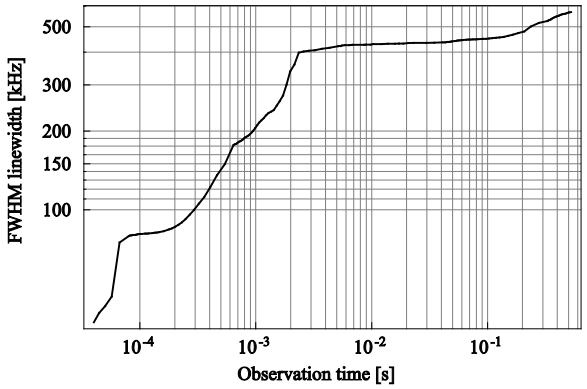

Figure 2. Linewidth of the free-running ECDL calculated from the frequency noise spectrum [2] as a function of the observation time.

The measured frequency noise power spectra density (PSD) of the free-running laser shows a general $1/f^{\alpha}$ trend between 1 Hz and 100 kHz (Fig. 1), with $\alpha \approx 1.8$. Additional noise observed in some spectral regions (e.g. the bump in the range 10^2-10^4 Hz) is of technical origin, mainly due to mechanical noise in the laser external cavity. The laser linewidth $\Delta\nu$ (FWHM) can be determined from the frequency noise spectrum according to $\Delta\nu = [8\ln(2)A]^{1/2}$ [2], where the surface A shown in Fig. 1 corresponds to the frequency noise PSD $S_{\delta\nu}(f)$ integrated over all spectral components for which the frequency noise exceeds the β-separation line given by $S_{\delta\nu}(f) = (8\ln(2)/\pi^2)\cdot f$. Due to the $1/f^{\alpha}$ type of noise, the linewidth of the free-running ECDL depends on the observation time (inverse of the low cut-off frequency considered in the frequency noise spectrum integration). The evolution of the laser linewidth as a function of the cut-off frequency is shown in Fig. 2.

Due to our lack of a suitable optical reference (e.g. another similar cavity or a second independent ultra-narrow linewidth laser) to quantify the frequency noise of the laser stabilized to the ULE cavity, only the in-loop error signal was considered to assess the performances of the stabilization loop. Absolute frequency noise of the laser (and true laser linewidth) can thus not be inferred from the analysis of this signal. However, Fig. 1 shows that the residual noise of the in-loop error signal lies well below the β-separation line in the entire analyzed frequency range. This means that the residual servo loop noise contributes only $<10^{-15}$ (@ 1 s) to the laser instability and no additional contribution to the laser linewidth is induced by the PDH stabilization. With a servo loop bandwidth of ~1 MHz, the laser thus faithfully follows the cavity and the laser frequency noise (and linewidth) will be ultimately limited by the cavity noise only.

B. Cavity Ring-Down Measurement

One of the important parameters characterizing the cavity is the finesse. The width of a cavity resonance has been determined experimentally from a ring-down time measurement. For this purpose, the laser was locked to a cavity resonance and the light transmitted through the cavity was monitored on a photodiode. Following a sudden laser switch off, the time decay of the photodiode signal was recorded on an oscilloscope (Fig. 3). Fitting the experimental

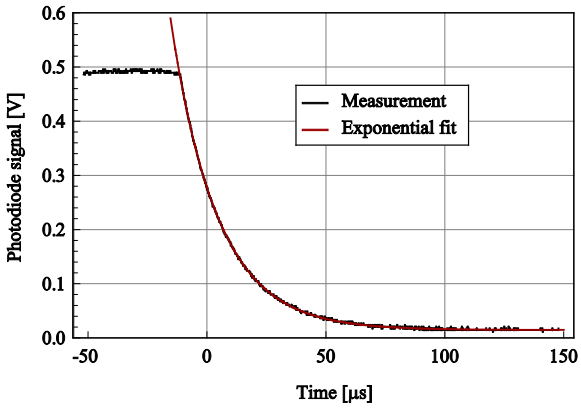

Figure 3. Cavity lifetime determined by a ring-down time measurement. A decay time of 19.6 µs is obtained from the exponential fit.

data by an exponential decay function gave a cavity decay time of τ = 19.6 µs, corresponding to a resonance width (FWHM) of 8.1 kHz. For the 1.5-GHz free spectral range of the cavity, this translates into a finesse of about 185'000.

III. CAVITY THERMAL EXPANSION

Length fluctuations of the Fabry-Perot cavity directly translate into frequency fluctuations of the laser, which tracks any change of the cavity resonance frequency. The use of ultra-low thermal expansion material allows to minimize cavity length fluctuations due to temperature variations. The temperature of the zero coefficient of thermal expansion (CTE) of the cavity (or cavity turning point) has been determined by measuring the tuning curve of the resonance frequency as a function of temperature. The resonance frequency was determined from the beat note between the ECDL locked to the ULE cavity and a fully stabilized OFC. The cavity temperature has been changed by heating or cooling the baseplate of the vacuum chamber using heaters or a set of 8 Peltier elements (for cooling). As the cavity temperature cannot be directly measured, it must be determined from the temperature measured on the surrounding aluminum cradle. The cavity temperature (T_{ULE}) is related to the cradle temperature (T_{cradle}) through the time constant τ of the heat flow between cavity and cradle:

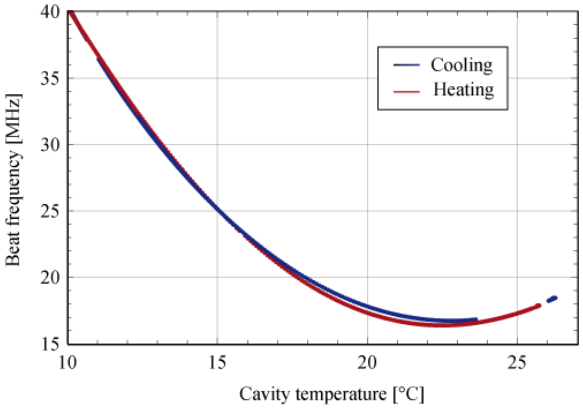

Figure 4. Determination of the cavity turning point from the beat frequency between the ultra-stable laser locked to the ULE cavity and a fully stabilized frequency comb (referenced to a H-maser) measured as a function of the cavity temperature.

$$T_{ULE}(t) = T_{cradle}(0)e^{-\frac{1}{\tau}t} + \frac{1}{\tau}\int_0^t e^{-\frac{1}{\tau}(t-\xi)} T_{cradle}(\xi)d\xi \,. \quad (1)$$

The time constant is unknown, but it can be determined if simultaneous measurements of the beat frequency and cradle temperature are performed once when the system is cooled and then when it is heated. Calculating the cavity temperature from (1) for both measurements, the time constant can be determined from the closest overlap between the heating and cooling curves [3]. Then the cavity turning point can be determined from the evolution of the beat frequency obtained as a function of the cavity temperature (Fig. 4). The turning point of our cavity was thus determined to be 22.6°C and the time constant 77'000 s. This value is achieved with a simple prototype cavity enclosure and a much higher value is expected for the final 2-layer enclosure.

IV. Conclusion and Prospective

A 1.55-µm ultra-stable laser has been developed by frequency-stabilization to a high-finesse ULE cavity. The horizontally-mounted cavity has a resonance width of 8.1 kHz, measured from the cavity ring-down time. The cavity zero CTE temperature has been determined to be 22.6°C, temperature at which the cavity will be stabilized when mounted in its designed 2-layer enclosure. A cavity time constant of 77'000 s has been achieved with a simple cavity enclosure.

The analysis of the in-loop error signal of the laser stabilization to the cavity shows that the residual servo loop noise contributes only $<10^{-15}$ (@ 1 s) to the laser instability and no additional contribution to the laser linewidth is induced by the PDH stabilization, meaning that the laser linewidth will be ultimately limited by the cavity noise only.

***Abstract*—We have demonstrated optical phase recovery from a Pulse-Position Modulated (PPM) laser beam. Our goal is to develop and validate a laser communication and ranging method that utilizes optical coherence within the well-established scheme of PPM with photon-counting detection. Recovery of the carrier phase within optical PPM signals will enable precision Doppler tracking and ranging at optical wavelengths, benefitting spacecraft navigation and scientific measurements based on the propagation of light signals. It also has direct implications for ideal quantum-limited optical communication receivers.**

I. INTRODUCTION

Free-space optical communication is projected for future space missions requiring high data-rates and/or high efficiency. The high energy of optical photons allows detection of individual photons; thus photon-counting techniques can be employed to overcome thermal noise in detection electronics, leading to shot-noise limited performance [1]. For communication in deep space, current paradigms employ Pulse-Position Modulation (PPM) [2]. In this scheme, the light is transmitted and detected as a single laser pulse within a symbol comprised of multiple time slots. It utilizes pulses that are of uniform height and width but displaced in time from some reference position based on the amplitude of the input signal at the instant of sampling. PPM offers higher noise immunity than pulse amplitude modulation (PAM) and pulse duration modulation (PDM) because the receiver simply detects the presence of a pulse within a given time slot, while the exact duration and amplitude of the pulse are not specifically important.

The PPM approach is known for efficient data transmission, but generally it is not considered useful for precision Doppler tracking or ranging, as the phase of the laser light is not utilized by the direct detection scheme. It may seem that the irregular modulation of the laser intensity and the photon-counting detection could corrupt the carrier phase information, thereby squandering the coherent nature of the laser source. In this paper we show that the phase information is indeed preserved, and furthermore, we have demonstrated optical phase locking with a PPM laser signal.

Jet Propulsion Laboratory, California Institute of Technology under contract with the National Aeronautics and Space Administration

In this effort we built upon our earlier work including calculations and experiments designed to establish the feasibility of a deep space coherent optical transponder based on an optical phase lock loop (PLL). We modeled, developed and tested optical PLL's that operate at power levels as low as 40 femto–Watts [3]. Having demonstrated such excellent performance, a PLL–based optical transponder is a highly attractive prospect for deep space tracking with the inherent capability to outperform any microwave transponder [4].

Here we describe our investigation of carrier phase recovery in a PPM signal, with the goal of developing a hybrid laser communication and ranging scheme that utilizes optical coherence within the well-established PPM paradigm. We discuss our analyses in both frequency and time domains. We first developed code to generate pseudo-random PPM signals and model the spectrum via FFT analysis. We then measured spectra of PPM signals, and recovered the phase of a modulated radio frequency (RF) carrier. Lastly, we demonstrated optical phase locking in the presence of PPM.

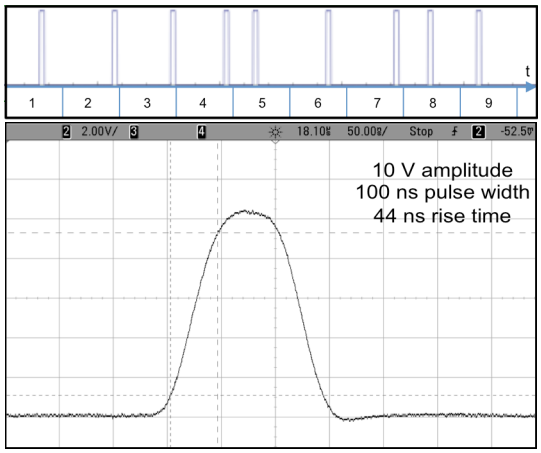

Figure 1. Top shows a sample of a code-generated PPM sequence with 9 symbols labeled below. Each symbol in this sample has 10 slots with the first empty to serve as an inter-symbol guard time reference. Below is s a scope trace of a single pulse from the signal generator.

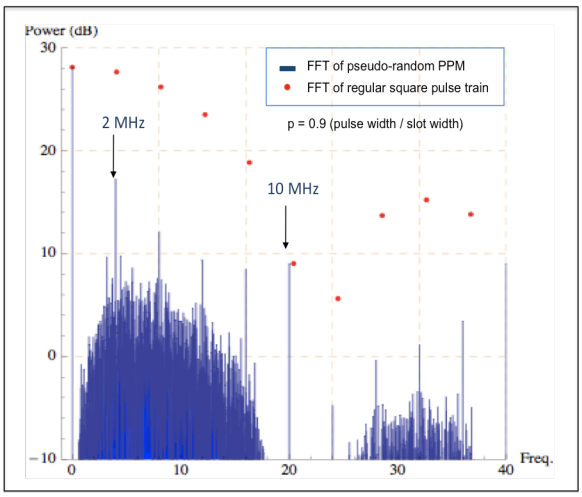

Figure 2. The plot shows the calculated FFT showing the spectrum of a 5-slot PPM with each pulse filling 90% of the slot width. For reference, in red is the FFT of a periodic train of square pulses, a pulse appearing in the same slot for every symbol. Note the apparent sinc-envelope and corresponding 2 MHz and 10 MHz features corresponding to the 500 ns symbol length, and pulse width of 100 ns.

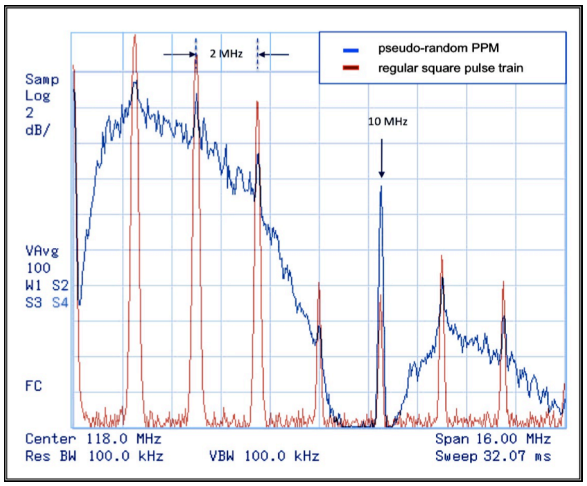

Figure 4. The measured power spectrum for a 5-slot PPM signal. Labeled is a large peak offset by 10 MHz corresponding to the pulse width of 100 ns. Also noted is the 2 MHz separation between peaks corresponding to the 500 ns symbol length. These peaks rise above a continuum in the frequency spectrum. The spectrum of a periodic pulse train is shown in light red, exhibiting the sinc-envelope.

II. PPM Spectral Analysis

We developed code to generate pseudo-random PPM data sequences for (1) numerical modeling of the PPM power spectrum, as well as (2) carrying out empirical spectral density measurements and (3) testing our carrier phase recovery techniques. The code enables adjustment of PPM parameters including total number of symbols, slots per symbol, slot-with, pulse height, pulse duration, resolution, rise-time, and reference slot position. The first slot of each symbol remains empty to serve as a reference, a standard "inter-symbol guard time" technique in PPM communication used to synchronize the receiver clock [5]. We generate randomly positioned pulses that fit within the PPM structure established by the code's input parameters (Fig. 1). These pseudo-random PPM sequences can then be uploaded to a signal generator for our laboratory tests, and/or analyzed with discrete Fourier transformation to calculate the frequency spectrum (Fig. 2). We can also tune the code to generate periodic pulse trains for comparison, and verify the validity of our simulations and experimental measurements.

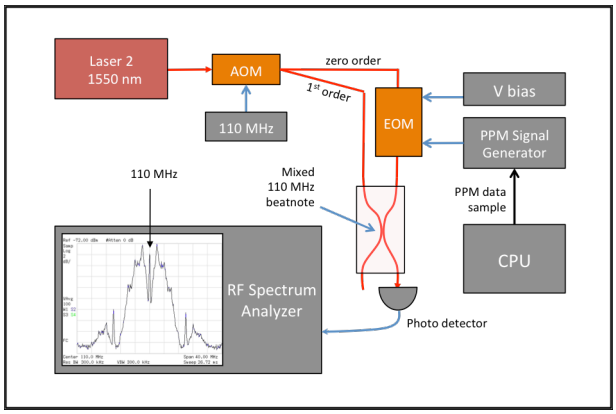

Figure 3. Diagram of the experimental set-up used to acquire the PPM signal's power spectrum. The spectrum is centered at 110 MHz, which is the RF driving the AOM shift. The fiber splitter's second channel can be utilized for real-time measurements as described in the next section.

To begin our investigation of PPM signals in the frequency domain, we measured the power spectral density of a PPM laser beam (Fig. 3). The RF spectrum was acquired by beating the PPM signal with a frequency-shifted carrier on a fast photo-detector and measuring with an RF spectrum analyzer. We directed a tunable 1550 nm DFB fiber laser through an acousto-optic modulator (AOM)). The frequency-shifted light was used as a reference, and the zero-order beam was intensity modulated by a Mach-Zehnder electro-optic modulator (EOM).

An arbitrary waveform generator, loaded with our pseudo-random PPM waveforms, controlled the modulation of the signal beam through the EOM. The EOM voltage bias was set to achieve the maximum extinction ratio for the pulsed signal. We directed this modulated optical signal through a fiber splitter/combiner, where it was mixed with the first-order shifted beam (110 MHz). We monitored the resulting power with a fast photo-detector, and analyzed the signal with a high-resolution RF spectrum analyzer. Two examples of measured power spectra are shown in Fig. 4, modulated by PPM and also a periodic pulse train for reference.

III. RF Carrier Phase Recovery

While a time-averaged frequency spectrum in the previous section exhibits mostly a continuum, underneath each pulse there exists optical carrier with instantaneous phase. Each pulse carries phase information that can be monitored and "stored" until the next pulse arrives. We

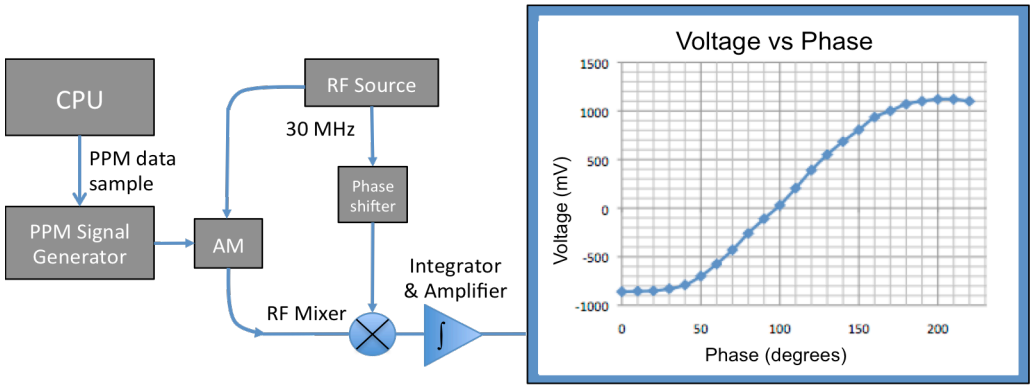

Figure 5. Diagram of the RF-based experiment designed to recover phase in a PPM signal. The mixed detection signal is integrated and amplified. We incremented the phase shift and measured the output voltage, recovering the expected sinusoidal behavior shown in the plot on the right.

accomplished this recovery by mixing the PPM signal with a reference carrier and integrating the resulting beat note. By choosing an appropriate time constant for the integration, the accumulated phase information can be acquired despite long "dark" times between pulses with low duty cycle.

To first demonstrate proof-of-principle for this approach, we operated in the RF domain with a 30 MHz carrier modulated by a slow PPM sequence. Fig. 5 illustrates this set-up. The PPM signal was mixed with the RF source reference, which could be phase-shifted through 2π radians. The resulting beat note was integrated and amplified to yield a voltage proportional to the average phase of the 30 MHz carrier. We were able to recover the phase of the pulsed signal, as shown in the plot on the right of Fig. 5. The same phase recovery procedure could be extended to optical carriers and higher frequency PPM as long as the bandwidth of the integrator is tuned accordingly.

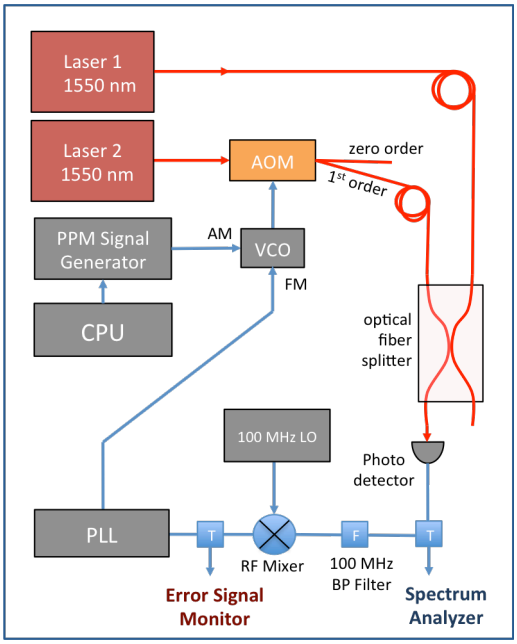

Figure 6. Diagram of the optical phase lock with PPM. Both the amplitude modulation (AM) and frequency modulation (FM) were accomplished with a voltage-controlled oscillator (VCO) driving an AOM, imparting the PPM signal on the optical beam.

IV. Optical Phase Lock with PPM

To demonstrate phase recovery in the optical domain, we phase-locked two lasers while one beam was modulated with a pseudo-random PPM code. We used a single AOM to amplitude modulate (AM) the first-order diffracted beam with the PPM waveform. A voltage-controlled oscillator (VCO) provided both amplitude modulation and frequency modulation (FM). In this way, we could feed back the frequency error signal to the PPM beam in order to phase lock it to the reference beam, a second free running fiber laser (Laser 1 shown in the set-up in Fig. 6). This approach is effectively the same as AM on one path while frequency tracking with the second. The two beams were combined in a fiber optic splitter and the beat note was measured on a fast photodiode. The resulting signal was monitored on a RF spectrum analyzer (Fig. 7). Most of the signal passed through a 100 MHz bandpass filter, and fed into an RF mixer, where it was mixed with a local oscillator (LO) of 100 MHz. This error signal was monitored on an oscilloscope and sent to the PLL. The PLL feedback controlled the FM of the VCO and served to phase lock the two laser signals. In this demonstration, we used a 500 ns symbol length containing five slots with 100 ns widths. This PLL set-up achieves optical phase locking between the two laser beams in the presence of a low-duty cycle PPM signal, thus demonstrating the preservation of optical carrier phase within a pseudo-randomly modulated signal.

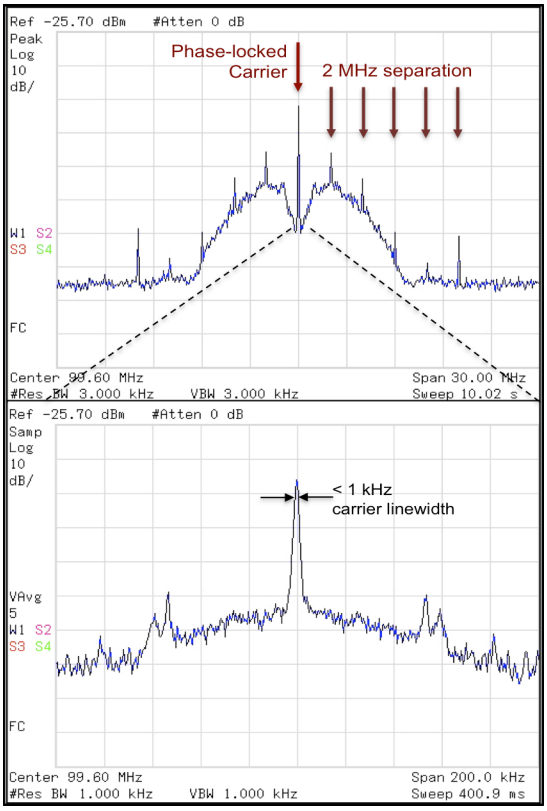

Figure 7. The measured power spectrum of a phase-locked PPM signal. The 500 ns symbol length is reflected in the 2 MHz spacing of sideband peaks (above). The zoomed-in spectrum (below) shows the phase locked laser linewidth less than 1 kHz.

V. CONCLUSIONS

We have conducted a series of simulated and laboratory experiments investigating the optical phase coherence of PPM signals. The experimental results show very good agreement with our simulations. We demonstrated that the carrier phase can be recovered from an RF-based PPM signal by employing a real-time technique to recover the phase information through the mixing of a PPM signal with a frequency-shifted local oscillator (LO) waveform. We also demonstrated that the optical carrier in the PPM can be tracked and recovered by implementing a phase lock between two laser sources, one of which was modulated with pseudo-random PPM. Future efforts will investigate these methods with photon-counting detection. We will also explore the lower limits of laser power with low duty cycles, in connection with our earlier optical transponder work demonstrating a phase lock at pico- and femto-Watt average power levels [3].

Both PPM and photon-counting are established techniques considered for optical communications in deep space [1], and carrier phase information is essential for sub-millimeter ranging measurements such as in a coherent optical link. When this phase is recovered, Doppler and range information become available for tracking similar to the current schemes with microwave signals, except with increased resolution due to the smaller wavelength of optical signals [4]. Micron-level range resolutions are readily achievable with a coherent optical link, which opens up new opportunities for performing scientific investigations based on the propagation of light signals. It also has direct implications for quantum-limited optical communication receivers.

***Abstract*—Highly stabilized lasers are an increasingly valuable tool for metrology. For many applications, however, existing Fabry Pérot systems are too bulky and cumbersome. We are investigating the use of miniature monolithic whispering gallery mode resonators as reference cavities for laser stabilization. We seek to exploit the benefit of small size and vibration resistance by suppressing thermally induced frequency fluctuations. We have theoretically investigated the viability of using a thin-film coating to achieve temperature compensation. We have experimentally investigated an active temperature stabilization scheme based on birefringence in a crystalline resonator. We also report progress of laser locking to the resonators.**

I. Introduction

Optical atomic clocks have attracted widespread interest due to their high stability and accuracy. These systems are facilitated by advances in laser technologies that enable optical trapping, cooling, and octave-spanning frequency combs, which provide a link from optical to microwave frequencies (see, e.g., [1]).

Limiting the short-term stability of optical frequency standards is the local oscillator – a highly stabilized laser capable of producing sub-hertz linewidths. Typical stabilization techniques utilize a Fabry-Pérot cavity fabricated from materials with extremely low thermal expansion coefficients. These cavities are further stabilized via operation under vacuum and with extensive thermal and vibration isolation. The net result is a large and complex local oscillator package.

Therefore, aiding the development of a portable and compact optical clock is a laser reference cavity that is both small and highly robust to mechanical vibrations and thermal fluctuations. At first glance, whispering gallery mode resonators (WGMRs) might not seem promising for such applications: because the light travels completely within bulk material, they are subject to higher levels of thermorefractive noise than is present in conventional Fabry-Pérot cavities. Furthermore, the most thermally stable materials, such as ultra-low expansion (ULE) and zerodur glass, are not suitable for WGMRs due to unacceptably high absorption at optical wavelengths. On the other hand, if the thermorefractive noise can be suppressed, WGMRs have potential to be high-performance cavities owing to their extremely high quality factor (Q) over a wide range of wavelengths, low sensitivity to mechanical noise, and small size, which enables precise and fast temperature control.

The dominant coupling mechanisms between temperature and resonant frequency in a WGMR are thermal expansion and thermorefraction. In case of the former, a change in resonator temperature leads to a change in its size – i.e., the cavity length – and a corresponding change in frequency. The latter refers to a temperature dependence of the host material's refractive index n, and is a quantity which varies widely from material to material. For WGMRs to be useful as reference cavities, both effects must be highly suppressed.

II. Thermal Compensation

We have explored two schemes for suppression of thermally induced frequency fluctuations: (1) a passive scheme whereby a material with negative thermorefractive coefficient is applied as a coating to a resonator to compensate for thermal expansion, and (2) an active scheme whereby a differential in frequency fluctuations between differently polarized modes in a birefringent crystalline resonator is used to stabilize its temperature.

A. Coated WGMR simulations

Coating a whispering gallery mode resonator with a thin-film of negative thermorefractive coefficient material could potentially be used to suppress the effects of thermal expansion. Such a compensation scheme was proposed by Han and Wang [2] and experimentally demonstrated by Jestin et al. [3], albeit with a resonator demonstrating relatively low Q. In such a heterogeneous resonator, the mode volume is shared between two materials so that part of the mode is contained in a medium demonstrating substantial negative thermorefraction (thermal expansion is always positive in the relevant materials).

We have performed simulations to investigate the viability of such a thin-film temperature compensation scheme following the procedure outlined in [2]. The method begins with a solution to Maxwell's equations over the geometry of the resonator, accounting for the different refractive index of resonator and coating (n_1 and n_2, respectively). The boundary condition demands continuity of tangential field components at resonator-coating and coating-air interfaces of the heterogeneous structure, yielding

$$\frac{1}{n_2}\frac{\chi_l'(z_4)}{\chi_l(z_4)} - \frac{C_l\psi_l'(z_3)+\chi_l'(z_3)}{C_l\psi_l(z_3)+\chi_l(z_3)} = 0 \tag{1a}$$

where the coefficient C_l is given by

$$C_l = \frac{\frac{n_2}{n_1}\psi_l(z_1)\chi_l'(z_2) - \psi_l'(z_1)\chi_l(z_2)}{\psi_l'(z_1)\psi_l(z_2) - \frac{n_2}{n_1}\psi_l'(z_2)\psi_l(z_1)}. \tag{1b}$$

978-1-61284-110-6/11/$26.00 ©2011 IEEE

The characteristic equation (1a) is derived in [4], and uses the following notation: The Riccati-Bessel functions are defined by $\psi_l(z) = zj_l(z)$ and $\chi_l(z) = zn_l(z)$, where l is the angular mode number; $j_l(z)$ and $n_l(z)$ are spherical Bessel and Neumann functions, respectively. The arguments are $z_1 = n_1 ka$, $z_2 = n_2 ka$, $z_3 = n_2 k(a+t)$, and $z_4 = k(a+t)$, and the prime denotes derivative with respect to the argument. Solution of equation (1a) depends on the radius of the disc, a, the thickness of the coating, t, and the refractive index of each material, all of which in turn depend upon temperature via

$$\begin{aligned} a &= a_0(1 + \alpha_l^{(1)}\Delta T) \\ t &= t_0(1 + \alpha_l^{(2)}\Delta T) \\ n &= n_0(1 + \alpha_n^{(i)}\Delta T) \end{aligned} \tag{2}$$

where $\alpha_l^{(i)}$ is the linear thermal expansion coefficient, $\alpha_n = (1/n_i)\partial n_i/\partial T$ is the thermorefractive coefficient, $i = 1, 2$ for the disc and coating, respectively, and the zero subscript indicates the initial ($\Delta T = 0$) value.

Thus, the temperature dependence of eigenfrequencies can be found from roots of (1a). We find these roots using a numerical solver in MATLAB, with an initial guess provided by asymptotic approximation. The derivatives are expanded using standard recursion relations (e.g., [5]). Furthermore, we make the approximation that both materials are non-magnetic and that the refractive index of air is identically 1. The characteristic equation has many roots for a given set of parameters; we choose the first one – corresponding to the "fundamental" whispering gallery mode.

First, we simulated the thermally induced frequency shift of a fused silica (SiO_2) resonator that has been coated with calcium fluoride (CaF_2). As shown in figure 1, we find that the coating has potential to substantially reduce the frequency shift when it is an optimal thickness. The shift is suppressed by about two orders of magnitude over a resonator where t varies $\pm$ 0.1 μm from this optimal value, and three orders of magnitude over the uncoated resonator (not shown for clarity). Furthermore, evidence of a turning point suggests the potential for extreme stability (see inset). However, a pitfall is the high sensitivity of the technique to coating thickness; an error of just 50 nm results in a ten-fold increase in thermal fluctuations, placing stringent tolerances on the fabrication process of such a device.

The simulations suggest that careful coating of an SiO_2 resonator could bring substantial stabilization. However, fused silica is an amorphous material. A crystalline resonator would offer several advantages, among them higher quality factor [6], and the possibility of birefringence (the benefit of which is described below). This motivates simulation of a crystalline magnesium fluoride (MgF_2) resonator coated with calcium fluoride. Such simulations suggest that the coating provides some improvement, though the gains are much less dramatic than in the case of the amorphous fused silica. Temperature induced frequency shift remains in the gigahertz per degree Celsius range, even for a coating of 5 μm (figure 2). Additionally, there does not exist a turning point for any reasonable combination of geometric factors and wavelength. This decreased improvement is due to the relatively low thermal expansion coefficient of SiO_2: 0.55×10^{-6}/°C [2] compared to 9.0×10^{-6}/°C for MgF_2 [7].

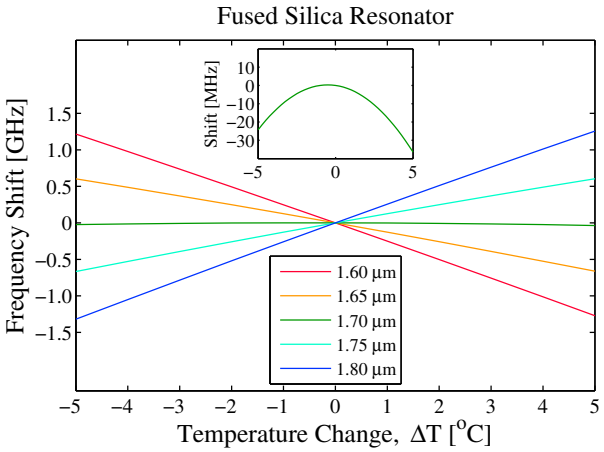

Fig. 1. Simulation results for an SiO_2 resonator coated with CaF_2. For a coating thickness of 1.70 μm, the frequency shift is considerably reduced. The inset has an expanded frequency axis for this optimal thickness, showing a turning point in thermal fluctuations.

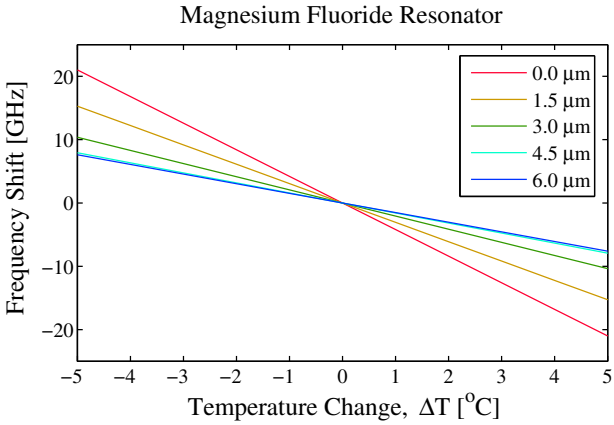

Fig. 2. Simulation results for a crystalline MgF_2 resonator with varying thicknesses of CaF_2 coating. Though some increase in temperature stability is predicted, the frequency shift remains monotonic and in the GHz/°C range.

The simulation results shown in figures 1 and 2 are performed for spherical resonators with a radius of 90 μm with light in the mode having a free-space wavelength of about 1 μm. This corresponds to an angular mode number l in the neighborhood of 800. While larger resonators can in principle be treated with the same simulation, the angular number gets very large if the 1 μm wavelength is maintained, exhausting computational resources.

B. Active Stabilization

We have developed an active temperature stabilization scheme that utilizes a differential in thermorefractive coefficients of the ordinary and extraordinary polarizations in

a birefringent resonator. Since the two polarizations have different thermal dependencies, a change in the frequency spacing between their modes corresponds to a change in the resonator's temperature. By selecting a TE and TM mode that are close together (in frequency) and measuring the difference between them in real time, one can measure temperature fluctuations. Feeding-back this measurement to a temperature control mechanism on or near the WGMR constitutes closed-loop temperature stabilization.

The experimental setup is as follows. Light from a fiber laser is coupled via an angle-polished fiber into a resonator made from magnesium fluoride. The laser frequency is swept over a few MHz, with a center frequency such that the two polarizations are simultaneously observable. Upon exiting the coupler, a polarizing beam splitter separates polarizations and each is detected with a separate photodiode (PD). Signals from the two detectors are acquired and processed digitally so that the frequency difference, Δf, between their peak centers can be precisely determined. The resulting error signal is passed through two proportional-integration stages to generate a correction signal. For temperature control, the resonator is placed in a house-made brass mount which contains two resistive heating elements, one above and one below the device, and in good thermal contact with it.

To predict the stabilization performance, we first determine the frequency differential's temperature dependence for a given, typical pair of modes. Such a pair is shown in figure 3. We make simultaneous, independent measurements of Δf and the resonator's temperature (with a precision thermistor) for several values of temperature. A fit to this data yields a value of $d(\Delta f)/dT \approx -90$ MHz/°C, a very sensitive function. Assuming we can make a shot-noise limited measurement of the mode locations (with a linewidth of 100 kHz), we can expect a frequency resolution of 0.1 Hz, corresponding to nK temperature resolution. This in turn yields a projected frequency stability of a few parts in 10^{14} [8].

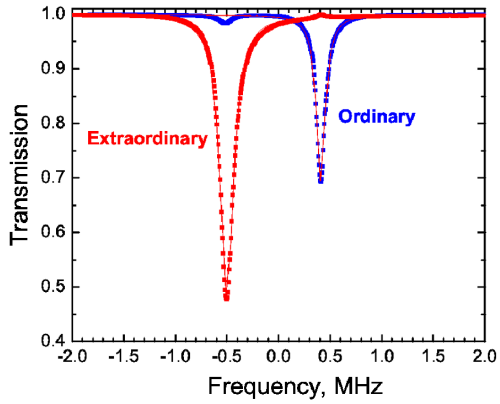

Fig. 3. Frequency spacing between the ordinary and extraordinary modes is a function of temperature and can be used for active temperature stabilization.

III. WGMR as a Reference Cavity

The ultimate goal of this work is to lock a laser to the temperature-stabilized WGMR. We have begun development of the locking system. Using the Pound-Drever-Hall (PDH) method [9], we have achieved preliminary stable locking. The magnesium fluoride cavity demonstrated Q=1.9×10^9 (corresponding to $\mathcal{F}$≈100,000), and is temperature stabilized by a conventional resistive heater and foam insulation.

The experimental setup is shown in figure 4 and described as follows. Light from a 1550 nm laser is coupled into the resonator via an angle-polished optical fiber, while a photodiode placed near the end of the fiber collects light from a single mode family. Our electronics employ a 1 MHz modulation frequency, which is split into two, with one portion being amplified and fed to an electro-optic phase modulator, while the other portion is used to demodulate the photodiode signal in an rf mixer. The resulting error signal (figure 5) is then fed to proportional-integrator-differentiator stages to generate the correction signal for the laser's piezoelectric tuning. So far, we have measured 3.2 kHz rms residuals over the loop bandwidth.

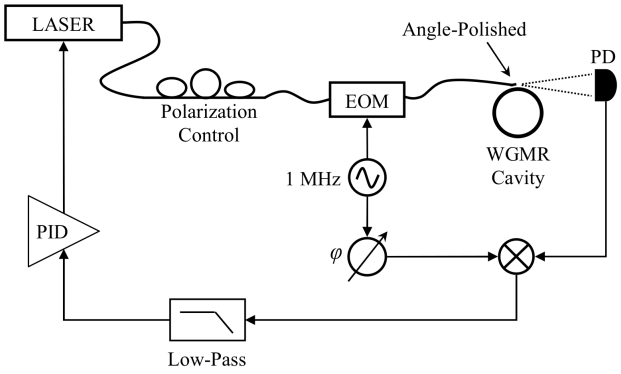

Fig. 4. Schematic of the experimental setup used for locking the Koheras fiber laser to the WGMR cavity. Locking has been achieved to an non-temperature stabilized resonator.

Fig. 5. Oscilloscope capture showing the photodiode signal (upper trace) and PDH error signal (lower trace). Sidebands are 1 MHz from the carrier.

IV. Conclusion

We have investigated temperature compensation schemes for whispering gallery mode resonators applied as frequency

reference cavities. Thermal compensation from a thin-film coating of material with negative thermorefractive coefficient is predicted to yield substantial improvements to an amorphous silica resonator, but insufficient improvement for a crystalline MgF_2 device. We note, however, that other material combinations may facilitate successful implementation with a crystalline resonator. A scheme utilizing the differential in thermorefractivity of differently polarized modes in a birefringent WGMR yields temperature resolution in the nK range and can be used for frequency stabilization. A cavity stabilized in this way has many advantages, chief amongst them being that it eliminates the need for thermal shielding, dramatically reducing the size of the apparatus. Our data support potential stabilization to a few parts in 10^{14} at 1 second. Furthermore, we believe that this technique is among the best performance of an active temperature control system operating near room temperature, and that it will have applications beyond laser stabilization.

Residual PM Noise Evaluation of Radio Frequency Mixers

C. A. Barnes, A. Hati, C. W. Nelson and D. A. Howe
National Institute of Standards and Technology
Boulder, CO U.S.A.

***Abstract*—Direct observation of phase-modulation (PM) noise is often difficult due to the high dynamic range that exists between the carrier and the modulated sidebands. A common tool used to reduce the dynamic range is the phase detector, which removes the carrier and down-converts its noise sidebands to baseband. The double balanced mixer (DBM) is the most widely used phase detector for high-resolution PM noise detection at most carrier frequencies. For Fourier offset frequencies close to the carrier, the residual flicker phase noise of the DBM is often the limiting factor of a PM noise measurement system. Careful evaluation of the phase detector under various operating conditions can lead to the optimization of a PM noise measurement system's sensitivity. This paper describes a survey of residual PM noise measurements for a variety of DBMs at 5 MHz. In order to attain quality measurements, careful attention is devoted to the reduction of ground loops during PM noise measurements. The input powers to the local oscillator (LO) and reference frequency (RF) ports of the mixers are varied to determine the optimal operating point of these devices.**

***Index Terms*— Flicker noise, mixers, phase detector, phase noise.**

I. INTRODUCTION

The measurement of close to carrier phase modulation (PM) noise of state-of-the-art oscillators is always challenging [1]. Quite often the residual noise of the phase detector used in these measurements is the source of difficulty [2], in particular, at Fourier offset frequencies below 100 Hz, where oscillator noise has a slope of f^{-3} and may be lower than the mixer noise floor, which follows a slope of f^{-1} [3]. The motivation for this paper is to locate mixers that offer low phase noise at 5 MHz for use in high resolution measurement systems. This paper describes a survey of PM noise measurements for 18 DBMs used as phase detectors [4, 5]. A study of the phase sensitivity of these detectors with operating power is also investigated. The measurement system used to characterize the detectors is described in section II, and the results of this survey are summarized in section III.

*This report summarizes the noise for various mixers by product name for completeness of this survey. No endorsements are implied.

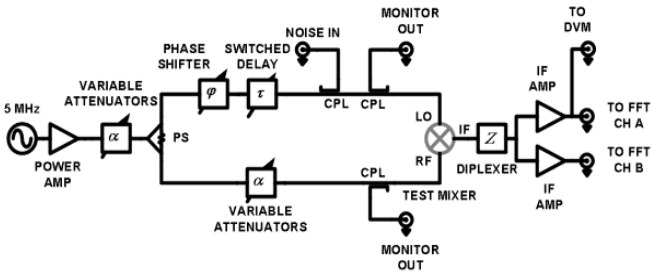

Figure 1. Block diagram of residual PM noise measurement system. PS: power splitter, CPL: directional coupler, IF AMP: low noise baseband amp, DVM: digital voltage meter, FFT: two-channel fast Fourier transform analyzer.

II. DESCRIPTION OF THE MEASUREMENT SYSTEM

The PM noise of the detectors for this survey is measured by use of a 5 MHz cross-correlated homodyne measurement system[6, 7, 8]. Fig. 1 shows a block diagram of the measurement configuration. The signal from a 5 MHz reference oscillator is amplified and split to drive the local oscillator (LO) and reference frequency (RF) ports of the detector. Variable attenuators are used to test the detectors at different power levels. A phase shifter is used to set a 90° quadrature condition between the LO and RF signals. In quadrature, the common-mode phase fluctuations of the oscillator and power amplifier cancel, and the residual noise of the detector is measured. The switched delay line and "Noise In" port are used to calibrate the system's phase sensitivity.

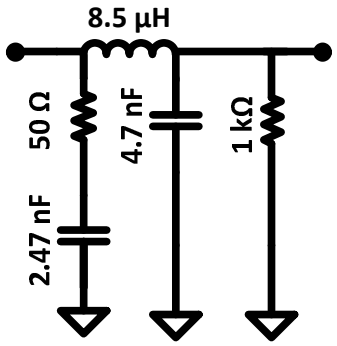

Figure 2. Mixer IF Diplexer schematic.

The detector is followed by a diplexer and a pair of baseband intermediate frequency (IF) amplifiers [9]. The diplexer, shown in Fig. 2, terminates and filters the high-frequency products of the mixing, while still maintaining a high voltage-to-phase conversion at baseband. This diplexer also allows for the baseband signals to be amplified without saturating the IF amplifiers with the 5 MHz and 10 MHz signals from the mixing process. The topology of the diplexer at the output of the phase detector plays a very important role in its performance [10, 5]. The pair of IF amplifiers is utilized to minimize the noise contribution of the fast Fourier transform (FFT) analyzer to the measurement. The uncorrelated input voltage noise of each IF amplifier is reduced by the use of cross-correlation. This allows measurement of the correlated residual detector noise [7]. This noise contribution of the IF amplifiers to the measurement is shown in Fig. 3.

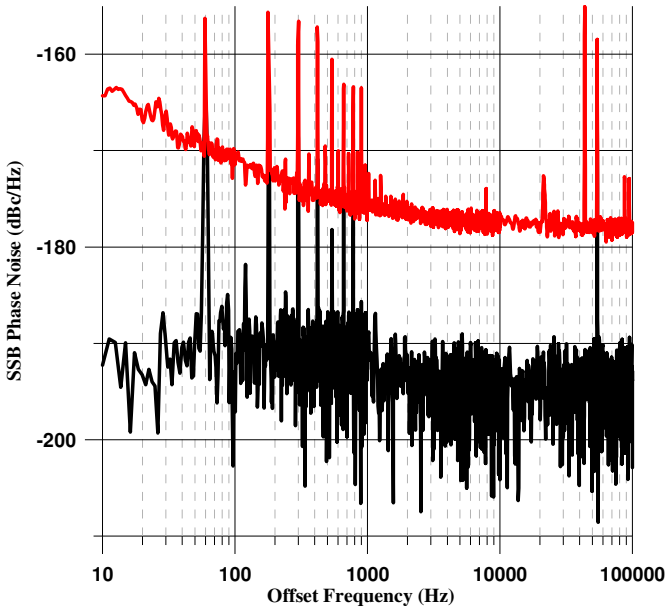

Figure 3 Plot shows that the PM noise of the phase detectors (Top) is higher than the noise floor of the IF amplifiers (Bottom).

In phase quadrature, the filtered output voltage of the detector is represented by

$$v = k_d \cos(\Delta\varphi + \pi/2) \quad (1)$$

where k_d is the mixer sensitivity in volts/rad and $\Delta\varphi$ is the differential phase deviation from quadrature between the LO and RF ports. For small phase deviations, k_d can be determined from a known phase shift introduced by the calibrated delay line. k_d is the ratio of DC voltage change to the introduced phase shift. This method of k_d calibration was also checked against single-sideband modulation and noise-injection methods [11, 12].

III. Measurement Results

For this survey 18 types of phase detectors have been compared. Each mixer was evaluated at two operating points.

1. Linear operation
   LO power = Nominal specified LO power
   RF power = 1 dB below the RF compression point.
2. Saturated operation
   LO power = Maximum mixer power 11 dBm.
   RF power = LO power.

Fig. 4 shows the range of PM noise for the measured devices on two separate plots. Due to the large number of devices evaluated, the measured residual PM noise of the detectors is reported at two offset frequencies; 10 Hz for specifying flicker PM noise and 100 kHz indicating thermal PM noise. The top and bottom plots show the 10 Hz and 100 kHz data respectively for each detector. Each offset frequency is displayed as a line with endpoints representing the linear and saturated measurement values.

Often the PM noise of the phase detectors decreased significantly when they were operated in saturated mode. As discussed in [1, 5], this is attributed mostly to the higher sensitivity, k_d, in saturated operation. For this survey, mixers with a nominal LO rating of +7 dBm and maximum rating of +17 dBm are classified as low-power. Mixers with a nominal LO power rating above +7 dBm are classified as high-power for this study. It can be seen in Fig. 4 that the variation of measured PM noise is greater in high-powered DBMs than for the low-power mixers. Of the commercial detectors, the HP10534A* has the lowest flicker and the ZAD-1H+* the lowest white noise in linear operation. The MCL ZRPD-1+* showed the largest improvement in its white noise between linear and saturated operation, and has the lowest white noise level overall. The PM noise of the best detectors surveyed in saturated mode are presented in fig. 5. The lowest level of flicker noise observed is in a custom mixer built and described in the following section.

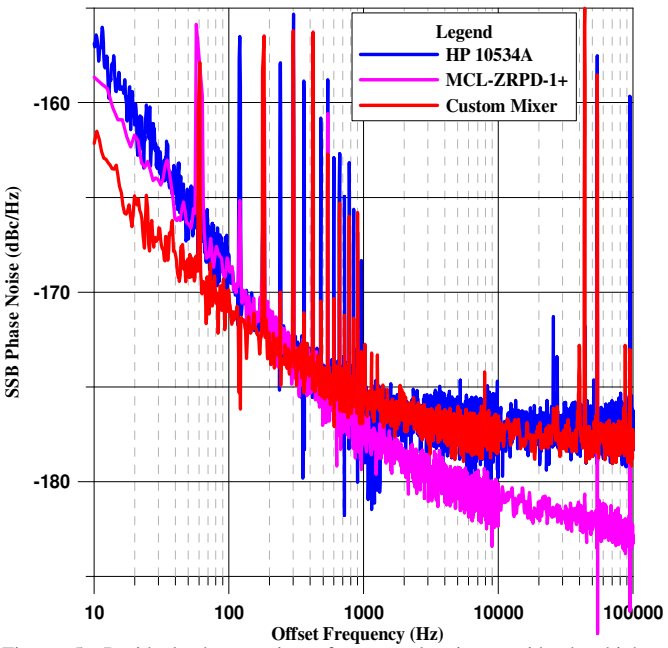

Figure 5. Residual phase noise of surveyed mixers with the highest performance in saturated operation.

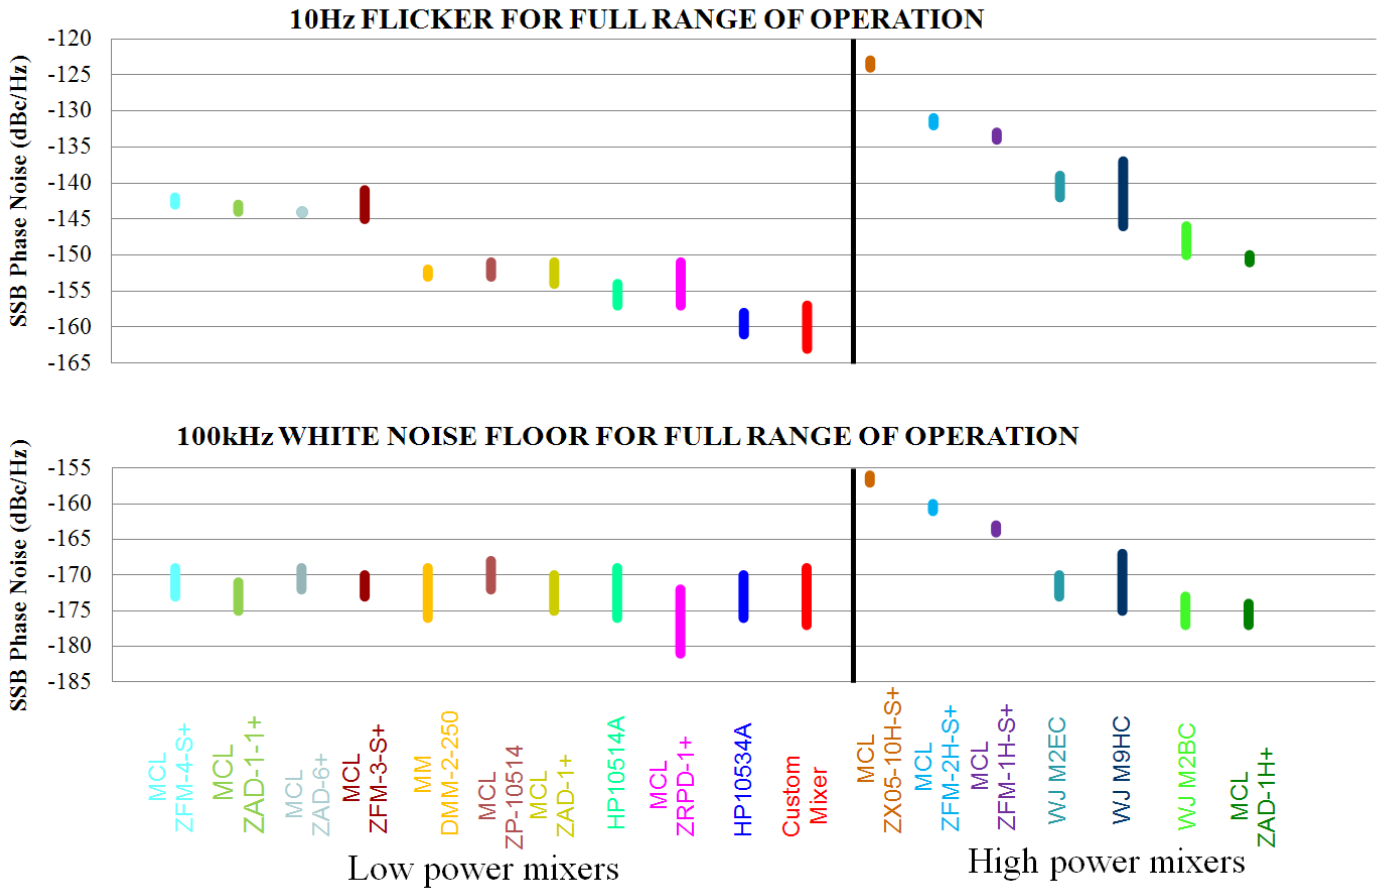

Figure 4. Residual PM noise summary of various phase detectors (endpoints indicate linear and saturated measurement limits).

IV. Custom Mixer Design

A. *Mixer Design*

The custom-built mixer listed in the summary of measurements was a simple double-balanced mixer with 2N2222A transistors in the diode ring. This design is discussed in a letter recently submitted for publication [13]. The custom detector is noteworthy because its flicker performance was the best in the detectors surveyed. Fig. 6 shows the general topology of the DBM. In this design there are four 2N2222A bipolar junction transistors (BJTs) used to construct a conventional double balanced diode ring.

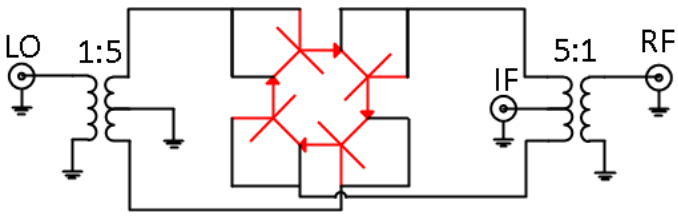

Figure 6. Double balanced mixer schematic. The diode ring in this double-balanced mixer is constructed by use of transistors with the collector input tied to the base.

We short the base to the collector of these BJTs and operate them as diodes by use of the emitter-base junction. The transformers used for this design are commercial off-the-shelf parts and have a 1:5 impedance ratio. This impedance ratio is chosen so that the input impedance of the reference frequency (RF) and local oscillator (LO) ports are nearly 50 Ω at 5 MHz. The mixer's input impedances are measured by use of the Smith chart display of a vector network analyzer.

B. *Mixer Characterization*

In order to measure the PM noise of the DBM, the nominal operating powers need to be found [3]. To determine the nominal LO power, a 4 MHz sinusoidal signal at -30 dBm is applied to the RF port of the mixer while the power of a 5 MHz signal at the LO port is varied. Conversion loss of the mixer is calculated by taking the power ratio of the 1 MHz beat at the intermediate frequency (IF) port to the RF signal at 5 MHz. A plot of conversion loss versus LO power is shown in Fig. 7. By use of this plot, the 1 dB compression point of the LO drive is found to occur at a level of +8 dBm. Operating the LO port in saturation is desired to reduce LO power fluctuation sensitivity. Taking the maximum allowed operating specifications of the transistors and transformers into account, a nominal LO drive of +11 dBm is selected. An

additional measurement of conversion loss versus RF power at the selected nominal LO is made and plotted in Fig. 8. The 1 dB compression point of conversion loss at the RF port occurs at +5 dBm. All conversion loss tests for the mixer were conducted with a 50 Ω load at the IF port.

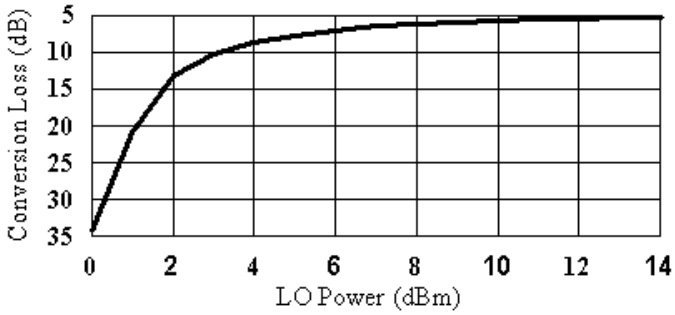

Figure 7. Conversion loss versus LO power of mixer with a -30 dBm RF power level. RF @ 4 MHz, LO @ 5 MHz, 50 Ω input impedance to FFT

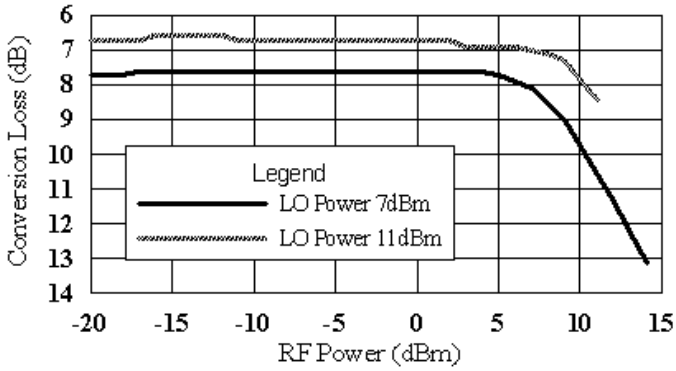

Figure 8. Conversion loss vs. RF signal power at constant LO drive powers. LO @ 4 MHz, RF @ 5 MHz, 50 Ω input impedance to FFT

Fig. 9 shows the results of the residual PM noise of this DBM design used as a phase detector. From these data it can be seen that the flicker noise of this device is L(10 Hz) = -161 dBc/Hz when the DBM is operated at LO = +11 dBm and RF = +5 dBm. In deep saturation (LO = RF = +11 dBm) the 10 Hz noise is improved to L(10 Hz) = -163 dBc/Hz. Both of these measurements show that this DBM has very low flicker noise as a phase detector.

V. Conclusion

We evaluated a number of phase detectors available in our lab at 5 MHz. A 40 dB range of flicker PM noise is observed among the surveyed detectors. Similar variation is also observed in the level of thermal PM noise. High-power mixers in general showed a higher level of flicker noise than that of the lower power detectors. We have found that for many phase detectors, the lowest noise floor is achieved while the device is operated in saturation. Since the sensitivity of the phase detectors depend on the impedance at the IF port, a further study of PM noise versus output termination design will be considered for future work. Specifically we will investigate the phase noise by use of non-absorptive terminations. Further investigation at other carrier frequencies will be conducted as well.

***Abstract*—We describe a prototype optical cavity and associated optics that has been developed to provide a stable frequency reference for a future space-based laser ranging system. This instrument is being considered for inclusion as a technology demonstration on the recently announced GRACE follow-on mission, which will monitor variations in the Earth's gravity field.**

I. Introduction

Launched in 2002, the Gravity Recovery and Climate Experiment (GRACE) mission [1] monitors changes in the Earth's gravity field by measuring changes in the distance between two spacecraft induced by that variable field. The distance variation is measured with a microwave ranging system with sub-micron precision. [2] The ranging measurement accuracy is limited by the signal-to-noise ratio and by the frequency stability of the microwave signal referenced to an ultra-stable oscillator (USO). [3] For the upcoming GRACE follow-on mission a laser ranging system with precision better than the GRACE microwave ranging system is under consideration as a technology demonstration. A laser ranging system easily provides improved signal-to-noise ratio over the microwave system. [4] Laser frequency stability better than the GRACE USO stability has been demonstrated in several laboratories using thermally stabilized optical reference cavities. We are developing a space-qualifiable laser frequency stabilization system for the proposed GRACE follow-on mission. The system includes a ULE optical cavity with the associated optics and electronics and will be capable of providing a fractional frequency stability of better than 10^{-13} for averaging times from 0.01 to 1 s.

Jet Propulsion Laboratory, California Institute of Technology

II. Cavity and Thermal Enclosure Design

The goal for this development is to achieve a frequency noise power spectral density of less than 30 Hz/ $\sqrt{}$Hz over the frequency range of interest, which is 10 mHz to 100mHz. For an orbital speed of 7 km/sec, this frequency range corresponds to distance scales on the Earth's surface of 350 km to 35 km. Below this frequency range accelerometer noise is expected to dominate the measurements, while measurements at higher frequencies are limited by data sampling.

The cavity is based on a design available from Advanced Thin Films, Inc., which has been used successfully in a number of laboratories around the world. [5,6] It consists of a 77.5 mm ULE spacer to which high reflectivity mirrors are optically contacted. The mirror substrates are also fabricated from ULE glass. The design finesse was 10000. The cavity is mounted to a vacuum flange using titanium flexures, which are bonded to the cavity spacer. The flange is attached to a titanium vacuum enclosure which forms the first stage of a two stage thermal isolation system. Laser light is injected into the cavity via an optical fiber, which is mounted along with the required mode-matching optics on a zerodur optical bench. The bench, in turn, is mounted to the cavity via additional titanium flexures. A 90/10 beamsplitter picks off a portion of the light reflected from the cavity, which is steered through a window on the bottom of the vacuum enclosure to a photodiode. Figure 1 shows the reference cavity and optical bench mounted on the vacuum flange, while Figure 2 shows the sealed thermal enclosure, which is mounted, again with titanium flexures to a baseplate. Also shown is the outer thermal shield. The outer surface of the vacuum can has been coated with gold to reduce radiative heat transfer. Heaters and RTD temperature sensors mounted directly to the outer shield,

978-1-61284-110-6/11/$26.00 ©2011 IEEE

and also to an additional baseplate on which the entire cavity system is mounted are used to control the temperature at each end of the enclosure.

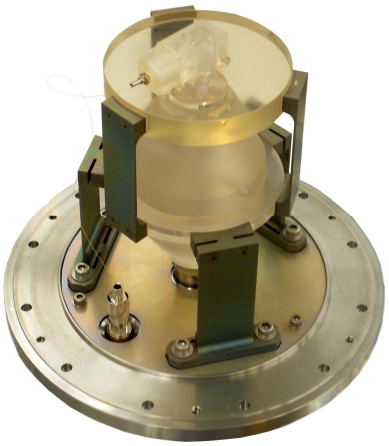

Figure 1. Reference cavity and optical bench mounted to a vacuum flange

Figure 2. Reference cavity assembly with outer thermal shield removed

III. PERFORMANCE TESTING IN A SIMULATED SPACE ENVIRONMENT

A neodymium:YAG laser with a non-planar ring oscillator (NPRO)configuration was used for performance tests of the cavity design. The laser was locked using a standard Pound Drever Hall technique [8], whereby the laser light is modulated (in this case at 5 MHz) and phase sensitive detection of the light reflected from the cavity generates the phase error signal as the frequency discriminator. A sketch of the setup is shown in Figure 3. A portion of the laser output was split off to beat with the output of a second, identical, laser, which was locked, to a second cavity in an independent vacuum chamber. The beat signal was detected on a high bandwidth photodetector and then mixed with a stable rf source to provide a signal within the 20 MHz bandwidth of a high accuracy digital phasemeter developed originally for GRACE-2 [9] and further developed for the LISA instrument [10]. Results of these performance tests are described in [7].

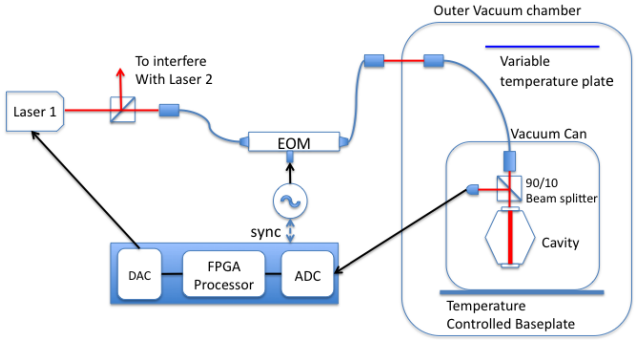

Figure 3. Test configuration for laser stabilization in simulated space environment

During space operations, the cavity will need to meet its performance requirements in a varying thermal environment, as the spacecraft flies in and out of the sun over a ninety-minute orbit. While the cavity will be mounted to a baseplate which is temperature controlled to within 0.1°C, some spacecraft surfaces will experience a temperature variation of not more than 1°C. To simulate this, the spacecraft is placed in a large vacuum chamber containing an 8" by 10" sheet of aluminum with a heater and temperature sensor attached. A function generator drives the heater such that the plate temperature varies by 2 °C over ninety minutes, a variation which is greater than that expected on the spacecraft. During these tests the thermal control was applied to the baseplate under the cavity only. Comparisons of the cavity under these conditions to a second independent cavity are shown in Figure 4. The results meet the current requirements for the GRACE follow-on mission.

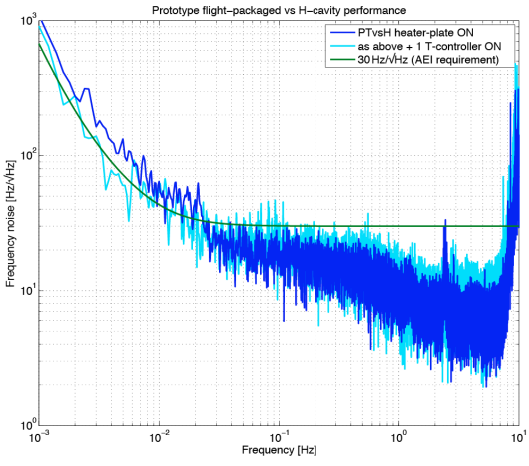

Figure 4. Power spectrum of difference frequencies of lasers locked to prototype and to a second cavity. The prototype is subjected a varying thermal environment as described in the text. Dark blue trace has no thermal

control applied to the prototype, light blue: with thermal control. Green: 30 Hz/√Hz requirement.

IV. FUTURE WORK

The prototype cavity assembly will be subject to thermal cycling and launch vibration tests in order to establish its readiness for consideration for a future space flight. A complete system test including an Interferometric Range Transceiver (IRT) developed under a previous IIP [4] will be performed.

***Abstract*— We report a frequency measurement of a single $^{40}Ca^{+}$ optical clock towards the 10^{-15} uncertainty level. In contrast with our previous measurement, in which the accuracy was limited by line broadening due to the magnetic field fluctuation, the use of a magnetic shield significantly reduced the spectrum linewidth of the clock transition. By a frequency comparison to an ^{87}Sr lattice clock, an Allan deviation of 7×10^{-16} was observed at an averaging time of 10^3 seconds. We preliminarily measured the clock transition frequency to be 411 042 129 776 397 (3) Hz with respect to the SI definition of the second. Further measurements are executed aiming at an accuracy of low parts in the 10^{-15} level.**

I. INTRODUCTION

As candidates for next generation definitions of the second, various efforts are being made to develop optical clocks with the uncertainty better than that of the cesium standards. The best uncertainty of 8.6×10^{-18} has been reported in a composite quantum system using $^{27}Al^{+}$ ions [1]. However, this technique requires sophisticated quantum logic operation and it is not easily accessible. Simpler clocks with modest accuracies have been also developed using Alkali-metal like ions ($^{88}Sr^{+}$, $^{177}Yb^{+}$). We are developing an optical clock using single $^{40}Ca^{+}$ ions [2]. The energy levels of $^{40}Ca^{+}$ that are relevant to the operation of the frequency standard are shown in Fig. 1. The lifetime of the $^2D_{5/2}$ state is about 1.2 seconds, which gives a high line Q to the $^2S_{1/2}$ - $^2D_{5/2}$ transition at 729 nm (411 THz). In 2008 we reported the absolute frequency of this transition with an uncertainty of 4×10^{-14}. In the next year, it was also reported by M. Chwalla *et al*. with an improved uncertainty of 10^{-15} level [3]. These two reports contributed to the acceptance of the $^{40}Ca^{+}$ transition to the 2009 CCTF list of recommended radiations. We measured this frequency to be 411 042 129 776 395 (5) Hz in 2009 [4]. These results are consistent with each other within the uncertainties. This paper reports on our improved frequency measurement towards the 10^{-15} uncertainty level, as well as the frequency stability of the clock laser locked to the $^{40}Ca^{+}$ clock transition.

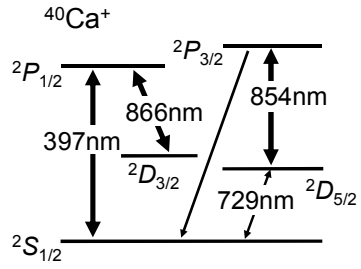

Figure 1. Partial term energy diagram of $^{40}Ca^{+}$ ions.

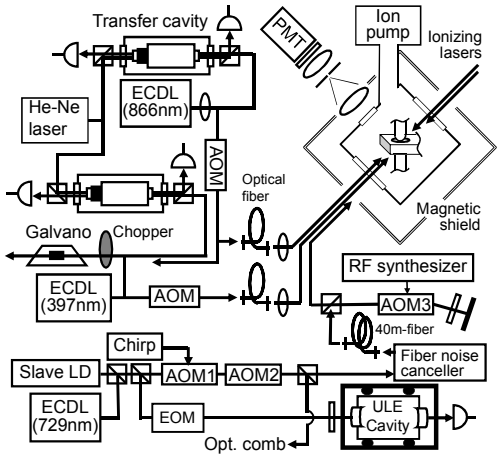

Figure 2. Experimental setup for Ca^{+} ions. AOM: acousto-optic modulator; EOM: electro-optic modulator; PMT: photo-multiplier tube; Galvano: Galvano tube. Roles of AOM1~3 are described in the text.

In this paper, we first outline the experimental setup, and then explain the clock transition measurement, frequency lock to the clock transition, and absolute frequency measurement. Finally, a conclusion is described.

II. Experimmental Setup

The experimental setup, which is based on that described in our previous paper, is shown in Fig. 2 [2]. The output of the 729-nm clock laser is distributed to the ion-trap chamber using a 40-m PM optical fiber. In order to minimize the phase noise due to the fiber transfer, we used a cancellation system [5]. The clock transition spectrum is observed by the electron shelving method [6] with a measurement sequence using laser pulses [2]. A stable dc magnetic field is used to resolve the clock transition into ten Zeeman components. In our previous measurement, the spectrum was broadened to a few hundred hertz mainly due to the ambient magnetic field fluctuation. Therefore, we have developed an ion trap chamber equipped with a two-layer magnetic shield. This shield decreases the amplitude of the ambient magnetic field by a factor of more than 25.

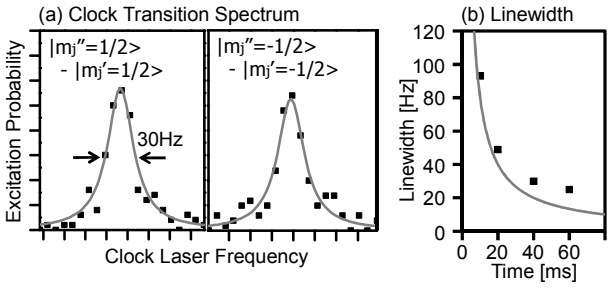

Figure 3. (a) Typical clock transition spectra and their Lorentz fitting. (b) Linewidth as the function of interrogating time of the clock laser. Gray line shows theoretical transit-time broadening using rectangular light pulses.

A typical transition spectrum is shown in Fig. 3 (a). It shows a pair of the Zeeman components of $|{}^2S_{1/2}, M_J=1/2\rangle$ - $|{}^2D_{5/2}, M_J=1/2\rangle$ and $|{}^2S_{1/2}, -1/2\rangle$ - $|{}^2D_{5/2}, -1/2\rangle$ transitions. Averaging of these two transition frequencies cancels the first order Zeeman shift. The linewidth is about 30 Hz when the interrogation time of the trapped ion by the 729-nm light was 40 ms. The measured linewidth at various interrogation times is shown in Fig. 3 (b). It was mainly limited by the transit-time broadening by rectangular 729-nm light pulses. Introducing the magnetic shield, the observed linewidth has been decreased to be about one digit smaller than that previously observed.

III. Frequency Stability Measurement

To certify the frequency stability of the $^{40}Ca^+$ optical clock, we stabilized the 729-nm laser frequency by the $^{40}Ca^+$ clock transition. The frequency was locked to the average of the two Zeeman components of the $|{}^2S_{1/2}, M_J=1/2\rangle$ - $|{}^2D_{5/2}, M_J=1/2\rangle$ and $|{}^2S_{1/2}, -1/2\rangle$ - $|{}^2D_{5/2}, -1/2\rangle$ pair, which was shown in Fig. 3(a). At the first we measured the stabilized frequency using an optical comb based on a femto-second pulse laser. A cryogenic sapphire oscillator (CSO) was used as the frequency reference. And next, we measured the frequency of the $^{40}Ca^+$ clock in comparison with that of an ^{87}Sr optical lattice clock.

In the short term, the clock laser frequency at 729 nm is stabilized using an ultra-low-expansion (ULE) optical cavity, which has a high finesse of about 2×10^5. Because of the material aging, however, its resonance frequency has a slow long-term frequency drift with a rate of about 0.03 Hz/s. In addition, very small thermal fluctuation of the optical cavity causes a non-linear frequency drift. The long-term linear drift was reduced using a frequency chirp with an acousto-optic modulator (AOM1 in Fig. 2). The residual drift was detected by the spectrum observation with the second AOM (AOM3). The residual drift was evaluated every 25 seconds and it was compensated using the third AOM (AOM2). Figure 4 (circles) shows the Allan deviation of the frequency stability measured using the CSO as the frequency reference. We believe that the Allan deviation of 1×10^{-15} at an averaging time of 10^3 seconds was limited by the stability of the CSO.

To measure the stability of the $^{40}Ca^+$ clock at the averaging time of more than 10^3 seconds, we compared the stabilized laser frequency to a 698-nm laser frequency that was locked to the ^{87}Sr clock transition. The ^{87}Sr clock was developed using the optical lattice technique [7]. The measured Allan deviation is also shown in Fig. 4 (squares). An Allan deviation of 7×10^{-16} at 10^3 s was measured. The Allan deviation was limited to about 5×10^{-15} at 10^3 s when we measured the stability without magnetic shielding. An improvement in the stability of about one digit over our previous measurements was attained.

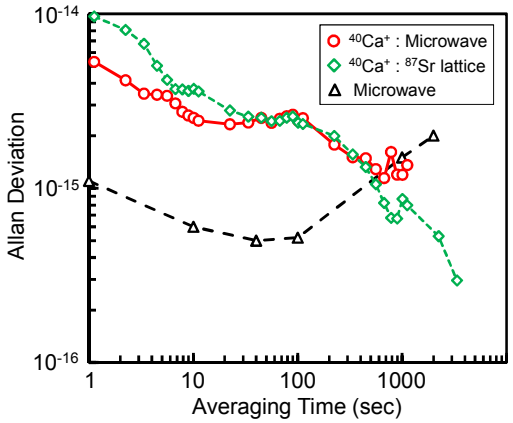

Figure 4. Frequency stability evaluated by Allan deviation between the $^{40}Ca^+$ clock, the ^{87}Sr lattice clock and the microwave frequency standard. Circles (red): Allan deviation between the $^{40}Ca^+$ clock and the microwave standard: Squares (green): between the $^{40}Ca^+$ and the ^{87}Sr clock; Triangles (black): Allan deviation of the cryogenic sapphire oscillator measured by the developer (University of West Australia).

IV. Absolute Frequency Measurement

The absolute frequency of the $^{40}Ca^+$ clock transition was evaluated from the laser frequency locked to the $^{40}Ca^+$ clock. It was measured by an optical comb with a hydrogen maser as the frequency reference. Here, the frequency of the hydrogen maser is evaluated every second by the Coordinated Universal Time (UTC) maintained in NICT. Time difference between the UTC(NICT) and the SI definition of the second on the

geoid surface (TAI) was corrected using the Circular T by the BIPM.

Systematic frequency shifts were evaluated as follows. In order to avoid the ac Stalk shift caused by the 397- and 866-nm light powers, we used a measurement sequence using the laser pulses [2]. A faint leakage of the 397- and 866-nm light powers during the interrogation time by the 729-nm laser causes a large ac Stark shift. Therefore, using a combination of a mechanical shutter and an AOM one we fully blocked the 397- and 866-nm light power, and we checked a negligible amount of frequency shift for our measurement by measuring the clock transition with various 397- and 866-nm powers. Black body radiation (BBR) frequency shift of 0.4 (0.5) Hz was evaluated from the room temperature. From the geographical height of the ion trap from the geoid surface, the gravitational shift was evaluated to be 3.4 (0.1) Hz [8].

TABLE I. SYSTEMATIC SHIFTS AND UNCERTAINTIES

Physical effect and drift	*Correction* (Hz)	*Uncertainty* (Hz)
Gravitational shift	3.4	0.1
Black body radiation shift	0.4	0.5
Electric quadrupole shift	0	2
Quadratic Zeeman shift (3μT)	0	0.1
ULE cavity drift	0	0.5
Magnetic field strength drift	0	0.5

The electric quadrupole moment of the D_J state interacts with the electric field gradient, causing an additional shift of a few hertz [9]. The value of the quadrupole shift ($\Delta\nu_Q$) at the M_J sublevel of the D_J state is expressed using

$$\hbar\Delta\nu_Q = \frac{dE_z}{dz}\Theta(D, j)\frac{J(J+1)-3M_J^2}{4J(2J-1)}(3\cos^2\beta-1). \quad (1)$$

where E_Z/d_Z is the electric field gradient along the symmetry axis of the trap potential (z), β is the angle between the axis z and the magnetic field, and $\Theta(D, j)$ is the strength of the quadrupole moment in terms of a reduced matrix element. From Eq. (1), the ratio of the quadrupole shift of the $|^2D_{5/2}, M_J = \pm1/2\rangle$ levels to the $|^2D_{5/2}, \pm3/2\rangle$ level and $|^2D_{5/2}, \pm5/2\rangle$ level is 4:1:-5. Therefore, the quadrupole shift can be canceled by averaging the transition frequencies of six Zeeman components of the $|^2S_{1/2}, \pm1/2\rangle$ - $|^2D_{5/2}, \pm1/2\rangle$ ($\Delta M_J = 0$ transition), $|^2S_{1/2}, \pm1/2\rangle$ - $|^2D_{5/2}, \pm3/2\rangle$ ($\Delta M_J = 1$), and $|^2S_{1/2}, \pm1/2\rangle$ - $|^2D_{5/2}, \pm5/2\rangle$ ($\Delta M_J = 2$). The uncertainty of 2 Hz was estimated from the standard deviation when we fitted the measured quadrupole shifts to the theoretical shift ratio of 4:1:-5. We considered other contributions to the transition frequency shift, such as the quadratic Zeeman shift, which were listed in TABLE I. The total correction was 3.8 (2.2) Hz.

We measured the absolute transition frequency on two separate days in this year, 16 February and 3 March in 2011. In each of the measurement, after observation of the transition spectrum, we stabilized the clock laser frequency to the average of the $|^2S_{1/2}, \pm1/2\rangle$ - $|^2D_{5/2}, \pm1/2\rangle$ transition pair. And then, we measured the clock laser frequency for about one hour by the optical comb. The Allan deviation was smaller than 3×10^{-15} at the averaging time of 10^3 seconds. Therefore it was considered that the long-term drift of the systematic shift including the quadrupole shift was smaller than 2 Hz for 10^3 seconds. The stabilized frequency was also measured for each of the $|^2S_{1/2}, \pm1/2\rangle$ - $|^2D_{5/2}, \pm3/2\rangle$ transition pair and the $|^2S_{1/2}, \pm1/2\rangle$ - $|^2D_{5/2}, \pm5/2\rangle$ one. The average frequency of these three measurements was used to evaluate the transition frequency. It was compensated for both of the first order Zeeman shift and the electric quadrupole shift.

The measured frequency was corrected using the Circular T. For the measurement on 16 February, we evaluated a correction of 0.1 (2.0) Hz using Circular T 278. For the measurement on 3 March, we evaluated a correction of 2.0 (2.0) Hz using Circular T 279. The uncertainty was estimated from the link uncertainty between the UTC(NICT) and the TAI. From the measured frequency, the correction using Circular T, and the shifts in TABLE I, we evaluated the absolute frequency of the $^{40}Ca^+$ clock transition to be 411 042 129 776 397 (3) Hz.

At the present, we have evaluated the absolute frequency from the measurements on two separate days. In 2009 M. Chwalla *et al*. reported the $^{40}Ca^+$ clock frequency to be 411 042 129 776 393.2 (1.0) Hz [3]. Although it overlaps with our measurement by the range of the frequency uncertainty, we will need further evaluation about the frequency difference between the two measurements. While we evaluated the BBR shift by the room temperature, it is preferable to measure the temperature at the ion trap electrode surface. Making full use of the advantage of the improved linewith and stability, we are now trying to re-evaluate the systematic shifts. The link uncertainty between the UTC(NICT) and TAI might be also a problem. Taking all effects into account, we will evaluate the absolute transition frequency, aiming at a total uncertainty of low parts in 10^{-15}.

V. CONCLUSION

We have improved our experimental setup using an ion trap equipped with a magnetic shield. The linewidth of the $^2S_{1/2}$ - $^2D_{5/2}$ clock transition was decreased to about 30 Hz. Stabilizing the clock laser frequency to the clock transition, the Allan deviance of 7×10^{-16} at 10^3 s was measured. We preliminarily evaluated the absolute frequency to be 411 042 129 776 397 (3) Hz with respect to the SI definition of the second. We now measure the transition frequency in order to evaluate the absolute frequency with an uncertainty of low parts in 10^{-15} level.

ACKNOWLEDGMENT

The ^{87}Sr optical lattice clock at NICT is developed by Dr. Atsushi Yamaguchi and Dr. Tetsuya Ido. The CSO was developed at the University of West Australia [10] and it is maintained by Dr. Motohiro Kumagai. The authors would like to express their appreciation to these collaborators.

I. Introduction

Inrecent years significant attention has been devoted to optical lattice clocks, in part because the prospects for a fractional frequency uncertainty of such clocks could achieve a level $10^{-17} - 10^{-19}$. On the other hand, the clock transition $^1S_0 - {}^3P_0$ in strontium atoms is being considered as one of the choices for a new definition of the SI second. Precise measurements of this transition at the best laboratories agree with uncertainties in the 10^{-15} range [1] -[4].

In the present paper we discussed the design of the strontium experiment at VNIIFTRI. The $^1S_0 - {}^3P_0$ transition with a hyperfine induced decay rate at λ_0 = 698 nm is used as the clock transition of ^{87}Sr atoms trapped in a 1D vertical optical lattice. The optical lattice formed by the standing wave of linearly polarized light at λ_L = 813 nm was kept on duration the experimental sequence. A preliminary cooling uses a MOT operating at the cycling transition $^1S_0 - {}^3P_1$ at 461 nm. Then the precooled atoms are trapped in the MOT using 698 nm diode laser. In order to probe the clock transition, an external cavity laser diode was stabilized to a high- finesse reference cavity made of ultralow extension (ULE) glass.

The preliminary results of the measurements are given.

II. Experimental Setup

Cooling and trapping of ^{87}Sr are conducted in two stages (Fig. 1). The energy levels related to the experiment are shown in the Fig. 2. All transition wavelengths, needed for cooling and trapping, are easily provided with commercial diode lasers. For example, to generate the 461 nm light we use a standard technique of doubling the frequency of a 922 nm Toptica diode/amplifier laser combination with a resonant cavity containing a BiBO non-linear crystal. The atoms coming out of an oven heated to 450-500°C are slowed down using a 30 cm long Zeeman slower. The trapping and oven chambers are evacuated by a 75 l/s and 10 l/s ion

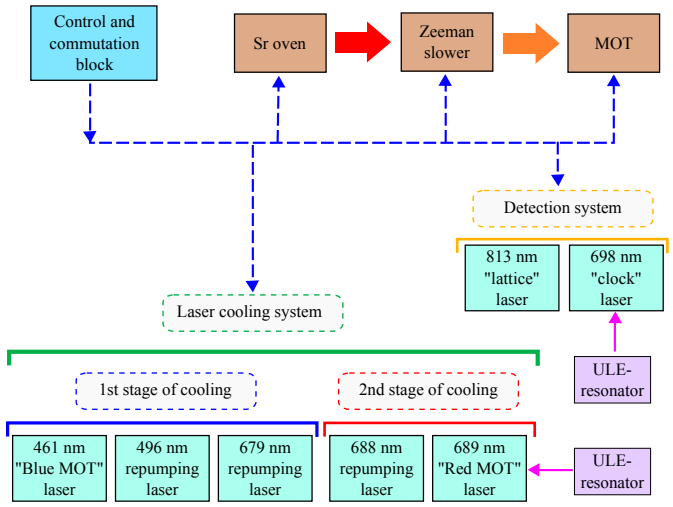

Fig. 1. A schematical drawing of our experiment.

pumps respectively, and vacuum levels $6.5 \cdot 10^{-11}$ mbar (oven chamber) and $1.6 \cdot 10^{-8}$mbar (trapping chamber) are achieved. Anti-Helmholtz MOT coils are made from 4mm OD copper tube, which ensures effective direct watercooling.

A vacuum chamber is mounted on vertically placed optical plate and put inside the system of the coils, intended to compensate the Earth's magnetic field, which have a form of a cube with sides equal 1 m (see Fig. 3). The measurements of the magnetic field generated by 3 pairs of these coils have been made; the currents, necessary for generation of compensatory magnetic field, have been determined for each pair of coils.

To stabilize "Red MOT" 689 nm and "clock" 698 nm lasers, two ULE-resonators are utilized [5]. Each one is placed inside vacuum chamber (vacuum is better than 10^{-7} mbar) and then mounted on 400×400 mm vibration-isolated platform. The characteristics of ULE-resonators are following: temperature excursions (without a laboratory climate control system) are smaller than 10 mK, finesse is 60000, free spectral range is 1.92 GHz.

The first stage MOT is operated on the $^1S_0 - {}^1P_1$ transition (with linewidth 32 MHz) at 461 nm. The number of atoms in the $^1S_0 - {}^1P_1$ MOT were increased by an order by using the 679 nm and 496 nm repumping lasers (see Fig. 4). The second stage cooling operates on the 689 nm $^1S_0 - {}^3P_1$ (linewidth 7.6 kHz) intercombination transition.

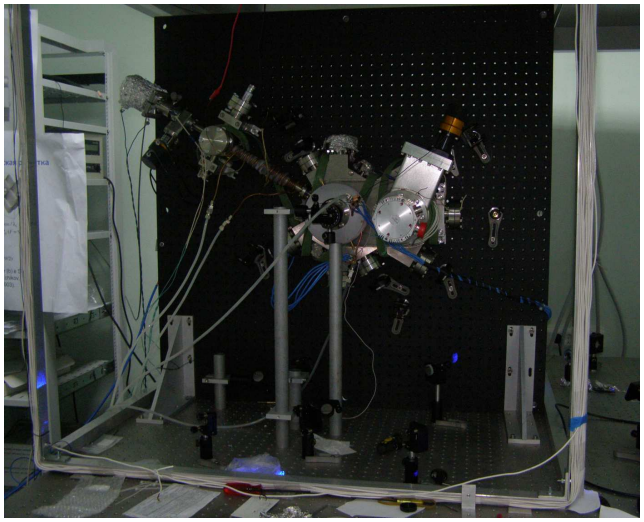

Fig. 3. The working chamber placed on optical table.

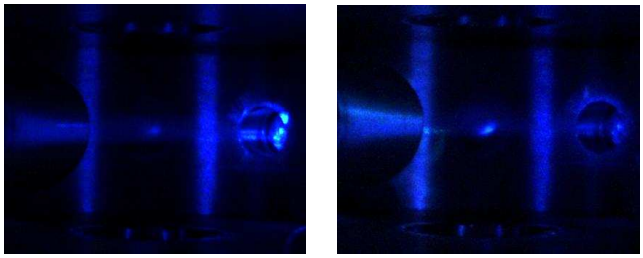
III. AOM IN RAMAN-NATH MODE

The second stage laser cooling of Sr atom in a optical lattice on 689 nm $^1S_0 - {}^3P_1$ transition requires an ECDL (external cavity diode laser) whose short-term line-width is comparable with the 7.5 kHz transition natural width. The line-width of the ECDL can be first narrowed by locking the laser to a stable optical cavity via the Pound-Drever-Hall technique. To date, a Pound-Drever-Hall method with AOM-RN, a new sample of acousto-optic modulator designed to operate in a pure Raman-Nath diffraction regime [6], as an optical phase modulator has been used for frequency stabilization of the 689 nm diode laser. To ensure long-term stability, the ECDL should be next locked to the $^1S_0 - {}^3P_1$ resonance via saturated absorption spectroscopy. Again, this can be done by means of FM spectroscopy of saturated absorption resonances in the Sr atomic beam with the same AOM-RN as a phase modulator.

The only seeming disadvantage of AOM-RN is the spatial divergency of its frequency modulated output spectrum. We show experimentally that this divergency, as in the case of saturated absorption spectroscopy in the atomic vapor [6], is not an obstacle to obtain the error signals by means of FM



(a) (b)

Fig. 4. A cloud of cold atoms trapped in Blue MOT (a) without any repumping (b) with 679 nm laser repumping.

sideband heterodyne technique with the use of high-finesse (up to tens of thousands) Fabry-Perot cavities as frequency discriminators.

The experimental set-up is shown in Fig. 5. Developed and designed in VNIIFTRI AOM-RN provides fm spectrum of a single-mode ECDL radiation at $\lambda = 689$ nm. This modulator has a center working frequency of 30 MHz and a modulation bandwidth of 20 MHz. Its acousto-optic interaction length is 2 mm. AOM-RN frequency modulated output spectrum consists of a strong carrier at frequency ω_{ECDL} and two weak sidebands at $\omega_{\mathrm{ECDL}} \pm \Omega$ corresponding to the 1st diffraction orders. Ω is the AOM-RN modulation frequency. Lenses L1 and L2 form a telescope system with AOM-RN in between. The Fabry-Perot (ULE) input radiation represents three collimated and parallel light beams with size of 2 mm in plane where all three beams lie. The ultra-low expansion (ULE) Fabry-Perot cavity with finesse about 60000 and $\mathrm{FSR} = 1.92$ GHz has been used as a frequency discriminator. A part of collimated AOM-RN output consisted, as before, of a carrier and two sidebands was fed via polarization maintaining fiber to the ULE-cavity. The AOM-RN modulation frequency was 19.99 MHz. The total radiation power at the fiber output was $\mathrm{P} = 0.34$ mW. Three dispersion-like error signals can be observed on curve 1 when the ECDL frequency ω_{ECDL} is scanned (see. Fig. 6). Each of them arises when the frequencies of the upper, carrier and lower sidebands match consecutively the resonance frequency of the ULE-cavity.

IV. CONCUSIONS

In summary, we have discussed the prospects of an optical clock operating on the $^1S_0 - {}^3P_0$ transition in ^{87}Sr isotope. As a first step for the realization of proposed optical clock, we have efficiently cooled and trapped ^{87}Sr atoms in a blue magneto-optical trap employing a Zeeman slower. The first stage MOT is operated on the $^1S_0 - {}^3P_1$ transition at 461 nm. We found, that the number of ^{87}Sr atoms were increased by an order by using the 679 nm and 496 nm repumping lasers. The experimental set-up with ULE-cavity and error signals are discussed.

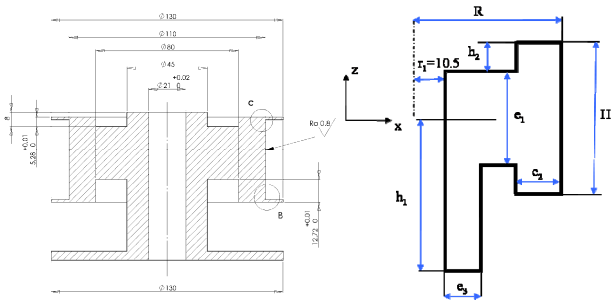
***Abstract*—Mechanical vibration induced frequency noise is dominated at low Fourier frequencies in a fiber spool stabilized laser. Environmental vibration causes mechanical deformations in the fiber which induce phase fluctuations and then convert into excess frequency noise to the lasers. Therefore, the spool which supports the fiber plays a critical role in this frequency noise conversion. We have studied several different structures of spool. The preliminary results are about $3x10^{-10}/m\ s^{-2}$ for accelerations along the spool axis. In this paper, we describe the development of a spool design which is optimized for low vibration sensitivity along all spatial directions. Both simulations by Finite Element Modeling (FEM) and vibration sensitivity measurements are presented.**

I. INTRODUCTION

Very low noise lasers is a powerful tool which has a variety of important applications, such as optical frequency standards, gravitational wave detection and generation of low phase noise microwave signals. Currently, the lowest noise lasers are realized by stabilizing laser frequency onto an ultra stable high-finesse Fabry-Perot cavity with PDH method [1-3]. However, this approach requires stable and fine alignment of free space optical elements and high vacuum. A radical alternative is to use an optical fiber delay line as a frequency reference to stabilize laser frequency. Recently we demonstrated that the fiber-stabilized laser showed a comparable frequency noise to the one obtained by PDH locking to a high-finesse cavity for Fourier frequency from 40 Hz to 30 kHz and a level below $1Hz^2/Hz$ at 1Hz [4, 5].

The fiber stabilized laser is mainly sensitive to mechanic noise, temperature fluctuation, acoustic noise and air-flow. At low Fourier frequencies, the mechanical vibration is critical. First study on low vibration fiber spool was done by Huang et al [6]. They use an anti-symmetric structure to mount two identical fiber spools to obtain very low vibration sensitivity ($\sim 10^{-11}/ms^{-2}$). We pursuit the effort in this direction and propose to design a spool with similar level of vibration sensitivity or better.



(a) (b)

Fig. 1. (a) Mechanical draw of the spool. (b) Simplified schematic of the spool.

II. DESIGN AND SIMULATION OF LOW VIBRATION SENSITIVITY FIBER SPOOL

Before this design, we studied several configurations, such as simple cylindrical spools and cylindrical spool symmetrically held on a central post, and found that the vibration sensitivity depends strongly on the holding conditions. To overcome this problem, we develop a spool with asymmetric support configuration that would be independent on the holding constraints. The mechanical draw of the spool is shown in Fig. 1 (a). Because the spool has an axial symmetry structure, we restrict our analysis to the half section (Fig. 1 (b)). The spool is made of Titanium because of its stiffness and small mass compared with other metal materials. Some similar works about spool materials have been done and published [7]. The analysis is done by FEM with the hypothesis that fiber delay variation follows the support surface deformation. We test the consistency of the support surface deformation by varying the boundary

conditions. By optimizing the post length, in such a way, the surface variation under acceleration is independent from the boundary conditions applied on the post base.

This geometry shows another interesting feature. If we plot the FEM calculated vibration sensitivity with different h_2 parameter (see Fig.1 (b)) values as shown in Fig. 2, we can observe that the vertical vibration sensitivity can be zeroed with an optimized value of $h_2 \approx 5.2$mm. Other geometrical parameters (see Fig. 1 (b)) also influence the vibration sensitivity. For example, increasing the central width e_1 moves the null sensitivity point close to $h_2=0$ while increasing the radius R displaces this point towards opposite direction. The increasing of e_1 value reduces the vibration sensitivity coupling to the holding post length and the boundary conditions. The final geometry of the spool is optimized to hold more than 2km of fiber. In addition, a modal analysis is also performed and shows the first resonance of about 1.5 kHz.

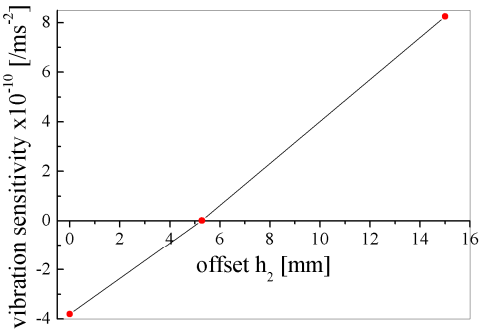


Fig. 2. Plot of FEM calculated vibration sensitivity with different h_2 parameter values

III. VIBRATION SENSITIVITY MEASUREMENT SETUP

The measurement is done in three steps. We first lock the laser source to the fiber interferometer and measure its frequency noise. Then, we shake the fiber spool vertically and measure the transfer function of frequency noise to vertical acceleration. And finally, the vibration sensitivity of the spool is calculated by the transfer function. The schematic of measurement is shown in Fig. 3. The interferometer part is enclosed by dash line.

A fiber laser at 1542.14 nm is used as the laser source, the laser beam goes to the Michelson interferometer passing through an acousto-optical modulator (AOM1). Another acousto-optical modulator (AOM2) is placed into the long arm of interferometer after a 300 m fiber spool and driven by a 70 MHz RF signal. Therefore, the heterodyne detection signal is 140 MHz. We use a home-made low phase noise tunable synthesizer to provide demodulation signal and a low-pass filter converts the demodulation signal into laser frequency correction signal. The correction signal simultaneously acts on a piezo-electric transducer (PZT) stretcher which provides a slow correction on large range and a voltage controlled oscillator (VCO) which drives AOM1 providing fast correction. The fiber spool stabilized laser is combined with a signal from PDH cavity stabilized laser to provide a beat note signal for frequency noise analysis. The fiber spool is housed in an aluminum cylindrical enclosure and placed on an active vibration isolation platform which can be used as a low level shaker by external modulation. In the same time, the other part of interferometer is placed on a passive vibration isolation platform and connected to the fiber spool by two output fibers. The transfer function of frequency noise to vertical acceleration $T_r(f)$ is measured by a vector signal analyzer HP89410. This instrument generates a chirp modulation signal injected in the active vibration isolation platform and then calculates the transfer function between acceleration noise $S_a(f)$ and the measured frequency noise $S_v(f)$ as follow:

$$T_r(f) = (S_v(f) / S_a(f))^{1/2} \quad (1)$$

The acceleration is measured by an accelerometer 356B18 (PIEZOTRONICS INC.) placed on the top of the aluminum enclosure. The vibration sensitivity of the spool $\Gamma(f)$ can be presented as:

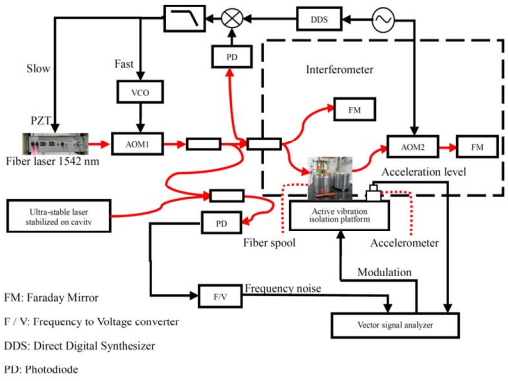

Fig. 3. Schematic of vibration sensitivity measurement, the optical signals are drawn in red while the electronic signals drawn in black

$$\Gamma(f) = \Delta L / (L\Delta V) = \Delta\tau / (\tau\Delta V) = T_r(f) / \nu_0 \quad (2)$$

Where ΔL, L, $\Delta\tau$, τ, ΔV, ν_0 represents length variation, total length, delay variation, total delay of the fiber spool and acceleration variation, optical frequency, respectively. Additionally, it should be noticed that the acceleration level is quite low (1mg RMS maximum level). At frequency higher than 60 Hz the acceleration rolls off of about 20 dB up to 110 Hz because of the response of the active vibration isolation platform.

IV. THE RESULTS AND DISCUSSIONS

In our experiment, the reference fiber is standard single mode fiber (SMF-28). Two output fibers of about 0.4 m are used as connections between the fiber spool and other optical components in interferometer. These output fibers are bare fiber (8/125/250μm) and can be looked as "free" fiber because

they are only fixed by few points. We notice that the vibration sensitivity of the fiber spool has dependency on the way to fix these fibers. As a consequence, we measure the vibration sensitivity of the fiber spool with different tensions on the "free" fiber. The results are shown in Fig. 4. The vibration sensitivity of new-design spool wound with 300 m fiber is around $5\times10^{-11}/ms^{-2}$. However, it is strongly influenced by the constraints on the "free" fiber. The Young's modulus of SMF-28 fiber is about two orders of magnitude lower than that of spool materials. Therefore, the vibration sensitivity of the "free" fiber should be same order higher than that of the fiber wound on the spool. Some studies about fiber vibration sensitivity have been doing in NIST [8]. Moreover, different constraints on the "free" fiber will change its vibration transmission and result in vibration sensitivity variation.

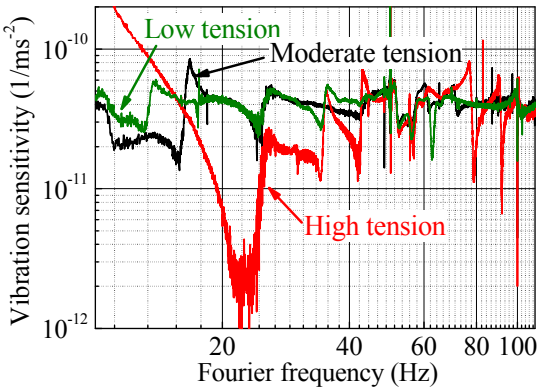

Fig. 4. Vibration sensitivity of fiber spool with different tensions applied on the "free" fiber

The impact of the "free" fiber on the overall vibration sensitivity is still being studied. Nevertheless, several ideas can be carried out to reduce its contribution, such as increasing the fiber length wound on the spool while reducing the "free" fiber length, removing the optical connectors instead of optical splicing. In addition, the studies of vibration sensitivity contributions from other optical components (AOM, FM, etc.) will be performed in the future. In this way, we want to demonstrate a compact ultra-low noise laser without vibration isolation platform that could be used for a variety of precision measurement applications.

Abstract— We demonstrate coherent detection of the emission from a terahertz frequency quantum cascade laser which is actively mode-locked by modulating its bias-current with a microwave synthesizer. Coherent sampling of the terahertz pulse train is achieved by phase-locking the repetition rate and the carrier frequency of the terahertz quantum cascade laser to the repetition rate of the of a commercial erbium-doped mode-locked femtosecond fibre laser. We show that the terahertz pulses from the quantum cascade laser are transform limited, and reconstruct the full emitted waveform.

Introduction

Quantum cascade lasers (QCLs) are unipolar semiconductor lasers based on electronic intersubband transitions in the conduction band of multi-layered heterostructures [1]. In contrast to interband diode lasers, where the lifetime of the electrons populating the upper laser state is determined by electron-hole recombination, the electron lifetime in QCLs is dominated by non-radiative phenomena, and in particular optical-phonon scattering. This leads to fast relaxation times, on the picosecond (ps) timescale, which have an important impact on the dynamical properties of this family of devices [2]. In particular, modulation bandwidths up to several tens of GHz have been demonstrated, which were recently used to show that the frequency separation, or roundtrip frequency, between the longitudinal modes of multimode terahertz (THz) frequency QCLs [3-7] can be stabilised using an external RF-synthesiser [8-11]. Under these conditions the laser is expected to operate in a regime of active mode-locking, producing a train of short pulses. The lack of suitable detection techniques in the THz range has prevented the measurement of these pulses. Difficulty in demonstrating QCL mode-locking has previously been encountered at mid-infrared (mid-IR) frequencies, and arises in part from the inefficiency of second-order autocorrelation techniques in the mid-IR (and THz) ranges, hindering the measurement of the emitted pulse train. The first reports of passive and active mode-locking of mid-IR QCLs were later identified as coherent dynamic instabilities resulting from the fast gain recovery time (~1 ps) preventing the formation of stable mode-locked pulses. Recently, however, mode-locking of a QCL operating at 6.3 μm has been demonstrated using 2nd order auto-correlation with a two-photon quantum well detector. Compared to mid-IR QCLs, THz QCLs based on bound-to-continuum active regions have generally longer non-radiative relaxation times of the upper laser state, of ~5-10 ps, as a result of the laser transition energy lying below the optical phonon energy.

We show that THz QCLs can be operated in a regime of active mode-locking. The measurement proof of mode-locking operation is obtained by sampling the electric field amplitude emitted by the QCL using a mode-locked fs-laser. In our work, we use off the shelf mode-locked erbium-doped fs-laser emitting at 1.55 μm (193 THz), for the asynchronous sampling of a mode-locked QCL emitting at 2.5 THz [7]. Mode-locking of the QCL is obtained by direct modulation of its bias current close to the laser roundtrip frequency[11]. Asynchronous sampling is made possible by phase-locking the QCL source to the fs-laser,[12] i.e. the pulse repetition rate of the QCL at ~13.3 GHz and its carrier frequency at 2.5 THz are simultaneously phase-locked to a harmonic of the repetition rate of the fs-laser-comb at 96.5 MHz. Furthers details in Refs [12,13]

***Abstract*— This work presents a new class of devices, AlN-based lateral overmoded bulk acoustic wave resonators (LOBAR), to investigate the Q limit imposed by the intrinsic loss of thin film AlN. The LOBAR devices utilize a rectangular AlN thin film plate with a small percentage (0.57%) inter-digitated transducer (IDT) fingers coverage to minimize the piezoelectric-metal interface loss. This design experimentally pushes the $f \cdot Q$ product value (1.17×10^{13}) for thin-film AlN to magnitude level close to the theoretical limit predicted by the Akhizer effect (AKE) for AlN ($2.5\text{-}5 \times 10^{13}$). To study the performance of the LOBAR design, the IDT to rectangular plate coverage ratio was varied. The results have shown that the Q of the LOBAR device scales nonlinearly and inversely with coverage ratio. Measurement of the highest Q LOBAR device for temperatures varying between 300 and 400 K have indicated that the AlN LOBAR has a temperature coefficient of frequency (TCF) of -16.25 ppm/K, and phonon-phonon dissipation (AKE) is not yet the dominant loss mechanism..**

I. Introduction

Driven by the increasing needs for high performance, multi-functional wireless services, several researcher groups have been working on the implementation of intelligent systems that realize more efficient ways of utilizing the increasingly crowded RF spectrum. One of the most popular approaches involves sensing the ambient radio spectrum and seeking for opportunistic use of idle RF channels [1]. Making such systems feasible for handheld mobile applications, requires the implementation of low cost and power spectrum analyzers. A very promising way of synthesizing such a system with low complexity is to detect the RF power density across the spectrum using passive narrowband channelizes and power detectors. Such approach has strong potential to enable low cost deployment of cognitive radios [2]. The same channelizer can also be used to assist feature-base spectrum sensing to significantly reduce the device count and power requirements. However, the implementation of such narrowband channelizers, which requirehigh Q ($>$ 10,000) and low motional impedance resonators (50Ω), remains a grand challenge. Micro-machined electrostatic and piezoelectric resonators have already demonstrated their capabilities to potentially meet these requirements at high and very high frequencies(3-300 MHz) [3][4]. However, at higher RF frequencies (∼3 GHz), such task becomes significantly more difficult due to $f \cdot Q$ limit imposed by phonon-phonon dissipation [5]. In the past, numerous research efforts have been focused on bringing the experimentally

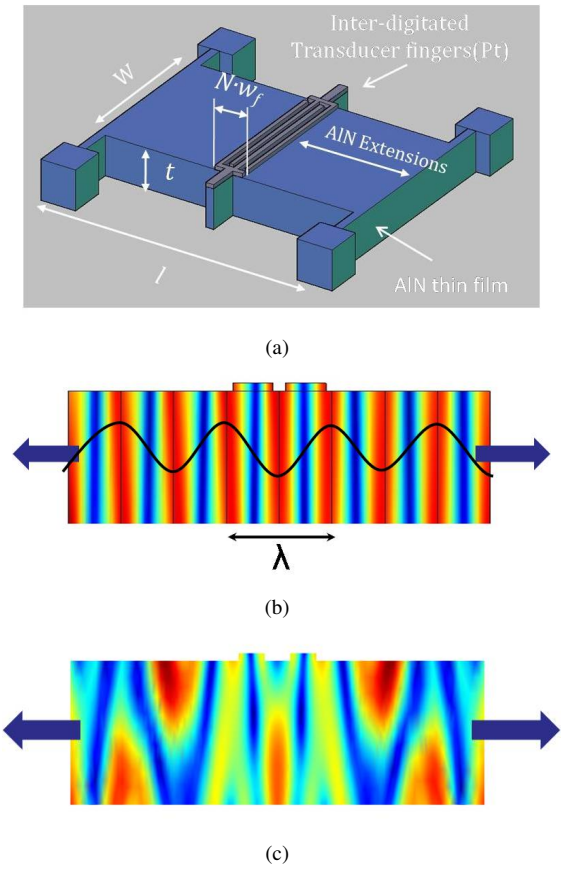

Fig. 1. (a) Mockup view of the AlN-LOBAR resonator (b) COMSOL simulation showing the lateral vibration generated in the AlN-LOBAR devices (c) COMSOL simulation showing the S1 lamb-mode (3.3 GHz) in the same device.

demonstrated $f \cdot Q$ product of different materials close to the their theoretically predicted values, and simultaneously enhancing the understanding of various loss mechanism in play [6]. Among these low loss materials, it has been show that Si can reach $f \cdot Q$ values (2-3 $\times$ 10^{13}) [7] [8] at GHz frequencies that are close to the theoretical limit(3.9×10^{13}) [5]. Instead, AlN-based resonators have an experimental $f \cdot Q$ that is about one order of magnitude lower than its theoretical limit[3][9][10][11].

This work reports on a new class of devices, the AlN

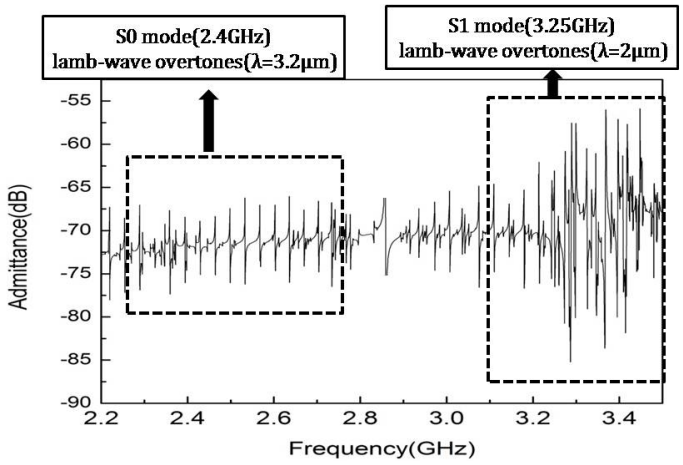

Fig. 2. COMSOL simulated admittance performance of one port AlN-LOBAR device having the dimensions shown in Table 1. A Q of 10,000 was assumed for AlN and a Q of 2,000 was assumed for Pt electrodes.

LOBAR, which permits to explore the ultimate $f \cdot Q$ in thin AlN piezoelectric films . Owing to the partial electrode coverage of the AlN LOBAR design, the device minimizes the piezoelectric-metal interface induced loss. Therefore, a high $f \cdot Q$ can be achieved. Effectively, the LOBAR device can be classified as a general instrument that can be readily adopted for experimentally studying the theoretical $f \cdot Q$ limits of many low loss acoustic materials (SiC [12], Si [8], Diamond [13], $LiNbO_3$ [14], and sapphire). In this paper we will demonstrate and study the LOBAR performance in AlN thin films.

II. DEVICE DESIGN AND MODELING

A. Device Operation

As shown in Fig. 1, the AlN LOBAR device, similarly to high overtone bulk acoustic wave resonators [15], utilizes a small volume piezoelectric transduction to induce vibrations in a larger resonant cavity. The prototype device has IDT placed in the center of the AlN thin film plate covering a small portion ($< 2\%$) of overall resonator. In operation, instead of launching thickness mode vibrations vertically into the substrate like the HBAR [16], the AlN LOBAR excites laterally S0 and S1 overtone vibrations into the AlN extensions as shown in Fig. 1(b) and 1(c). The center frequency of the S0 mode is defined by the lateral dimension of the IDT fingers. The S1 mode of vibration is also excited by the same IDT, but its center frequency is set primarily by the thickness of the AlN thin film plate. The LOBAR design incorporates multiple advantages. First, the piezoelectric-metal interface loss is greatly minimized by limiting the metal coverage on AlN. This is in line with what has been shown experimentally for AlN contour mode resonators [17]. Second, the well defined acoustic boundaries of the LOBAR in the lateral and vertical dimensions should yield lower energy loss into the supporting substrate (differently from the HBAR whose lateral boundaries are not well defined). Third, the device is easily fabricated with well-establish surface micromachining processes [18][19].

TABLE I

THE DEVICE DIMENSION FOR THE COMSOL SIMULATION.

$W(\mu m)$	$l(\mu m)$	$t(\mu m)$	$w_f(\mu m)$	t_f(nm)[1]	N[1]	CR[1]
48	560	1	1.6	50	2	0.57%

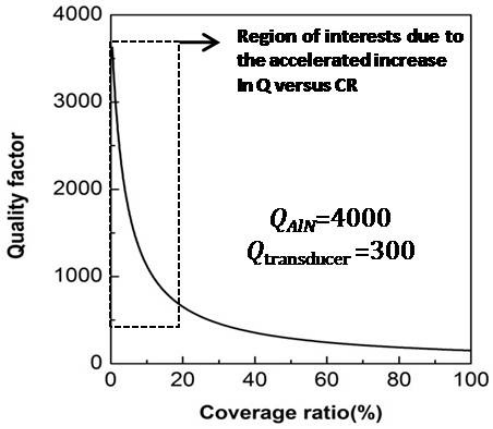

Fig. 3. Theoretical analysis of the quality factor versus coverage ratio. Arbitrary assumptions (close to what seen experimentally in GHz devices) on the transducer and AlN Q were made.

B. COMSOL Analysis

A one port device with the dimensions shown in Table I was simulated in COMSOL to predict its performance across the spectrum. The simulated results, shown in Fig. 2, indicate that two groups of overtones exist. The first group of overtones centered around 2.4 GHz are S0 (longitudinal) vibrations, whose center frequency is set by the lithographically defined IDT finger width (1.6 μm). The second group of overtones appearing between 3.0 and 3.5 GHz are the S1 mode lamb wave vibrations, of which center frequency (3.25 GHz) is determined by the thickness of the AlN thin film (1 μm in this case). The mode shape of one of the overtones (3.4 GHz) is shown in Fig. 1(c) to clearly show that most of the vibrations occur across the thickness of the film, although they propagate laterally.

C. Damping Model

In order to understand how the coverage ratio of the electrodes (IDT to total rectangular plate length ratio) affects the overall Q of the device, a simple linear damping model is used. Damping coefficients, ζ, are assigned to the transducer and extension section (uncovered portion of the AlN plate) of the LOBAR device.

$$\zeta_{unmetalized-AlN} = \frac{1}{2 \cdot Q_{unmetalized-AlN}} \quad (1)$$

$$\zeta_{Transducer} = \frac{1}{2 \cdot Q_{Transducer}} \quad (2)$$

As shown in Eq. 3, the overall damping coefficient of the device is related to the damping coefficients of the transducer

[1]where N is the number of fingers, and t_f is the thickness of the IDT electrodes, and CR is the coverage ratio.

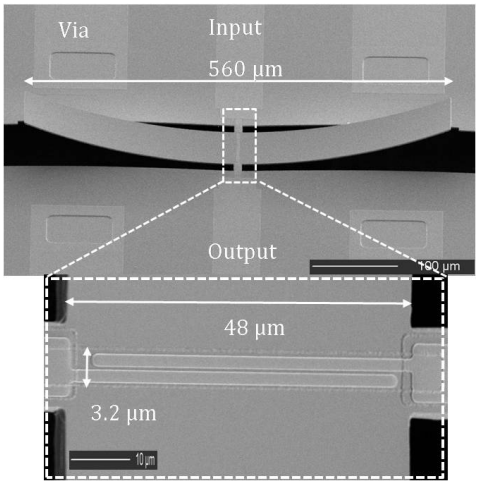

Fig. 4. The SEM of the fabricated AlN resonator with a coverage ratio of 0.67%. The device is made out of a 48×560 μm thin film AlN plate with 2 IDT fingers, each having a width of 1.6 μm. The anchors are placed in the center of the two sides of plate to provide signal routing and mechanical support.

and AlN extension via the coverage ratio.

$$\zeta_{Total} = \zeta_{unmetalized-AlN} \cdot (1 - CR) + \zeta_{Transducer} \cdot CR \quad (3)$$

$$Q_{Total} = \frac{1}{2\zeta_{Total}} \quad (4)$$

Fig. 3 shows that the quality factor of the overall device increases as the coverage ratio decreases for a given Q value of the transducer and extension sections. Due to the nonlinear relationship between Q and coverage ratio, an accelerated increase in Q is observed as the coverage ratio is reduced to below 10%. In order to reveal the Q limit imposed by the AlN material at high frequencies, a coverage ratio study should be performed for low percentages ($< 2\%$) so as to minimize the piezoelectric-interface loss.

III. EXPERIMENTAL RESULTS

Multiple devices are simultaneously fabricated using a fabrication process similar to the one described in [19]. One of the fabricated devices, with the same dimension as the one in the COMSOL model, is shown in the Fig. 4. The zoomed-in view shows excellent definition of the IDT fingers. The released AlN thin film exhibits upward curvature due to stress gradient accumulated in the fabrication process.

A. Transmission Response

The fabricated devices were measured at room temperature and atmospheric pressure with a probe station and network analyzer. On-chip TRL calibrations were performed for all these measurements. The measured transmission response, plotted in Fig. 5, shows multiple overtone resonances across the spectrum from 1.5 to 3.5 GHz with an even spacing of 16MHz. As predicted by the COMSOL simulations, the lateral mode (S0) overtone resonances center around 2.4 GHz. These S0 mode overtones ranging from 1.5 to 2.6 GHz attain average

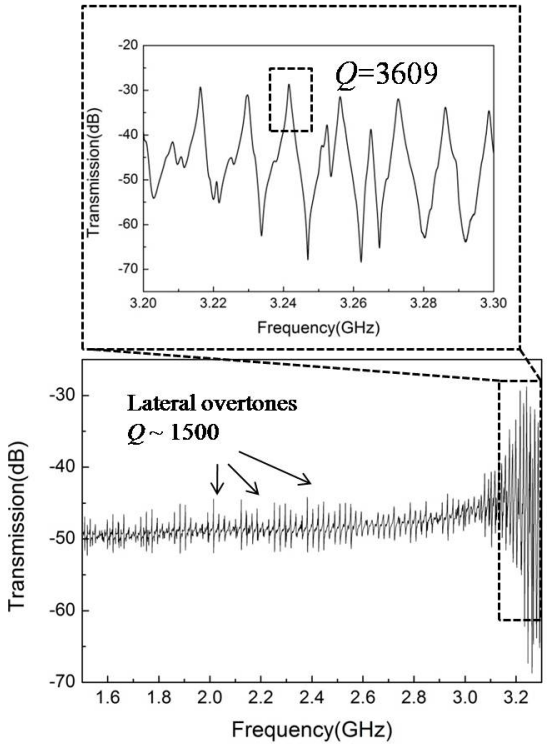

Fig. 5. Measured transmission response of the two-port AlN LOBAR device.

TABLE II
DIMENSIONS OF THE DEVICES USED IN THE COVERAGE STUDY AND THE MEASURED Q AND EXTRACTED R_m OF THESE DEVICES.

$Device$[1]	$W(\mu m)$	$l(\mu m)$	N	CR	R_m	Q
A	48	560	2	0.57%	3062	3609
B	48	480	2	0.67%	2912	3294
C	48	400	2	0.8%	3100	2935
D	48	320	2	1%	3021	2624
E	48	480	4	1.14%	3108	2284
F	48	320	4	2%	3087	1600

Qs of about 1500. S1 mode vibrations are also excited around 3.3 GHz with multiple overtone resonances. In comparison with the S0 mode, the S1 mode resonances have a smaller insertion loss due to the higher value of the electromechanical coupling coefficient (due to d33 $>$ d31). The highest Q among these overtones was recorded experimentally at 3.244 GHz. A value of 3609 was measured, resulting in a $f \cdot Q$ product of 1.17×10^{13}. This is the highest $f \cdot Q$ ever demonstrated for AlN-based micro-resonators (Fig. 6). This result is also very close to the theoretical limit for AlN [5]. This demonstration has effectively verified that AlN is indeed a high Q material at GHz frequencies, has great potentials in achieving higher Qs, and expand the use of AlN-based micro-resonators into new applications.

B. Coverage Ratio Study

[1]The AlN thickness in these devices is kept to 1 μm.

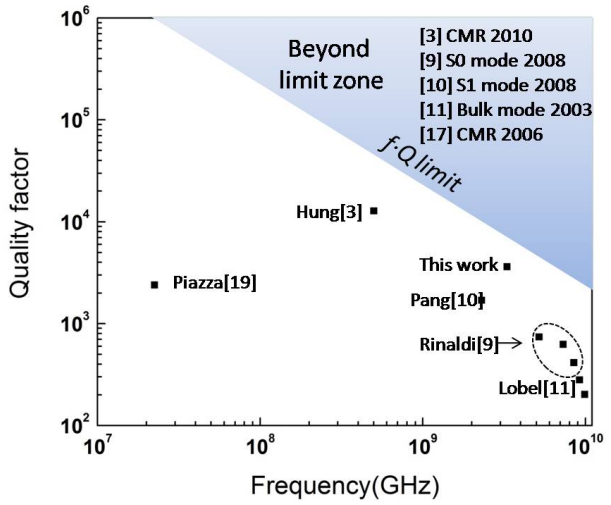

Fig. 6. Comparison of $f \cdot Q$ achieved by the state-of-art AlN-based micro-resonators.

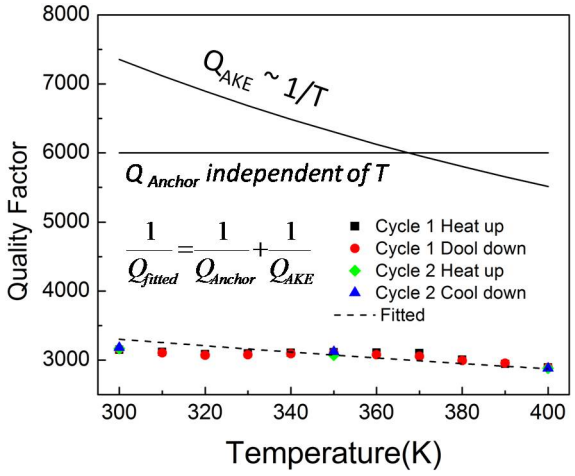

Fig. 7. The Measured Q of the LOBAR device versus temperature. Fitting of the measurements is done assuming phonon scattering and anchor loss are the two major damping mechanisms.

To experimentally investigate the effect of piezoelectric-metal interface induced loss on the quality factor of the AlN LOBAR devices, a coverage ratio (CR) study consisting of 6 devices with different dimensions and CR was performed. The device parameters are listed in Table II. The lateral dimensions of device A, B, C, and D are fixed to be 48 μm while their longitudinal dimension varies from 560 to 320 μm to attain coverage ratios from 0.57 to 1 %. Device E and F, despite having the same dimensions as device A and B, further increase the coverage ratio to 1.14 and 2 % by increasing the number of IDT fingers to 4. The measured Q values show an inverse scaling versus coverage ratio as predicted by the damping model. The extracted motional resistance R_m remains roughly constant as the coverage ratio varies. Therefore, although reducing the CR of the electrodes results in high Q, a trade-off between Q and electromechanical coupling, k_t^2 has to be made.

C. Temperature Study

The fabricated LOBAR devices were tested from 300 to 400 K under atmospheric pressure using the Lakeshore probe station. The devices were cycled between 300 and 400 K three times before each measurements. The device shown in Fig. 4 exhibits a TCF of -16.25 ppm/K as opposed to the -25 ppm/K commonly demonstrated by AlN contour mode resonator [19]. This is because the composition of AlN LOBAR is mostly un-metalized AlN and the TCF of these devices should be close to the theoretical value derived for sputtered AlN thin films [19]. The measured Q of the device shows little change versus temperature. As previously reported, phonon scattering due to Akhieser effect imposes a lower limit on Q than thermoelastic dissipation [5] in high frequency, extensional mode resonators,. The theoretical limit of Q thus can be formulated as:

$$Q_{AKE} = \frac{\rho c^2}{2\pi\gamma^2 c_v T}\frac{1}{f} \quad (5)$$

where γ is the Gruneisen's parameter, c is the acoustic velocity, c_v is the heat capacity per unit volume, T is the temperature, and f is the frequency of operation. As shown in Fig. 7, the Q of the LOBAR shows little dependence on temperature between 300 and 400 K. This indicates that other damping mechanisms independent of temperature (differently from the Akhizer's effect) are still contributing to setting the Q of the overall device. It is believed that anchor loss is playing a key role. Future studies on a larger set of devices will help in clarifying the origin of these damping mechanisms and engineer ways to is required in order lift the LOBAR Q limit close to Q_{AKE}.

IV. CONCLUSION

To summarize, a new class of piezoelectric micro-resonators, the LOBAR, has been demonstrated using sputtered AlN thin films. The fabricated devices exhibit multiple S0 and S1 mode overtone resonances across the GHz frequency spectrum. The highest Q of 3607 is observed for one of the S1 mode overtones, resulting in a $f \cdot Q$ product of 1.17×10^{13}. This is the highest $f \cdot Q$ product ever demonstrated for state-of-art AlN-based micro-resonators. These devices have moved one step closer to experimentally reach the theoretical $f \cdot Q$ limit imposed by the AlN material. A study on the electrode coverage ratio also validated the damping model used for understanding the working principle behind LOBAR type devices.

ACKNOWLEDGMENT

The authors would like thank DARPA for funding support through the chip scale spectrum analyzer project (CSSA) and Nipun Sinha for help with the device fabrication.

***Abstract*—This paper presents tunable width-extensional mode bulk acoustic resonators that are piezoelectrically-actuated and sensed using thin layers of AlN on the sidewalls as well as the top surface. By using both longitudinal and transverse piezoelectric effects of conformally-sputtered AlN layers on sidewalls and top surface of a 20 μm thick resonator, a low motional resistance of ~35 Ω was achieved for a 100 MHz silicon resonator operating in air. The motional resistance is improved by at least 10x compared to similar devices with capacitive transduction. Furthermore, it is shown that the resonance frequency of these piezoelectrically-transduced devices can be tuned by varying the electric signal power from 0 to 7 dBm.**

I. Introduction

Lateral bulk acoustic wave (BAW) resonators implemented in single crystal silicon (SCS) are of great interest for signal processing applications. Since the resonance frequencies of such resonators are defined lithographically, devices with multiple frequencies can be implemented in the same batch and integrated with CMOS circuitry. Furthermore, superior acoustic properties of SCS such as high bulk acoustic wave velocity, small intrinsic dissipation in different frequency regimes [1, 2] and extended linear-elastic region alleviate the implementation of resonators with small form factor, improved power handling, and high quality factor (Q). Although advances in micromachining techniques (i.e., fabrication of small capacitive gaps, deposition of high quality piezoelectric thin films, etc.) have enabled the realization of high-frequency SCS BAW resonators [2], large motional resistance of these devices remains a major obstacle to utilize them in low insertion loss filters.

Most transduction techniques that have been used to actuate and sense silicon BAW resonators [3-5] require a relatively large DC polarization voltage (V_p) to provide sufficient electromechanical coupling required for low motional resistances. Piezoelectric transduction, on the other hand, has the advantage of high electromechanical coupling without requiring V_p. However, all demonstrations of lateral micromechanical resonators have so far used the transverse piezoelectric coefficient e_{31} of a planar piezoelectric layer such as AlN [6-9]. While low motional resistances have been demonstrated using this technique for AlN-on-Si resonators [6], achieving low resistances (< 50 Ω) has been challenging due to limited transverse piezoelectric coupling, which is mainly a result of smaller e_{31} compared to e_{33} and small transduction area. To overcome this limitation, high-order modes are used in high-frequency lateral BAW resonators to increase the transduction area, which in turn leads to a larger die area [8]. Moreover, the efficiency of transverse piezoelectric transduction of silicon lateral BAW resonators is significantly degraded by the increase in proportional thickness of silicon in the resonator stack. However, thick silicon substrates are desirable for improvement of Q, power handling and linearity. Furthermore, the resonance frequency of BAW devices with transverse piezoelectric transduction cannot be tuned without sacrificing transduction area and considerably degrading the motional resistance.

Using the technique presented here, in addition to the AlN layer on top surface of the resonator AlN layers on the vertical sidewalls of the resonator are simultaneously used to employ the larger longitudinal piezoelectric coefficient e_{33} to actuate and sense bulk acoustic waves through the resonator sidewalls. In this configuration since Mo electrodes on the sidewalls connect equi-stress areas of AlN layers, charge cancellation is substantially reduced. Moreover, since transduction occurs on two sidewalls in addition to the top surface, it is scalable with resonator thickness which makes this method preferable for high-frequency resonators with small width (frequency-determining dimension). Because the sidewall AlN layers are mainly responsible for actuation and sensing, the top AlN layer can be dedicated to tuning purposes without a considerable reduction in effective transduction area.

II. Multi-Face AlN Transduction

Figure 1 shows the cross-section of a silicon BAW resonator with multi-face AlN transduction. Since the top and bottom Mo electrodes are conformally deposited over the resonator surface, an input voltage signal results in electric fields E_{Top} and E_{SW} perpendicular to the top surface and sidewalls, respectively. E_{Top} and E_{SW} induce transverse and longitudinal mechanical stress in top and sidewall AlN layers, respectively (Fig. 1a), which results in excitation of the width-extensional bulk acoustic mode (Fig. 2). This resonance mode has an amplified strain in the AlN films on

978-1-61284-110-6/11/$26.00 ©2011 IEEE

top and sidewall of the resonator and induces electric charge on the Mo electrodes (Fig. 1b).

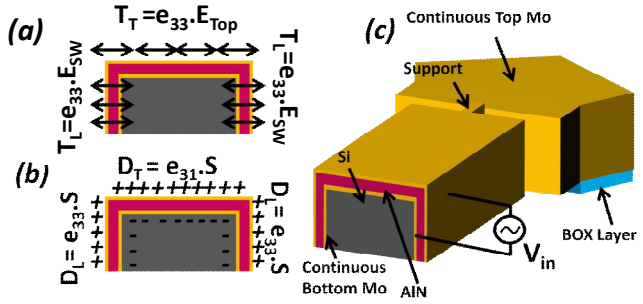

Figure 1: Silicon Bulk Acoustic Resonator (SiBAR) with Mo/AlN/Mo on top surface and sidewalls: (a) actuation mechanism; (b) sense mechanism; (c) resonator cross-section; E_{Top} and E_{SW} are applied electric fields and D_T and D_L are excited electric-displacement on top and sidewall AlN layers, respectively.

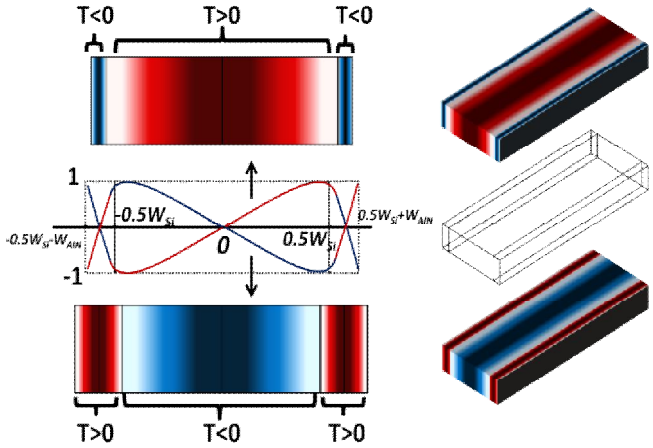

Figure 2: Stress field (T) and deformation in two half-cycles of resonance for a SiBAR with multi-face AlN transduction.

III. Modeling

Considering each AlN layer (two sidewall layers and one top layer) as a separate electromechanical transducer, a SiBAR with multi-face AlN transduction can be modeled as a three-port device. Figure 3 shows the general form electrical equivalent circuit of the resonator around the first width-extensional mode.

In this model, transformers represent the two piezoelectric transduction mechanisms with longitudinal (η_1) and transverse (η_2) coupling coefficients.

In the equivalent circuit of Fig. 3, D_1, K_1, and M_1, and D_2, K_2, and M_2 represent equivalent damping, stiffness and mass of the SiBAR with top AlN and sidewall AlN, respectively. C_{SW} and C_{Top} are the capacitances of sidewall and top AlN layers, respectively. The ratio between η_1 and η_2 can be estimated from (1):

$$\frac{\eta_1}{\eta_2} = \frac{|e_{33}|}{|e_{31}|} \cdot \frac{A_{SW}}{A_{AlN,Top}} \qquad (1)$$

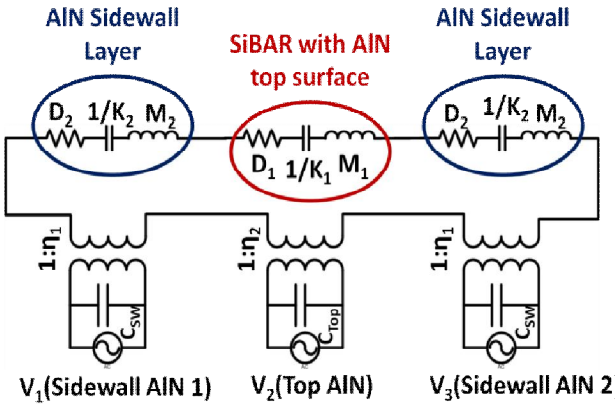

Figure 3: Electrical equivalent circuit for general SiBAR with multi-face AlN considering three ports for electromechanical transduction. V_1, V_2 and V_3 are shorted if the top Mo layer is continuous over the sidewall and top surfaces of the device, resulting in a one-port resonator.

where A_{SW} is the sidewall surface area and $A_{AlN,Top}$ represents the area of the vertical cross-section of top AlN layer.

Since the top Mo layer is conformally deposited on the sidewall and top surfaces (Fig. 1), all three ports are electrically connected together; hence, the resonator can be treated as a one-port device.

The resonator motional resistance R_m can be estimated from (2):

$$R_m = \frac{D_{tot}}{(2\eta_1 + \eta_2)^2} \qquad (2)$$

where D_{tot} represents the total mechanical damping in the resonator. Since $|e_{33}| \approx 3|e_{31}|$ and A_{SW} is much larger than $A_{AlN,Top}$, η_1 is much larger than η_2 (in this work $\eta_1 \approx 100\eta_2$), implying that actuation and sensing of the bulk acoustic resonance is more efficient using piezoelectric films on the sidewalls rather than the top surface. Thus, bulk acoustic resonators with sidewall piezoelectric transduction should provide a considerably lower R_m than those employing top surface AlN actuation and sensing. Additionally, since η_1 is directly proportional to A_{SW}, R_m can be further reduced by increasing resonator thickness. This is a superior advantage of sidewall transduction over top surface transduction, where a piezoelectric layer with large surface area is required to achieve small values of R_m.

IV. Fabrication Process

The fabrication process of one-port SiBARs with multi-face AlN layers consists of two masks and three steps (schematically shown in Fig. 4). First, the resonator body is patterned in the silicon device layer of a thick SOI wafer using the Bosch DRIE process. This is followed by thermal oxidation and annealing in N_2 ambient at 1100°C to improve the smoothness of sidewalls surface after Bosch DRIE. The BOX layer is then partially etched in HF to prevent deposition of Mo/AlN on the BOX layer in the next step. This is done to allow access of HF to the BOX layer during the final release step. Silicon structures are then covered with RF sputter deposition of a thin AlN layer sandwiched between top and

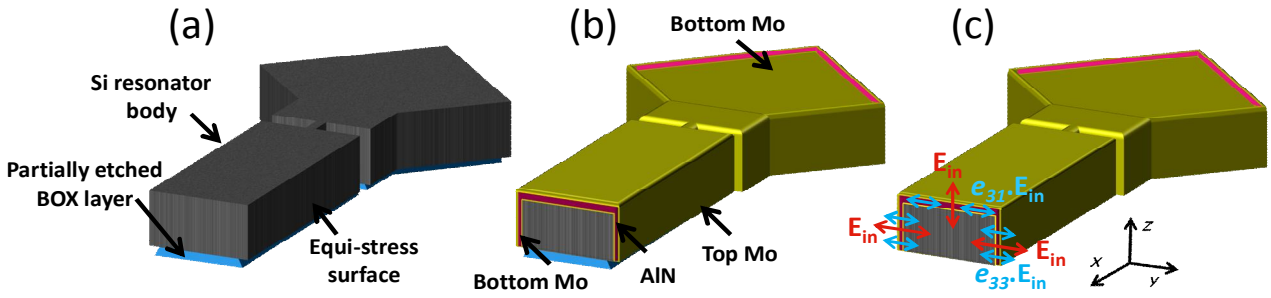

Figure 4: Resonator fabrication process: (a) patterning Si device layer and partially etching the BOX layer; (b) deposition of Mo/AlN/Mo layers, etching top Mo and AlN on one pad to expose ground contact; (c) releasing device in HF.

bottom Mo electrodes on the top surface and sidewalls. Then, the top Mo and AlN layers are etched from one pad to access the bottom Mo which serves as an electrical signal ground. Finally, the device is released by etching the BOX layer in HF. Figure 5 shows an SEM image of a fabricated one-port SiBAR with multi-face AlN and schematic of the electrical interface for measurement.

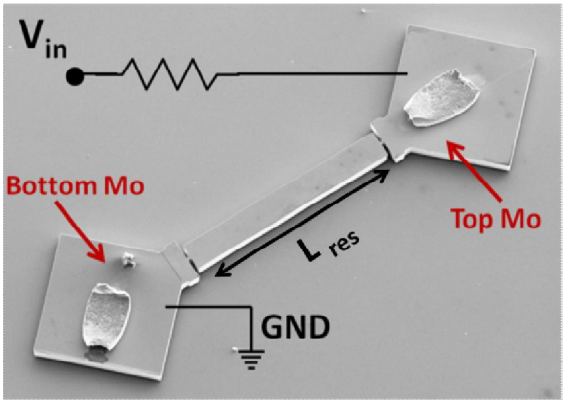

Figure 5: SEM image of the resonator and electrical interface scheme for measurement.

Figure 6 is the cross-sectional SEM picture of the resonator before release in HF. Figure 7 shows the continuity of AlN and Mo films from the top surface to sidewalls at the edges of the resonator, with sidewall AlN thicknesses approximately half of the top surface AlN.

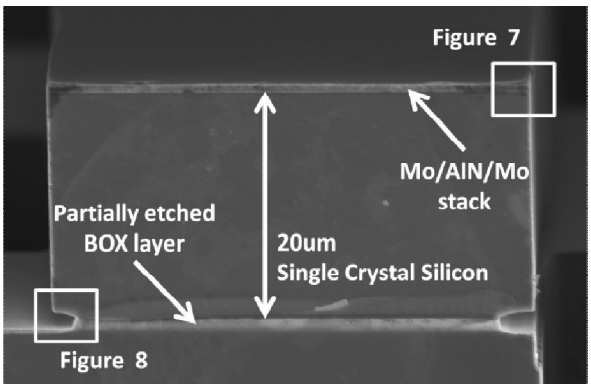

Figure 6: SEM image of the device cross-section; BOX layer partially etched to enable full release in HF.

Figure 8 shows the quality and uniformity of sidewall AlN towards the bottom of the resonator. Uniform thickness of the AlN sidewall film results in efficient actuation of the desired width-extensional resonance mode over the entire thickness of the resonator and eliminates charge cancellation in the sensing mechanism.

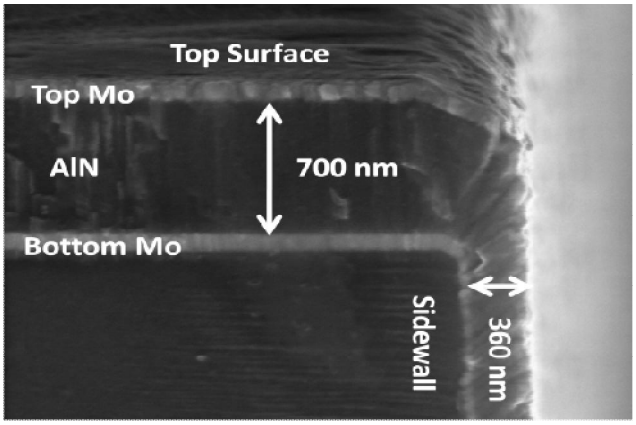

Figure 7: Continuity of AlN and Mo films from the top surface to sidewalls at the resonator edges.

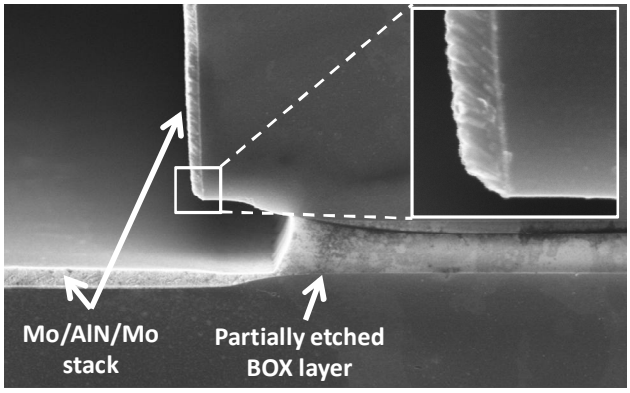

Figure 8: Close-up SEM image, detailing the quality and uniformity of sidewall AlN towards the bottom of the resonator.

V. Measurement Results

Experimental results are obtained using a vector network analyzer. Fig 9 shows the measured reflection coefficient

(S_{11}) as well as the resonator impedance extracted from S_{11} response of the one-port resonator of Fig. 5. A quality factor (Q) of 3500 can be extracted from [10]:

$$Q = \frac{\omega}{2R} \cdot \frac{\partial X}{\partial \omega} \qquad (3)$$

where ω is the angular frequency and R and X are the real and imaginary components of resonator impedance, respectively. An R_m of 35 Ω has been achieved at 99.85 MHz, which is at least ten times less than its capacitive and transverse piezoelectric counterparts [3-6].

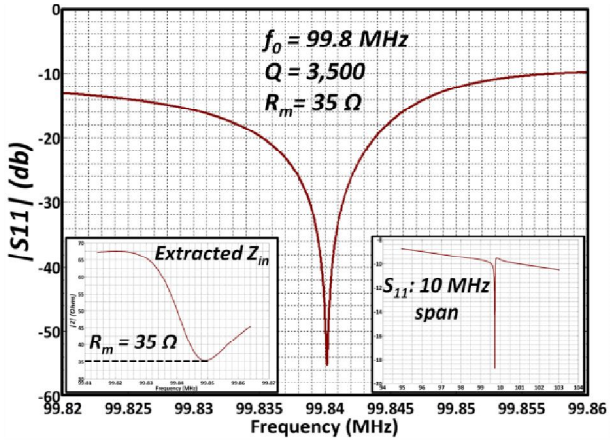

Figure 9: Reflection coefficient ($|S_{11}|$) of the resonator in Fig. 5; (insets) $|S_{11}|$ resonator impedance and response over a 10 MHz span.

Figure 10 shows the resonator frequency shift for input powers higher than 0 dBm, where leakage current increases in sidewall AlN thin layers [11]. This leakage current changes the electric field boundary condition in the top AlN layer as a result of the finite resistance of the excitation source (schematically shown in the equivalent circuit of Fig. 10 inset). As shown in Fig. 10, tuning does not degrade the amplitude of reflection coefficient ($|S_{11}|$) and the motional resistance of the one-port device.

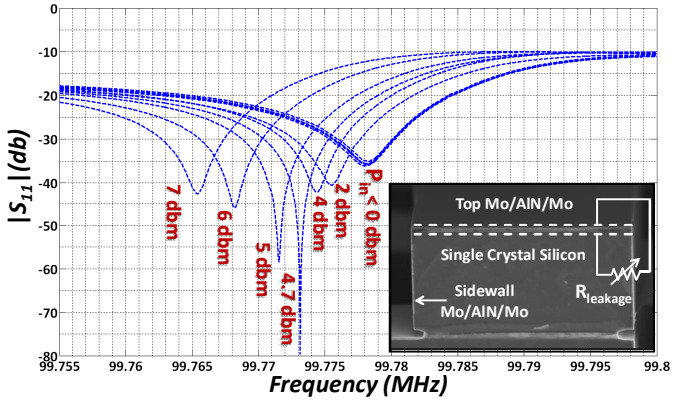

Figure 10: Tuning of AlN-on-Si resonator with input power levels from 0 to 7 dBm; inset shows tuning concept.

VI. Conclusion

This work presents very low motional resistance tunable silicon bulk acoustic resonators with piezoelectric AlN layers on the sidewalls and top surface of the resonator. Exploiting the larger longitudinal piezoelectric coefficient of sidewall AlN layers as well as the substantially reduced charge cancellation as a result of the electrode configuration, this technique demonstrates very high transduction efficiency for silicon bulk acoustic resonators. The electrical equivalent model is presented to demonstrate the advantage of this transduction technique as well as the possibility of efficiency improvement by using thick silicon substrates. Resonators with R_m values as low as 35 Ω have been implemented at 100 MHz using a two-mask, three-step fabrication process. The feasibility of tuning these devices without degrading R_m has been demonstrated by sweeping the applied signal power from 0 to 7 dBm.

Voltage-Controlled Tuning to Optimize MEMS Resonator Array-Composite Output Power

Mehmet Akgul, Zeying Ren, Clark T.-C. Nguyen
Department of Electrical Engineering and Computer Sciences
University of California, Berkeley
Berkeley, CA, USA

***Abstract*—A voltage controlled electrical stiffness tuning method has been demonstrated to correct phase and amplitude mismatches between the constituent resonators in a half-wavelength (λ/2) mechanically coupled array-composite towards maximizing its output power. Via tuning, a nine-disk array-composite using 3 output resonators achieves an output current 2.91× larger than that of a single one of its constituent resonators, and only a bit short of the 3× theoretical maximum. Without tuning, the array-composite achieves only 2.78× the current of a single device, and the deviation from ideal is expected to increase with the number of resonators in the array. The amount of tuning available can be tailored in numerous ways, from sizing of electrode-to-disk gap spacing, to specifying the number of devices in the array involved with tuning, to simple variation of voltages across selected electrode-to-resonator gaps. By raising the power output of a high-*Q* micromechanical disk-array composite resonator, the method and design of this work stand to greatly lower the phase noise of oscillators referenced to such devices.**

I. Introduction

Among the various transduction methods [1]-[4] used by micromechanical resonators, capacitive transduction has historically achieved the highest *Q*'s, with values reaching past 160,000 at VHF [3] and 14,600 at 1.2 GHz [4]. Such high *Q*'s, combined with small size and the potential for on-chip integration with CMOS, make this technology very attractive for various applications, from very narrowband low insertion loss filters for RF frequency gating spectrum analyzer implementation [5]; to low phase noise, low power oscillators for radar and communications [6].

Still, adaptation of capacitive micromechanical resonators has so far been slowed by their higher than conventional impedances and limited power handling capability (governed by linearity) relative to other technologies, such as piezoelectric resonators. However, there is no theoretical reason why the impedances and linearities of capacitive resonators cannot achieve the desired levels. In fact, a 60 MHz capacitive resonator recently attained an impedance as low as 140Ω on par with piezoelectric resonators, but with a much higher *Q* >70,000 [7]. The power handling and linearity performance of capacitive transducers has also been studied extensively [8][9], with single 156 MHz capacitively transduced disk resonators demonstrating measured IIP_3's of 19.5dBm that meet GSM requirements.

If even better linearity is needed for more demanding applications, mechanically coupled array-composite resonators, cf. Figure 1, that sum the output currents of identical mechanically coupled resonators designed to resonate in phase, have been shown to improve performance dramatically over stand-alone devices [3][10]. Specifically, arraying reduces motional resistance by increasing the total output current for the same input voltage amplitude; and simultaneously improves linearity by reducing the resonator displacement required to source a given amount of power, thereby reducing the percent of the electrode-to-resonator gap traversed by the mechanical structure. Ideally, arraying improves the linearity and motional resistance by factors equal to the number of resonators used in the array [3]. However, due to fabrication non-idealities, random variations in the resonator and coupling beam dimensions across the array often compromise the degree to which output currents actually add. Because of this, previous array-composites have fallen short of their expected impedance and linearity improvements, especially when the number of resonators used in the array is large [3][10].

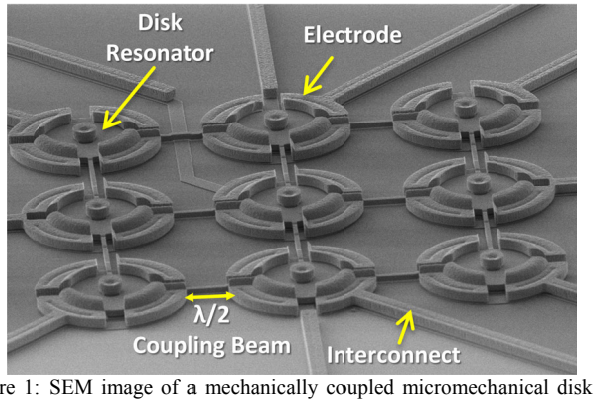

Figure 1: SEM image of a mechanically coupled micromechanical disk array-composite with individual electrode access to each of the resonators constituting the array.

This work attempts to better understand the effect of mismatches between the elements of an array-composite resonator by investigating how stiffness tuning some of the resonators in the array influences the amplitude and phase matching of resonators being summed. In particular, voltage-controlled electrical stiffness tuning applied to several resonators in the array-composite generates maxima in the individual and combined output currents measured off three resonators of the array when 1) their phases are matched; and 2) their phases are close to that of the input drive signal. Tuning over a 7V range induces a measured 16% change in combined array-composite output current, which corresponds to a 1.3dB change in output power that can impact the linearity of a channel-select filter or

the phase noise of a high-Q MEMS-based oscillator.

II. High Frequency, High Q, Low Impedance Capacitively Transduced Mechanical Resonators

This work utilizes capacitively transduced radial-contour mode micromechanical disk resonators [11], such as shown in Figure 2. This device consists of a conductive disk suspended by a center stem 700 nm above an electrically contacted ground plane and surrounded by electrodes spaced only 80 nm from the disk edges. A voltage applied to the ground plane, i.e., V_P in the figure, is effectively also applied to the disk itself and creates voltage drops across the disk and each of its electrodes that then activates the capacitive transducer. Under normal operation, a combination of a dc-bias voltage V_P and an ac excitation voltage v_i is applied across one electrode (the input electrode), as shown in the figure. When the frequency of v_i matches the resonance frequency of the disk, the disk begins to vibrate, generating a dc-biased (with V_P) time-varying capacitance at the output electrode that then sources an output current i_o.

Although often maligned for supposedly insufficient electromechanical coupling compared with other transducer choices, e.g., piezoelectric, capacitive transducers are actually among the strongest of the bunch when dimensions scale down to tens of nanometers. To see this, one can employ the expressions for electrode-to-resonator overlap capacitance C_o, motional capacitance C_x, and resonance frequency f_o, for a radial-contour mode disk resonator, given by [11],

$$C_o = \frac{\varepsilon_o A_o}{d_{gap}} \;,\; C_x = \frac{V_P^2}{\omega_o^2 m_{re}} \frac{\varepsilon_o^2 A_o^2}{d_{gap}^4} \;,\; f_o = \frac{\alpha}{R_d} \sqrt{\frac{E}{\rho}} \qquad (2)$$

where A_o is the electrode-to-resonator overlap area, ω_o is resonance frequency in radians, α is a mode shape dependent constant that equals 0.342 for the fundamental contour mode shape in polysilicon, E is the Young's modulus, and other variables are defined in Figure 2. Combining these yields the equivalent k_t^2 for a capacitively transduced disk resonator:

$$k_t^2 = \frac{\pi^2}{2} \frac{C_x}{C_o} = \frac{1}{4 f_o} \frac{\varepsilon_o}{\gamma \alpha} \frac{1}{\sqrt{E \rho}} \frac{V_P^2}{d_{gap}^3} \qquad (3)$$

From (3), the electrode-to-resonator gap spacing clearly offers a very strong knob by which to tailor electromechanical coupling. Plotting (3) for the case of the 159-MHz disk used in this work versus electrode-to-resonator gap spacing alongside the range for k_t^2 of contour-mode AlN piezoelectric resonators [12][13] yields the curves of Figure 3. The right side of the curve, where electrode-to-resonator gap spacings are large, reveals why capacitive transducers were so maligned: the electromechanical coupling is orders of magnitude lower than that

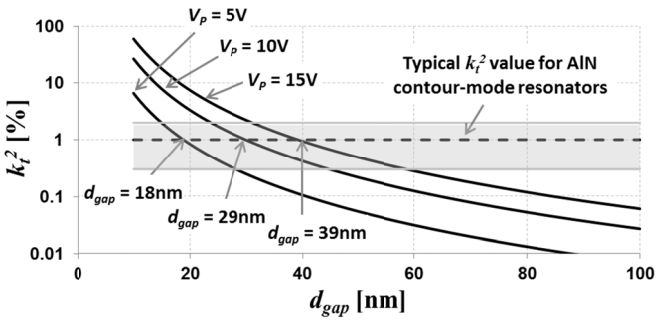

Figure 3: Simulated plot of k_t^2 for a polysilicon contour mode disk resonator operating at 159 MHz, plotted as a function of the electrode-to-resonator gap spacing for three different bias voltages. The shaded band indicates the k_t^2 range for AlN contour-mode resonators in the literature [12][13].

of AlN piezoelectric resonators. However, the left side, where the gap spacing shrinks to tens of nanometers, tells a completely different story. In particular, for the case of V_P =10V, when the gap spacing falls below about 29 nm, a complete reversal occurs, where the electromechanical coupling of the capacitive transducer begins to exceed the typical 1% of AlN contour-mode resonators. The increase in electromechanical coupling with decreasing gap spacing was recently verified in [7], where the electrode-to-resonator gap of a 61-MHz wine-glass disk was reduced to 37 nm from 92 nm to effect a change in motional resistance from 5,350Ω to 140Ω, all while still retaining a Q of 73,173—the only on-chip room temperature resonator in existence able to attain simultaneous high Q >70,000 and low impedance < 150Ω.

Unfortunately, however, the motional resistance of the resonator, as given by the equation in Figure 2, like its coupling coefficient, is inversely proportional to resonance frequency. In other words, the same 37 nm gap that allowed an R_x = 140Ω at 61 MHz in [7] would yield a much higher R_x of 2.3kΩ at 1 GHz. To counteract this increase, more aggressive gap scaling is needed. For instance, to achieve R_x = 50Ω for a polysilicon disk resonator operating at 1 GHz with an assumed Q of 30,000 and a dc bias voltage V_P =10V, the required gap is 9 nm. Needless to say, this is a very small gap that not only begs the question of whether or not such a small gap can be achieved with high yield, but that also raises nonlinearity concerns, since the 3rd-order intermodulation intercept point IIP_3 starts to drop quickly when the gap passes a certain threshold, effectively imposing a "gap scaling limit" [9].

When the gap scaling limit is met, but the impedance requirement still has not been, the next best course of action is to employ one of the other available knobs: either the dc-bias voltage V_P or the disk thickness h. If the supply voltage is limited, then thickness must be increased, which is unfortunate, since this would require a higher aspect ratio, so becomes increasingly difficult as lateral dimensions shrink to attain higher frequencies. Fortunately, the thickness knob is really a knob to change electrode-to-resonator overlap area A_o, which can be increased without increasing thickness by merely using many resonators so that their total combined overlap area increases. This, of course, is the main idea behind the mechanically coupled disk array-composites under study, here.

III. Mechanically Coupled Array-Composite

By summing the output currents of multiple resonators to

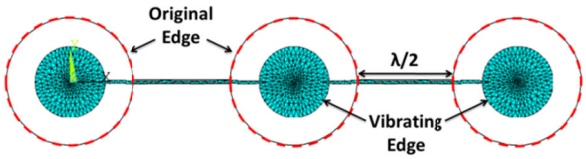

Figure 4: ANSYS modal analysis result for three identical disk resonators mechanically coupled with half-wavelength coupling beams.

attain a larger overlap area and in turn produce a larger total output current, an *N*-resonator array lowers the effective motional resistance linearly with the array size *N*, as described by

$$R_{x,Array} = \frac{v_i}{i_o} = \frac{v_i}{N \times i_x} = \frac{R_x}{N} \qquad (4)$$

where i_x and R_x are the motional current and resistance of a single resonator, respectively; and v_i is input voltage. Note that (4) is valid only when all the resonators generate identical output currents that are in phase and at precisely the same frequency. Given the very high *Q*'s >10,000 of the individual resonators, minute differences between the resonators likely to occur during any practical microfabrication process create slight frequency differences that prevent output currents from adding in phase. As a result, simply connecting the output electrodes of discrete resonators together is not an effective arraying method.

A much better approach uses mechanical coupling beams to physically link the arrayed resonators, as shown in Figure 1. A mechanically linked *N*-resonator array forms an *N* degree-of-freedom system with *N* modal frequencies, each associated with a specific mode shape [10]. This ensures that all resonators resonate at the exact same frequency for a given excited mode, very conveniently eliminating frequency mismatches, allowing same-frequency summing of resonator outputs. Still, most applications, e.g., oscillators, require a frequency response with only one output frequency, not *N* of them. So although its higher power output is welcome, the *N* peaks generated by this mechanically coupled array are not.

One way to eliminate the undesired modes is to use mechanical coupling beams that act as springs with infinite effective stiffness [3]. Specifically, since the coupling beams behave like mechanical transmission lines at this frequency, they can be given infinite effective stiffnesses by merely dimensioning them to correspond to a half-wavelength ($\lambda/2$) at the desired mode frequency. More specifically, the coupling beam lengths should be set equal to an odd multiple of the half-wavelength ($\lambda/2$) of the longitudinal waves travelling in the resonator medium with an acoustic velocity of $\sqrt{E/\rho}$:

$$L_{beam} = \frac{n}{2f_o}\sqrt{\frac{E}{\rho}},\ n = 1,3,5,\ldots \qquad (5)$$

where f_o is the resonance frequency . With effectively infinitely rigid couplers, the mechanically coupled resonators behave as a single array-composite resonator, selectively resonating at a single mode frequency that takes on a shape in which all the resonators move in phase, as shown in Figure 4. The remaining modes are (ideally) pushed to infinity.

In effect, an ideal half-wavelength coupled array of resonators, with its single mode frequency response, effectively realizes an array-composite resonator that behaves like a single of its constituent resonators, except with lower impedance, better linearity, and better power handling capability.

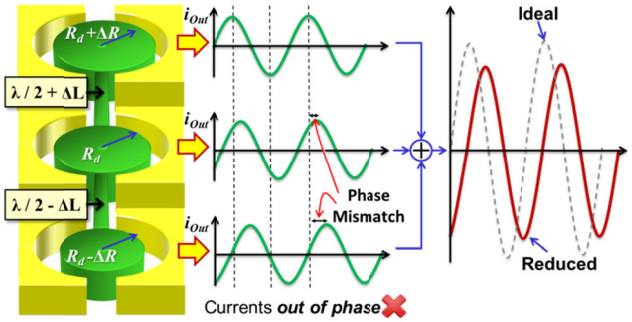

Figure 5: Schematic description of the effect of mismatches between resonators and coupling beams on array performance.

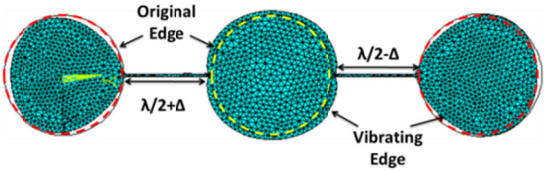

Figure 6: ANSYS simulation for a three-resonator array with 1% error in disk radii and coupling beam lengths in a worst case mismatch scenario.

IV. Effect of Non-Idealities on Arrays

The analysis in the previous section assumes an ideal case, where all the disks that form the array are identical and all coupling beam lengths exactly match the $\lambda/2$ condition of (5) at the common resonance frequency of the disks. In this perfect scenario, all disks resonate in phase and generate identical output currents that lead to the advertised *N*-times reduction in R_x. However, in practice, various process variations in lithography, etching, etc., lead to deviations from a perfect match between the array elements. As a result, the disk radii and coupling beam lengths in the array structure have a random distribution around the ideal design values, as illustrated in Figure 5. Hence, each coupled disk would have a slightly different resonance frequency were it to resonate by itself. Furthermore, variations in the coupling beam lengths create deviations from the half-wavelength condition, meaning the beams are no longer infinitely rigid couplers. Although the mechanical coupling beams still impose a common resonance frequency, they now do so with the following consequences:

1. Different disks reach their resonance displacement maxima at different times. Thus, the output currents generated by individual resonators are not precisely in phase.
2. Mismatches between coupled resonators and coupling beam lengths distort the mode shapes of constituent resonators, causing them to deviate from the ideal circular contour mode shape, as shown in Figure 6, which presents the mode shape predicted by ANSYS for a three-resonator array in a worst case mismatch scenario with 1% error in the disk radii and coupling beam lengths. The result is significant distortion of the mode shape compared to the ideal case of Figure 4. This mode shape distortion diminishes the resonance amplitude of the resonators, which then leads to reduced output current.
3. Spurious modes ensue that are no longer suppressed by infinite stiffness coupling beams.

As a result, even though all the resonators in the array generate an output current precisely at the same frequency—a

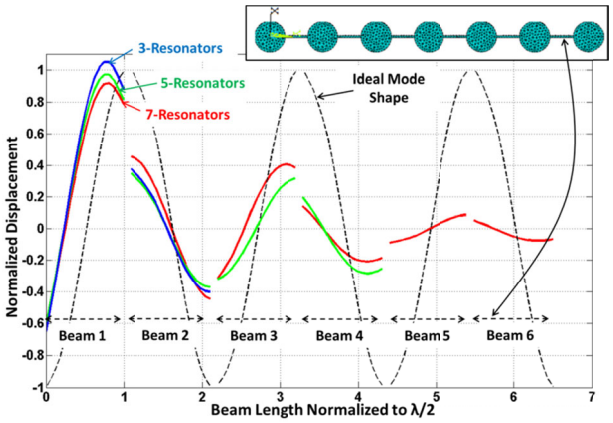

Figure 7: ANSYS harmonic analysis showing coupling beam mode shape displacements (normalized to the ideal mode shape) for mechanically non-ideal coupled disk resonator arrays with varying array sizes (3, 5, and 7 resonators, as marked) for a 1% worst-case dimensional mismatch between the array elements; compared to the ideal mode shape plotted as the dashed curve.

requirement imposed by mechanical coupling—the individual output currents are smaller and out-of-phase, so sum to a value lower than the theoretical maximum, as shown in Figure 5. This underperformance will likely get worse as frequencies rise, since smaller dimensions would likely amplify mismatches, and the larger array sizes needed to maintain low impedance and good linearity would further distort the individual element mode shapes, as verified by the FEA-generated plot of Figure 7. Indeed, any method for tuning out mismatches becomes more important at higher frequencies.

V. Voltage Controlled Electrical Stiffness Tuning of Resonator Array-Composites

Since frequency and stiffness deviations comprise the ultimate consequence of process-induced non-ideality, controlling stiffness is perhaps the best way to counteract such non-idealities. The capacitive transducers used in this work offer a very convenient method for controlling stiffness via mere adjustment of the voltages applied across their capacitive gaps, which changes the electrical stiffness across these gaps. Electrical stiffness [14] arises from the electric field force between the conductive resonator and its parallel-plate electrode that rises and falls as the resonator gets close and far, respectively, from the electrode. This force is in phase with resonator motion, so comprises an effective electrical stiffness k_e, given by

$$k_e = \frac{\varepsilon_o A_o}{d_{gap}^3} V_\Delta^2 \qquad (6)$$

where A_o is the electrode area, and V_Δ is the DC voltage difference between the electrode and the resonator. Note that this electrical stiffness acts to increase the resonator's displacement, so acts to oppose the mechanical stiffness of the resonator. Its effect on the resonance frequency of a single resonator can thus be modeled by

$$f_o = \frac{1}{2\pi}\sqrt{\frac{k_{re}}{m_{re}}} = \frac{1}{2\pi}\sqrt{\frac{k_m - k_e}{m_{re}}} \qquad (7)$$

where k_{re} is the total effective resonator stiffness at the location of the tuning electrode (i.e., usually at its midpoint), obtained by subtracting the electrical stiffness k_e from the mechanical stiffness at that location k_m; and m_{re} denotes the equivalent dynamic mass at that location. Note that for contour mode disks, location is not an issue, but it can be for more general mode shapes, e.g., wine-glass [3][6].

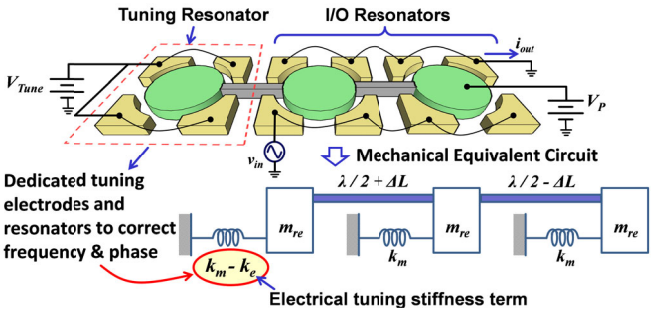

Figure 8: Schematic description of the voltage controlled electrical stiffness tuning method applied to selected tuning electrodes of an array-composite resonator to electrically tune out mechanical mismatches.

Equation (7) applies very well to individual resonators and has been used successfully to correct the passbands of small percent bandwidth filters, such as in [15], where constituent resonators are coupled by quarter-wavelength beams. For the case of the half-wavelength coupled array resonators of this work, however, (7) must be modified to account for the fact that a half-wavelength coupled array realizes an array-composite resonator with an effective combined stiffness equal to the sum of the stiffnesses of its constituents. Thus, a change in electrical stiffness applied to one resonator, such as shown in Figure 8, affects them all, i.e., affects the whole array-composite. For an N-resonator array-composite, where M resonators are used for input/output and (N-M) for frequency tuning, the expression for the array-composite frequency becomes

$$f_o = \frac{1}{2\pi}\sqrt{\frac{Nk_{m,s} - Mk_{e,V_P} - (N-M)k_{e,V_T}}{Nm_{re,s}}} \qquad (8)$$

$$k_{e,V_P} = \frac{\varepsilon_o\, 2\pi\, R_d\, h}{d_{gap}^3} V_P^2, \quad k_{e,V_T} = \frac{\varepsilon_o\, 2\pi\, R_d\, h}{d_{gap}^3}(V_{Tune} - V_P)^2 \qquad (9)$$

where $k_{m,s}$ and $m_{re,s}$ are the dynamic stiffness (with no bias voltage) and mass for a single resonator, respectively; while k_{e,V_T} and k_{e,V_P} are the electrical stiffness for a single resonator with and without the tuning voltage V_{Tune} applied to its electrodes, respectively.

Equations (8)-(9) indicate that the amount of tuning available can be tailored in numerous ways, from sizing of electrode-to-disk gap spacing, to specifying the number of devices in the array involved with tuning, to simple variation of voltages across selected electrode-to-resonator gaps. The voltage-control knob provides an especially convenient method to tune individual frequencies so as to minimize mode shape mismatches between the elements of a mechanically coupled resonator array. Note that a designer has a choice of whether to use a constituent resonator in an array composite as an input device, an output device, a frequency tuning device, or any combination of these, including all three.

It should also be noted that the arrays of Figure 1 and Figure 9 do not offer the ability to directly tune the coupling beams. Such tuning is possible with the right design, but most such designs become somewhat cumbersome, so are not implemented here. If coupler tuners are not available, then at least the frequency of the array-composite can be adjusted to minimize the average coupler deviation from half-wavelength at whatever their dimensions. In effect, pulling the resonance

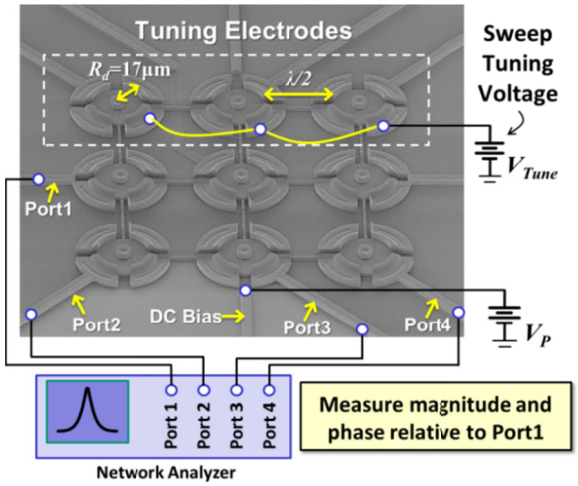

Figure 9: SEM of the fabricated and measured resonator array-composite tuning test structure and schematic of the experimental setup.

frequency closer to the optimum value that provides an average best fit match to the $\lambda/2$ coupling condition for the actual fabricated devices with non-idealities minimizes mode shape distortions and the resulting phase mismatches between individual disk output currents, hence maximizes array output.

VI. Experimental Results

To observe the extent of mismatches stemming from fabrication-induced non-idealities between resonators and the mechanical coupling beams that are otherwise matched in layout, disk array-composites were fabricated in polysilicon using a five-mask fabrication process similar to that of [16]. Figure 9 presents the scanning electron micrograph of a fabricated array structure that differs from previous ones [3] in that (1) it includes electrodes that can individually address each constituent resonator, so provides a mechanism for studying the degree to which an actual fabricated array-composite resonator deviates from the ideal, i.e., the degree to which the phases and resonance amplitudes of its constituent resonators are matched; and (2) it features electrode-resonator combinations specifically equipped to tune the effective electrical stiffness of the entire array structure via adjustment of tuning voltages. The structure consists of nine 17μm-radius contour mode disk resonators designed to operate at 159.8 MHz, with each disk mechanically coupled to its neighbors via half-wavelength beams of length L_{beam} = 26μm to form a 3×3 array-composite resonator.

Figure 9 also includes the test set-up used to gauge the impact of process non-idealities on the disk array-composite and evaluate the efficacy of the proposed corrective tuning method. Here, an Agilent E5071C four-port network analyzer drives the array-composite device into resonance from an input resonator, denoted as Port 1; and simultaneously records the phase and magnitude information of the output currents generated by three output resonators, denoted as Ports 2-3-4. A DC polarization voltage of V_P = 5V is applied common to all disk resonators, and three of the resonators in the array serve as dedicated electrical stiffness tuners, to which a DC tuning voltage separate from V_P is applied to effect selectable amounts of stiffness control. By sweeping the tuning voltage while recording with the network analyzer, the change in the

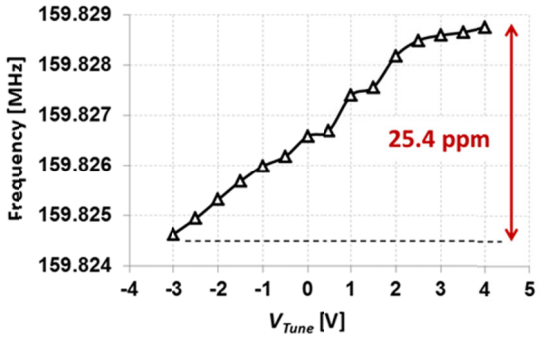

Figure 10: Measured plot of array-composite frequency vs. tuning voltage.

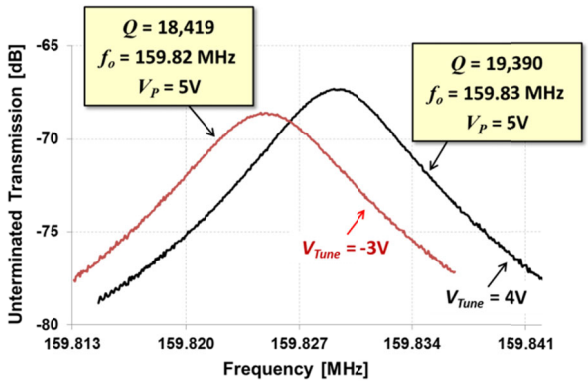

Figure 11: Frequency characteristics for the combined port 2-3-4 output of the array-composite measured at two different tuning voltages.

phase and magnitude of the individual resonators can be plotted as a function of the applied tuning voltage.

To first gauge the amount of tuning provided by the three tuning electrodes, Figure 10 presents a plot of array-composite frequency versus applied tuning voltage. Here, a tuning voltage excursion of 7V provides a 25.4 ppm change in frequency. Although small, this tuning range was still enough to affect noticeable changes in total array output current, as indicated by Figure 11, which plots measured frequency characteristics for the combined output currents from Ports 2-3-4 as a function of the tuning voltage. Here, a 1.3dB change in output is seen over a 7V excursion in tuning voltage.

To better elucidate some of the mechanisms behind tuning-based output improvement, Figure 12 presents measured curves of magnitude and phase of the individual currents generated by each output resonator (ports 2, 3, and 4) plotted as a function of the applied tuning voltage. There are two groups of curves presented in this plot: the solid curves indicate the phase mismatch of each output resonator current relative to the input resonator drive signal, with reference to the *y*-axis on the left; and the dashed curves present the output current amplitudes measured in dBm, with reference to the *y*-axis on the right. The results clearly demonstrate reduction of the phase mismatch between output resonators and input resonator, by more than 20° for the output resonator denoted Port2 as its phase mismatch reduces to almost zero, and by more than 10° for the other two output resonators.

For each output resonator, two maxima are observed: one where the phase of the resonator in question has its lowest phase mismatch with the input resonator; and one where all output resonators are matched in phase. Clearly, phase match-

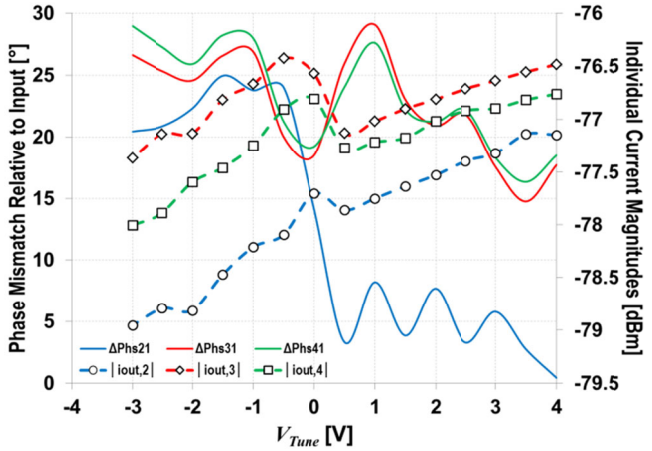

Figure 12: Measured individual output current phase mismatch relative to input (solid line curves – left *y*-axis) and amplitudes (dashed line curves – right *y*-axis) for each output resonator (ports 2, 3, and 4) vs. tuning voltage.

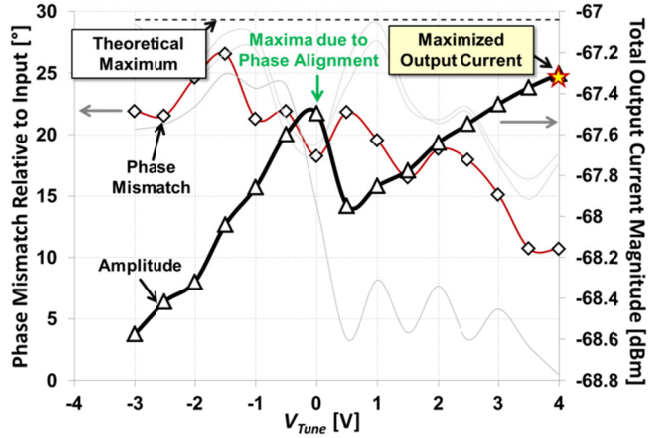

Figure 13: Measured curves of combined total output current phase mismatch relative to input (◇ data markers– left *y*-axis) and amplitude (△ data markers – right *y*-axis), plotted against the applied tuning voltage.

ing is an important consideration for optimized performance of even individual resonators making up an array composite.

Figure 13 plots the phase and amplitude of the total combined output current from the three output resonators against the applied tuning voltage and against a line indicating the maximum output current magnitude expected from an ideal array-composite with no mismatches. Interestingly, for the case of this nine-resonator array-composite, three of which are used for output, the output current is within 2 dB of the ideal over a 7V range of tuning voltage. This might raise questions on the need for tuning at all, but a quick glance at Figure 7 reminds one that a larger array would likely experience a much larger current drop for which correction by tuning would be important. In addition, where transmit power is concerned, every 0.1dB of loss is generally of great concern, especially in space applications. At any rate, Figure 13 attests that voltage-controlled electrical stiffness tuning is clearly an effective means for controlling and minimizing phase mismatches, and more importantly for maximizing the total output current amplitude.

VII. Conclusions

By restoring output power to levels closer to ideal, the described voltage-controlled electrical stiffness tuning method to correct phase and resonance amplitude mismatches between the constituent resonators in mechanically coupled array-composites allows such mechanical circuits to achieve their true potential, even in the midst of finite fabrication tolerances. Clearly, some more refinement in the tuning method, e.g., to allow more precise tuning of individual resonators, would be beneficial, and investigation into just how large an array can be tuned via the described methods is needed. Work towards these continues with the goal of someday making possible assembly of on-chip array-composites employing thousands of capacitively transduced micromechanical resonators to achieve motional resistances down to 1Ω, IIP_3's greater than 50 dBm, and power outputs in the several Watt range, all while retaining the high Q >30,000 typical of such devices.

Acoustic Bragg Reflectors for *Q*-Enhancement of Unreleased MEMS Resonators

Wentao Wang, Dana Weinstein
HybridMEMS Lab, Massachusetts Institute of Technology
Cambridge, MA, USA
Email: wangwt@mit.edu

***Abstract*—This work presents the design of acoustic Bragg reflectors (ABRs) for unreleased MEMS resonators through analysis and simulation. Two of the greatest challenges to the successful implementation of MEMS are those of packaging and integration with integrated circuits. Development of unreleased RF MEMS resonators at the transistor level of the CMOS stack will enable direct integration into front-end-of-line (FEOL) processing, making these devices an attractive choice for on-chip signal generation and signal processing. The use of ABRs in unreleased resonators reduces spurious modes while maintaining high quality factors. Analysis on unreleased resonators using ABRs covers design principles, effects of fabrication variation, and comparison to released devices. Additionally, ABR-based unreleased resonators are compared with unreleased resonators enhanced using phononic crystals, showing order of magnitude higher quality factor (*Q*) for the ABR-based devices.**

I. Introduction

The need for monolithic integration of Micro Electromechanical (MEM) devices with CMOS is critical for successful implementation of high frequency active MEMS resonators. Monolithic integration of these devices can provide basic RF and mm-wave building blocks with high *Q*, small footprint, and low power for use in wireless communication, microprocessor clocking, navigation and sensing applications. Nevertheless, the majority of MEMS resonators require a release step to freely suspend the moving structures. This necessitates complex encapsulation and packaging, restricting fabrication to MEMS-last or Back-End-of-Line (BEOL) processing of large-scale devices [1].

Toward the goal of Front-End-of-Line (FEOL) CMOS integration, the authors have previously demonstrated the first fully unreleased MEMS resonator operating at 39 GHz with *Q* of 129 [2]. The Si bulk acoustic resonator, surrounded on all sides by SiO_2, demonstrates the feasibility of direct integration of resonator into the FEOL CMOS processing, offering on-chip low power clock generation and high-*Q* tank filters.

Whether unreleased RF MEMS resonators are realized in a CMOS or custom process, their implementation provides high yield, low cost, robustness in harsh environments, and minimal or no-packaging solutions.

This work is funded by the MARCO Center for Materials, Structures and Devices (MSD) and the DARPA Young Faculty Award.

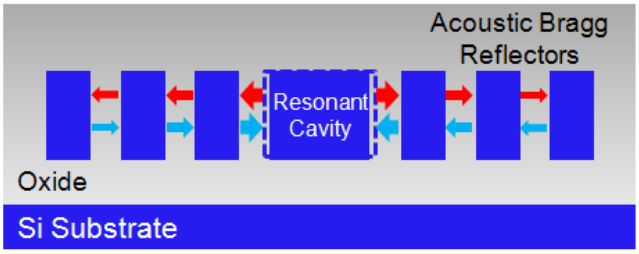

Figure 1. Sideview of unreleased resonator and ABRs lithographically defined in the same mask process. The resonant mode is longitudinal in the horizontal direction, exciting plane waves which are confined by the ABRs. Oxide cladding the resonator and ABRs illustrates the structures achievable in standard SOI CMOS processing.

As a result of the leakage of acoustic energy by wave paths into the surrounding medium, the performance of an unreleased resonator is degraded relative to its released counterpart [3]. This energy loss can be mitigated by adding acoustic isolation structures. In this work, two types of structures are proposed and investigated for the localization of acoustic vibrations in place of λ/4 suspension beams found in most released structures: the acoustic Bragg reflector (ABR) and the phononic crystal (PnC), with a focus on the former.

The acoustic Bragg reflector is named after its optical analogue, which is used as thin film optical mirrors to improve reflectivity at a designed wavelength. The ABR is composed of periodic layers of two materials of low and high acoustic impedance. At each layer interface of the ABR, a fraction of the acoustic wave energy is reflected. To form a coherent superposition of these reflected waves, these layers can be optimized at odd multiples of quarter wavelength, resulting in the overall reflectivity identical to that of free or rigid boundary conditions.

In 1965, W. E. Newell introduced the idea of employing ABRs to thickness mode piezoelectric resonators for wireless applications in high frequency integrated circuits [4]. This work was further developed in fully integrated surface micromachining technology for solidly mounted resonators (SMRs) [5]. These ABRs are composed of multiple depositions of alternating materials, resulting in acoustic isolation in one dimension at a single frequency per wafer. In-plane isolation can be achieved using lithographically defined

ABRs, as demonstrated in a suspended plate [6]. This configuration enables resonators of multiple frequencies to be fabricated side by side on the same chip.

PnCs provide an alternative solution to lithographically defined acoustic isolation. They have been recently explored by several groups for microscale applications, including acoustic mirrors for resonators in suspended plates [7], acoustic waveguides, and filters [8].

This paper presents the study of fully unreleased resonator surrounded by lithographically defined ABRs, embedded in a homogeneous cladding layer (Fig. 1). This one-mask design enables resonator banks of various frequencies on the same chip, providing multiple degrees of freedom in ABR design. With the goal of direct integration into FEOL CMOS processing, resonator performance is investigated for materials commonly found in the CMOS stack. The characteristics of these unreleased structures are compared with freely suspended resonators, released resonators isolated with lithographically defined ABRs, and PnC based unreleased resonators.

II. Bandgap of Acoustic Bragg Reflectors

Existing ABR analysis is based on a transmission line analogy, borrowing results from impedance transforming properties of cascaded transmission lines [4]. However, a more fundamental analysis can be performed conveniently from the wave propagation point of view through superposition, as shown in Fig. 2.

The acoustic impedance Z of an elastic medium for longitudinal wave is defined by material properties as

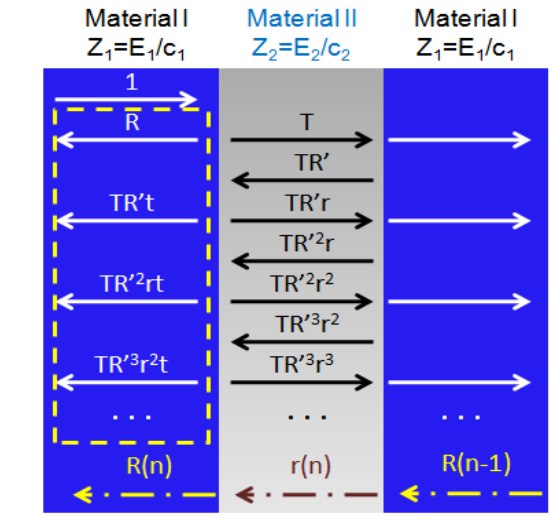
$$Z = \frac{E}{c} = \sqrt{\frac{(1+\nu)(1-2\nu)\rho E}{(1-\nu)}} \qquad (1)$$

where E, ρ, ν are the Young's modulus, density, and Poisson's ratio respectively.

In Fig. 2, an acoustic wave travelling to the right in material I is incident on an interface with material II, separated into reflected and transmitted components of R and T. At the next interface, the transmitted component T is reflected at an assumed lumped reflectivity of R' from the following stack of materials. The reflected wave now travelling to the left with amplitude TR' is then reflected (r) and transmitted (t) at the first interface. As a result, infinite reflections occur inside material II with amplitude decreasing in geometric progression. By summation of all the reflections, we acquire the recursion formula

$$R(n) = R + \frac{Ttr(n)e^{-i2\delta_2}}{1 - rr(n)e^{-i2\delta_2}} \qquad (2)$$

in which δ_2 is the phase change over the propagation length in material II, r(n) and R(n) are the lumped reflectivities of the nth ABR bi-layer as shown in Fig. 2. Similarly, the other recursion formula can be acquired:



$$R = \frac{Z_1 - Z_2}{Z_1 + Z_2} \quad T = \frac{2Z_1}{Z_1 + Z_2} \quad r = \frac{Z_2 - Z_1}{Z_1 + Z_2} \quad t = \frac{2Z_2}{Z_1 + Z_2}$$

$$R' = r(n) \qquad R(n) = R + \frac{Ttr(n)e^{-i2\delta}}{1 - rr(n)e^{-i2\delta}}$$

Figure 2. Derivation of recursion formula of reflectivity for ABRs through wave superposition. A summation of all the reflected components in the dashed line box generates relationship of lumped reflectivity R(n) and r(n) of the nth ABR bi-layer.

$$r(n) = r + \frac{tTR(n-1)e^{-i2\delta_1}}{1 - RR(n-1)e^{-i2\delta_1}} \qquad (3)$$

With these two relations, the properties of the ABR can be extracted through numerical calculation. Fig. 3 shows the result of ABR reflectivity of various bi-layer numbers, in which the ABR bi-layer consists of Si and SiO_2.

An ideal ABR composed of an infinite number of bi-layers is approximated numerically using 100 ABR pairs. As shown in Fig. 3, this ideal ABR provides total reflection over several frequency ranges called the bandgaps. The reflectivity in the bandgap is strongly dependent on the number of ABR pairs. However, numerical results show that only 7 bi-layers are enough to approximate the bandgap shape, providing 98.7% reflectivity at the center of bandgap.

The convergence rate toward total reflection differs based on the materials composing the ABR structure. Material pairs with higher acoustic impedance contrast ratio (Z_1/Z_2) form a wider bandgap, and require fewer ABR pairs for same level of reflectance. The performance of several quarter-wavelength material pairs available in CMOS are exhibited in Fig. 4. The sign of reflectivity is determined by the order of materials in the ABR bi-layer. If the first material in the bi-layer has a higher acoustic impedance, the overall ABR will approach a free boundary condition (positive reflectivity). On the other hand, if the first material has a lower acoustic impedance, it will approach fixed boundary condition (negative reflectivity).

Materials of large acoustic impedance contrast such as W/SiO_2 [9], AlN/SiO_2 [5], Mo/Al [10] have previously been used to form ABR pairs in SMRs. This large contrast

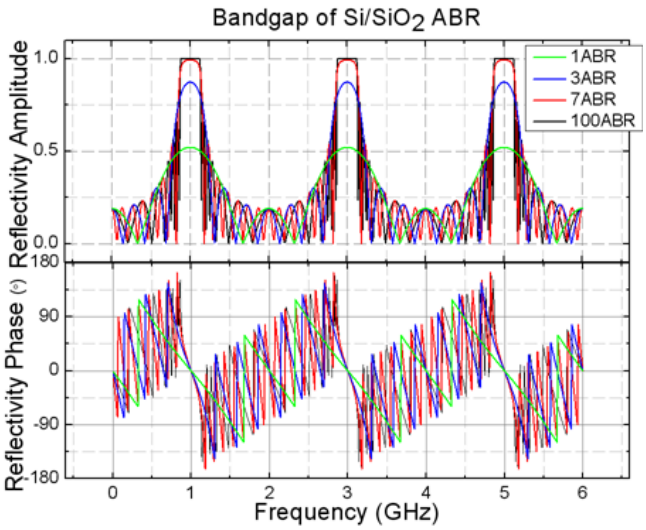


Figure 3. Frequency response of ABR amplitude (top) and phase (bottom). The bandgap approaches ideal shape with increasing number of ABRs. When the ABR pair number is small, the bandgap is attenuated and bandwidth increases.

minimizes the number of pairs required to achieve good acoustic isolation, reducing the number of deposition steps during fabrication. This will not complicate fabrication for unreleased resonator ABR design, since the entire ABR structure can be defined lithographically in one step. Si/SiO_2 ABRs are selected for the design and analysis in the paper, due to their FEOL CMOS compatibility, low internal loss, and small achievable footprint.

III. Acoustic Bragg Reflectors for Unreleased Resonators

The acoustic energy loss analyzed here in the unreleased resonators is analogous to anchor loss in freely suspended devices. In most released and unreleased resonators, this energy localization can be the limiting mechanism for Q. Accordingly, this analysis is focused on the mechanical domain, taking maximum or average strain as signal output. This mechanical-only analysis in turn allows the result to be applied for various sensing mechanisms that rely on the electrical signal modulated by strain, such as dielectric, piezoelectric, piezoresistive, or Field Effect Transistor sensing [11].

A. 1D Analysis of Unreleased Resonator with ABRs

Using the superposition method outlined in section II, a one dimensional unreleased resonator embedded in an Si/SiO_2 ABR stack can be analyzed numerically using the maximum strain as the output (Fig. 5). This is a best-case ideal resonator output; in practical design the mode cannot be perfectly one-dimensional. Finite width may introduce non-idealities such as plate modes and extra wave leakage, as discussed in the following sections.

In this analysis, the resonator is excited by a pair of equal and opposite forces on both edges, and after superposing wave components in both directions, strain is calculated at the center of the resonator. Resonant peaks appear periodically at odd harmonics, which agrees well with the shape of the ABR bandgap. The Q of the peak increases rapidly with the increase of ABR pairs as the reflectivity approaches 1. These properties confirm the ABR analysis results in Fig. 3.

Because both the lengths of the ABR layers and resonant cavity are lithographically defined, the dimensions are subject to fabrication variations. Over-etching may change the relative thickness of the Si layer to the SiO2 layer in one ABR periodicity, which subsequently shifts performance of the entire system including frequency, Q, and amplitude of vibrations. However, the finite bandgap generated by the ABR provides some level of tolerance to such variations. Analysis indicates that fabrication tolerances of 10-15% results in up to 10% degradation in targeted performance. The fabrication variation affects performance more as the ABR pair number increases, which is reasonable due to the narrowing of equivalent bandgap as shown in Fig. 3.

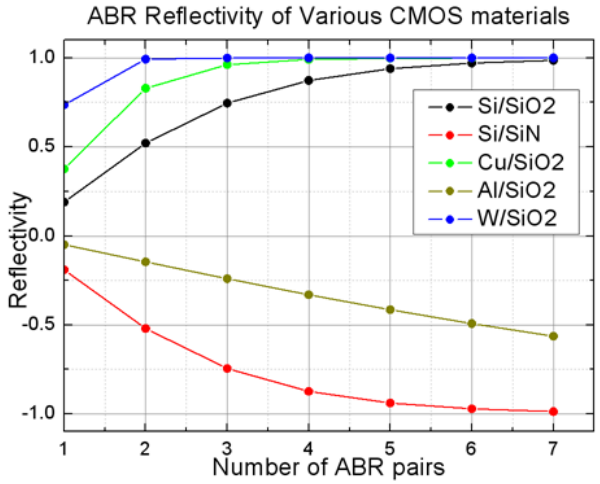

Figure 4. For finite number of ABR pairs, the reflectivity increases with the pair number and converges to 1 or -1 rapidly for materials commonly found in CMOS.

Figure 5. Numerical calculation results of maximum strain output of unreleased resonator embedded in ABR. The strain is normalized to the maximum strain at 7 ABR pairs.

B. *Comparison of Released and Unreleased Resonator with ABRs*

Two dimensional finite element simulations were performed in COMSOL Multiphysics 4.1 to demonstrate the contribution of ABRs to unreleased resonator performance. The frequency response of ABR-enhanced unreleased structures is compared with freely suspended resonators, simple unreleased resonators (no ABRs), and released resonators isolated with lithographically defined ABRs (Fig. 6). All resonators, driven by a pair of equal and opposite forces on both edges, are designed for 1st harmonic longitudinal vibrations at 1 GHz. The output signal is taken as the average strain across the entire resonant cavity. Perfectly matched layers (PMLs) are imposed at boundaries corresponding to energy sinks for waves propagating to infinity.

When defining PML parameters in COMSOL, it is recommended to match the PML to the desired acoustic wavelength. Although energy absorption is only optimized around the targeted wavelength, comparison of simulations with varying PML settings has shown robustness of PML performance over a broad range of frequencies for a single matched wavelength. For example, simulations of the resonator shown in Fig. 6(b, c) were performed with PMLs

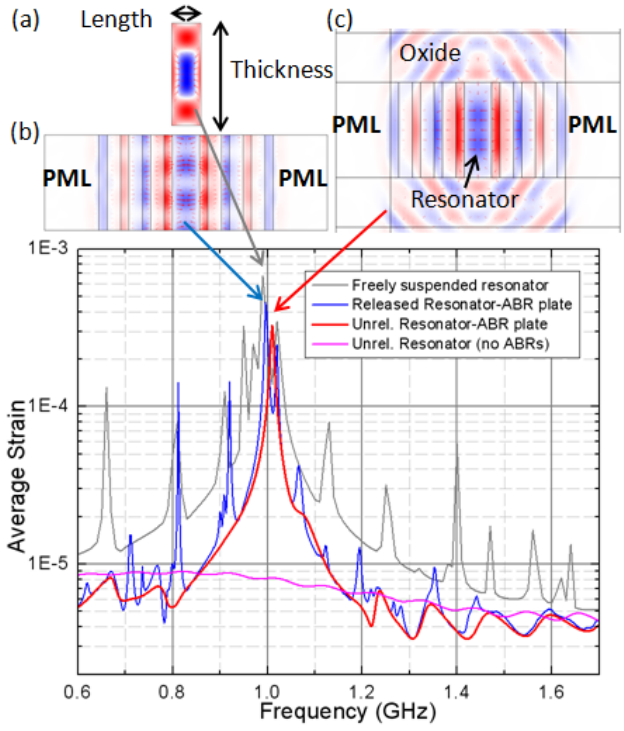

Figure 6. Frequency sweep in COMSOL for sideviews of free bar (a), released resonator-ABR plate (b), unreleased resonator-ABR structure embedded in oxide (c), and simple unreleased resonator embedded in oxide. Frequency response is for resonators of thickness-length ratio of 6.5 and ABR number of 7. Characteristic x-strain contour plots are given at an aspect ratio of 3.5 and ABR number of 3.

targeted at 1 GHz and 3 GHz wavelength, demonstrating maximum variation of less than 2% between the two simulations across a 3 GHz frequency sweep.

The released bar (Fig. 6(a)) provides the sharpest peak, which diverges for infinitesimal frequency steps due to the absence of internal damping in simulation. It is evident that due to the excitation of various plate modes, there are numerous spurious modes around the targeted frequency. At the other extreme, the unreleased resonator in oxide provides almost no peak at all, due to homogeneous energy dissipation into the surrounding medium. Comparison is made focusing on the released resonator-ABR plate (Fig. 6(b)) and the unreleased resonator-ABR structure (Fig. 6(c)). The output signal of the unreleased structure approaches that of the released one with increasing thickness-length aspect ratio. At an aspect ratio of 6.5, the unreleased resonator-ABR structure provides an output signal only 20% less than its released counterpart. The unreleased device also exhibits clear spurious mode suppression, providing a single peak at the desired frequency of 1 GHz.

Of all configurations, the unreleased resonator-ABR structure provides the purest mode due to damping of undesired plate modes in the non-resonant direction. Depending on the aspect ratio of the device, this out-of-plane damping may contribute to a reduced Q of the targeted mode, with a high aspect ratio being favorable for low loss. Nevertheless, it only requires an aspect ratio of approximately 7 for the output of unreleased resonator-ABR structure to match that of the released resonator-ABR plate. This effect results from the higher thickness uniformity of the mode present in the unreleased resonator (Fig. 6(c)), providing a larger effective area for sensing.

C. *In-Plane ABR Design*

To this point, analysis and optimization has been addressed for the sideview structure of both released and unreleased resonators. The lithographic definition of the ABRs under consideration affords a third degree of freedom in design to optimize for the quality factor and suppression of spurious modes. In the sideview case in the previous section, the resonator and ABRs are assumed to extend infinitely in the third dimension. In practice, the finite length of the structure introduces non-idealities and damping, which can be mitigated by in-plane ABR design.

Fig. 7 presents several in-plane ABR configurations for a 1D 2nd harmonic longitudinal-mode unreleased resonator. One half of the resonator is used for driving and the other half for sensing, providing maximum transduction area and selective excitation of the 2nd harmonic. As in the case of released resonator-ABR plate, the extra reflectors result in standing waves in the direction perpendicular to the longitudinal wave, causing signal cancellation and reduction in Q relative to the case of the infinite structure. Inclusion of corner ABRs also introduces spurious plate modes as exhibited in the inset in Fig. 7.

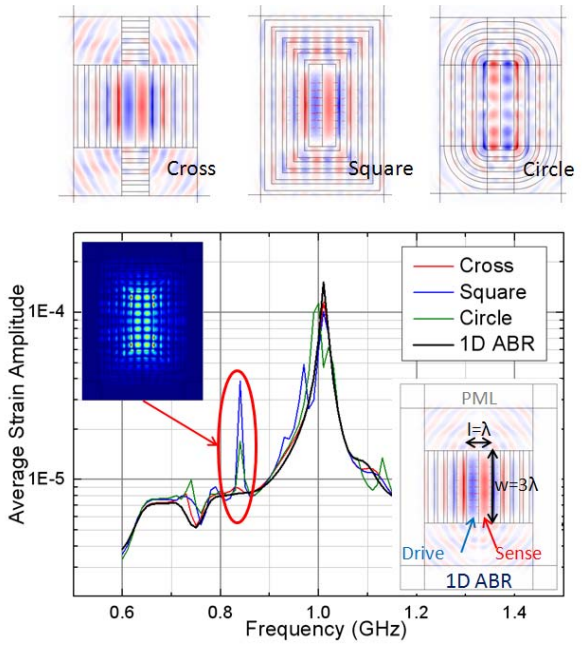

Figure 7. Frequency sweep around the 2nd harmonic in COMSOL on layout designs of cross, square, circular and 1D ABR structures (topview). Adding ABRs for longitudinal waves on the sides of the resonator does not enhance *Q*. Instead, it tends to introduce spurious modes. The inset presents the spurious mode for the square layout.

This result suggests that the 2D ABR design should serve to minimize any extra 2D in-plane vibrations and target a single mode. In the case of the longitudinal-mode resonator with 1D ABRs, in order to localize energy without mode distortion, side reflectors should coherently reflect only shear waves rather than longitudinal waves (Fig. 8). The shear reflectors do not act as standing wave boundary conditions to distort the 1D longitudinal mode, thereby providing higher *Q* and larger output signal.

This enhancement is more evident for higher harmonics. The reduced wavelength of the 6th harmonic in Fig. 8 results in a more uniform mode along the width of the resonator. In this case, the vibrations near the sides of the resonator are increased such that the contribution from the side ABRs is larger. As can be seen in Fig. 8, the 6th harmonic at 3 GHz exhibits a significantly larger amplitude and higher *Q* than the 2nd harmonic at 1 GHz due to the increased width to wavelength ratio. In this case, the shear ABRs also serve to enhance the *Q* by a factor of 2 relative to the 1D ABRs and by a factor of 4 relative to the cross configuration. This quality factor can be further enhanced by increasing the thickness-to-height aspect ratio of the resonator and surrounding ABRs.

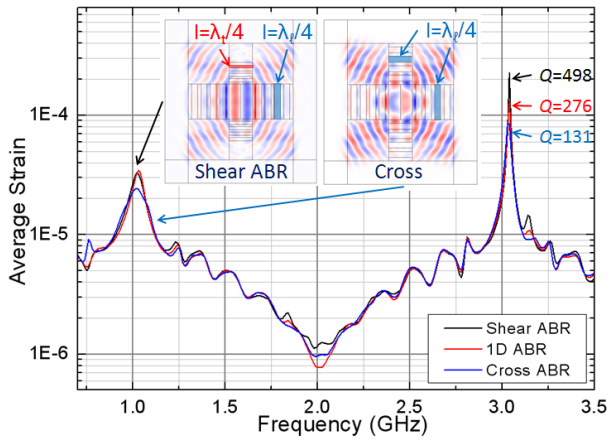

Figure 8. Frequency sweep in COMSOL including the 2nd and the 6th harmonic on unreleased resonator with side reflectors (topview). The width-length aspect ratio of the unreleased resonator is 1.5. Designing side reflectors at quarter shear wavelengths provides more uniform mode and larger signal output.

IV. Acoustic Bragg Reflectors vs. Phononic Crystals

The ABR can be understood as one dimensional case of the phononic crystal (PnC). The PnC is an acoustic wave analogue of photonic crystals, where a periodic array of scattering elements in a homogeneous matrix material causes complete rejection of acoustic waves at a band of frequencies. Much attention has been drawn to the implementation of PnCs for MEMS resonators. One widely used structure is an in-plane wave transmission line resonator analogous to the Fabry–Pérot interferometer [7]. Typically, air holes are etched as scattering elements in a silicon slab (or slab made of other materials) to form a PnC structure. There are also solid scattering approaches to fill these holes with materials with distinct acoustic impedance from the slab [12].

Solid scattering design can be utilized to localize vibrations in unreleased resonators. To compare the performance of a 1D ABR structure to that of a PnC, a silicon square lattice PnC with oxide scattering elements is considered. The fabrication process would be identical to that of the ABR, except for a change in layout, with holes in place

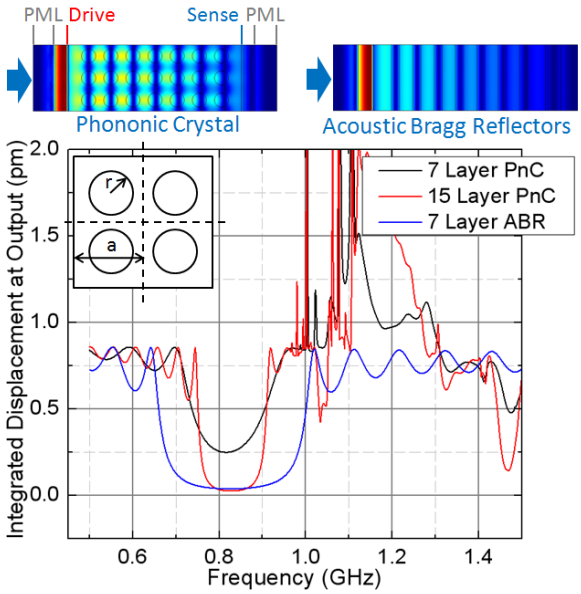

Figure 9. Acoustic bandgap comparison between phononic crystal and acoustic Bragg reflectors. The ABR provides a wider bandgap with no eigenmodes beyond the bandgap, and it requires a smaller footprint. The inset shows a 2x2 unit cell for the PnC used in this analysis. The contour plots show the topview of the transmission line structure, with amplitude of displacement decreasing with penetration depth.

of trenches defined by lithography. Similarly to the ABR, the central frequency of the bandgap for the PnC is dominantly dependent on periodicity, or lattice constant 'a', which approximately equals a half wavelength, while the width of bandgap is related to the filling ratio r/a (Fig. 9, inset). A COMSOL parameter sweep of the bandgap with respect to filling ratio shows the widest bandgap at filling ratio of ~0.3 for Si/SiO_2.

To compare the bandgap formed by the ABR and PnC, a transmission line configuration is investigated in COMSOL, with acoustic excitations generated on the left-hand side and sensing on the right, enclosed in PMLs on both ends (Fig. 9). Periodic boundary conditions are added on top and bottom so that the bandgap property is not distorted by the width dimension. The comparison result shows that the ABR has several advantages over the PnC for unreleased resonators:

- ABRs provide a much wider bandgap than that of PnCs for given impedance contrast of materials and for the same footprint.
- To achieve a near-perfect bandgap, it requires much fewer layers for the ABR compared to the PnC, requiring a smaller footprint.
- At frequencies beyond the bandgap, there exist spurious eigenmodes for the PnC, which results in undesired strong resonance. On the other hand, the ABR provides a perfect bandgap without introducing spurious modes.

As an outcome of these advantages, for the same footprint and material set, if we compare the PnC or ABR applied to an unreleased resonator driven on both ends, the ABR offers clear benefits, with a 9x higher Q, 20x larger signal output, and suppression of spurious modes at both low and high frequency (Fig. 10).

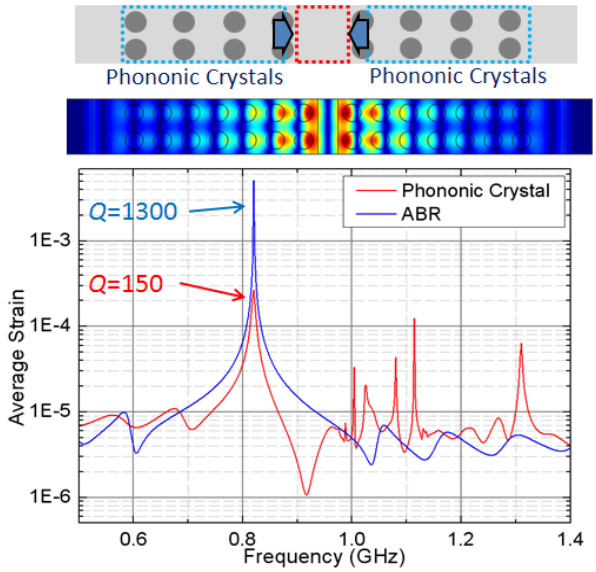

Figure 10. Comparison of performance of unreleased resonator embedded in the PnC and ABR. The contour plot is a topview simulation result in COMSOL with periodic boundary condition added on top and bottom. A pair of equal and opposite forces is applied on both edges of the resonator.

V. Conclusions

The design of the unreleased resonator with ABRs was optimized to suppress spurious modes and enhance the quality factor. With sufficient thickness-to-length aspect ratio, the unreleased design is able to provide signal level and Q that are comparable to its released counterparts. At high frequencies (>1 GHz) where resonator damping is dominated by anchor loss [13], the unreleased resonator with ABRs can outperform released devices.

Since the ABRs are lithographically defined in the same step as the resonator itself, their fabrication does not require any additional depositions or masks. In addition, it enables flexibility in ABR layout configuration, which can be implemented to optimize the ABR geometry for a single mode, resulting in high Q design with a finite footprint. Compared with the PnC, the ABR is more efficient in acoustic energy localization both in performance and footprint, and does not introduce any spurious modes.

The design of unreleased resonators enhanced with acoustic Bragg reflectors can provide basic building blocks for RF circuit designers with high-Q on-chip signal generation and processing that can be directly integrated into the FEOL in CMOS processing. Unreleased design also provides high yield, low cost, robustness in harsh environments, and minimal or no packaging for MEMS resonators.

***Abstract*—This paper reports on the design, simulation and characterization of small form factor, tunable piezoelectric MEMS resonators for real time clock applications (32.768 kHz). The structures were fabricated on a thin-film AlN-on-SOI substrate to enable piezoelectric actuation of an out-of-plane flexural mode, as well as electrostatic frequency tuning by utilizing the handle layer as a DC voltage electrode. Resonators of only a few hundred of µm in size exhibit greater than 3100 ppm of tuning using voltages no larger than 4 V; this tuning sufficiently compensates for frequency variations across temperature from -25 to 100 ºC. The devices exhibit low motional impedance that is completely independent of the tuning potential.**

I. INTRODUCTION

Advances in wireless communications and computer processing applications have led to the steady growth of the electronics timing market, which is currently at the $5 billion mark. This niche is mainly composed of resonators, oscillators and clock generators, whose implementation is dominated by quartz crystal technology. This has been partly due to historical reasons [1], but mainly because quartz exhibits excellent temperature-stable characteristics and reasonable quality factor values, which are desired for high-accuracy applications [2]. In recent years, silicon-based MEMS resonators are becoming strong contenders in the timing applications market as a result of their small form factors, high fQ products and the possibility of direct integration with interface circuits [3]. However, most research efforts in this field are presently being invested in high-frequency devices in the MHz to GHz range, leaving conventional tuning fork quartz resonators as the prevailing devices for real-time clock (RTC) applications. The low-frequency operation (32.768 kHz) and precise fabrication steps required for the implementation of quartz tuning forks make these structures large in size with surface areas in the millimeter range [4]. Additionally, to achieve vacuum levels necessary for high-Q performance, quartz resonators require metallic encapsulation, which further complicates their manufacturing and increases cost.

At such low frequencies, silicon microresonators operating in flexural modes can be utilized to overcome these complications; however, these devices exhibit large temperature coefficients of frequency (TCF) of about -30 ppm/ºC, so passive compensation techniques [5, 6] and frequency-tuning methods are required to counteract this effect [7].

Several techniques for passive temperature compensation of frequency in flexural silicon MEMS resonators have been reported. For example, thermally-dependent axial loads can be applied to a device to counteract the effects of the temperature coefficient of Young's modulus (TCE) [8]. However, this type of approach requires a significant amount of additional area to accommodate for the compensation structure. Another common technique is the use of composite resonators, where different materials with opposite values of TCE are stacked to cancel out or minimize the overall TCF [9]. Nevertheless, interfacial material losses tend to degrade the quality factor which compromises the device performance. Hence, in applications where minimal size and maximum performance are a necessity, electrical frequency tuning tends be a better option, as long as the device offers enough tuning range to enable compensation for both temperature and process variations.

As of today, very few 32 kHz MEMS resonators have been reported [10, 11]. These devices rely on electrostatic actuation and sensing; thus, they require a polarization voltage V_P to operate. To achieve low motional impedances, high aspect ratio capacitive gaps and/or large V_P values are necessary, both of which severely compromise power handling. Furthermore, electrostatic tuning is needed to compensate for TCF; hence, the polarization voltage of the device must be used to adjust the frequency utilizing a temperature compensation scheme. This in turn changes the motional impedance of the device, complicating the implementation of frequency-stable oscillators with a wide operating temperature range. In order to overcome these limitations, thin-film piezoelectric-on-SOI flexural resonators can be utilized to enable piezoelectric actuation as well as electrostatic frequency tuning [12]. Small form factor, highly-tunable low-frequency devices can be realized by carefully designing their geometry as well as the size and shape of their drive and sense electrodes. This paper reports on the optimization, implementation, and characterization of such structures utilizing a CMOS-compatible process flow that is also compatible with high frequency piezoelectric bulk acoustic resonators.

II. TUNABLE PIEZOELECTRIC MEMS RESONATOR

A. Design and Operating Principle

Figure 1 shows a schematic diagram of the proposed 32 kHz piezoelectrically-actuated, capacitively-tunable resonator. This novel structure is composed of an external frame of four clamped-clamped beams anchored at the corners to the surrounding substrate. The beams are mechanically coupled to each other through a suspended rigid plate that provides sufficient structural support without compromising device compliance. More importantly, the plate contributes additional mass to achieve low-frequency operation and a large capacitive electrode area for increased electrostatic tuning.

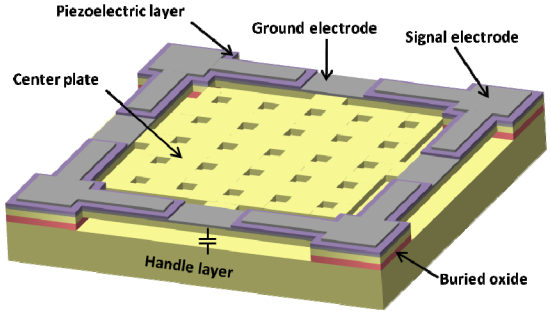

Figure 1. Small form factor piezoelectrically-transduced and electrostatically tunable 32 kHz resonator.

The resonator was implemented on an AlN-on-SOI substrate to allow piezoelectric transduction. A pair of drive and sense signal electrodes were carefully defined on top of each tether by etching the AlN and top molybdenum layers of the piezoelectric stack. The bottom molybdenum, which is in electrical contact with the single crystal silicon (SCS) device layer, serves as the ground electrode.

By applying an AC voltage between each pair of drive and ground electrodes, shear stress is generated over the beams by transverse piezoelectric coupling, which is determined by the d_{31} coefficient of AlN. This stress produces a bending moment that excites the structure into its first out-of-plane flexural mode (Fig. 2). The displacement, amplified by the quality factor of the structure, can be sensed by collecting the charge generated at the opposite pair of signal electrodes. Exciting a vertical mode rather than a lateral vibration is advantageous because the frequency value of a flexural structure is highly dependent on the dimensions along the displacement axis. The displacement magnitude of in-plane modes is determined by lithography, making the resonance frequency highly prone to process variations. In the case of out-of-plane modes, displacement occurs along the device thickness, which can be more precisely controlled through deposition steps.

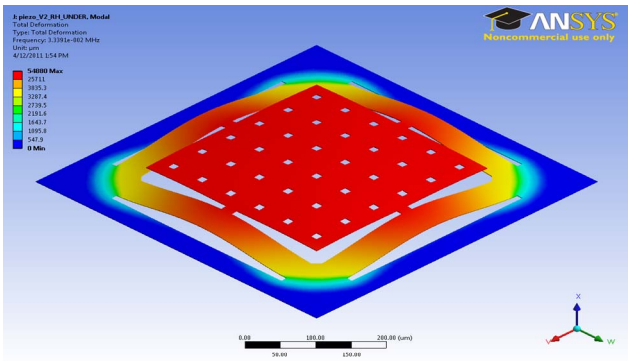

Figure 2. ANSYS® modal simulation results of fundamental out-of-plane flexural mode of piezoelectric 32 kHz resonator.

Although the structure does not require a polarization voltage to resonate, electrical access to the handle layer enables it to be used as a DC tuning electrode. Because the device layer is directly connected to ground, any potential applied to the handle layer will cause an electrostatic spring softening effect that can be utilized to tune the central operating frequency to compensate for temperature and process variations.

B. Device Optimization

Different design techniques were utilized to optimize the device motional impedance, frequency-tuning range, size and manufacturability. Single clamped-clamped beams can be used to implement a simpler version of the resonators proposed in this work; however, their length has to be greatly increased in order to achieve low-frequency operation, which significantly reduces the structural stiffness. This results in devices with large surface-area-to-volume ratios that are highly prone to stiction. To overcome this issue, the presented design takes advantage of mass loading, provided by a rigid plate rather than a decrease in stiffness, to achieve the target resonance frequency. This makes the structure more robust without compromising the overall area.

In piezoelectrically-transduced resonators, the motional impedance is inversely proportional to the square of the electromechanical coupling. To maximize this value and achieve low impedance, the signal electrodes should be carefully sized and shaped to guarantee that, at no point of the covered area, the induced stress experiences a change in sign; this avoids charge cancellation and maximizes coupling. It can be shown that for clamped-clamped beams operating in their fundamental mode, the electrodes should cover up to $1/4^{th}$ of the beam length in order to achieve maximum electromechanical transduction [13]. For the presented design, FEM simulations were used to sweep the electrode length and verify these results. As shown in Figure 3, the optimal point occurs when the electrode is 22.5% of the beam length rather than 25%. This is due to the undercut of the device layer, which changes the effective beam anchor location and hence its maximum and minimum stress points.

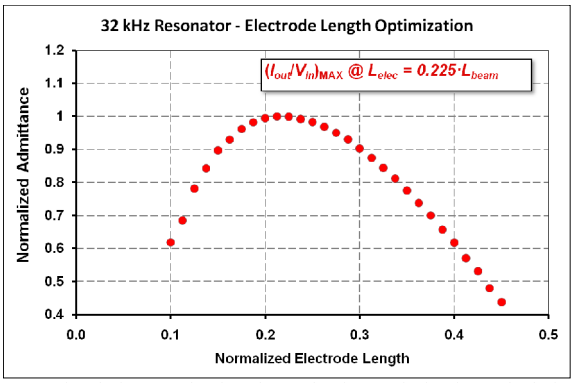

Figure 3. Simulation results for electrode size optimization. Ideal size is slightly smaller than theoretical value due to undercut of device layer.

III. Fabrication Process

For compatibility purposes, these low-frequency structures were implemented with a similar process flow utilized for high-frequency thin-film piezo-on-substrate (TPoS) bulk-acoustic wave resonators [14]. SIMOX SOI wafers with device layer of 1.5 µm and buried oxide (BOX) of 1 µm, were used as the starting substrate. A stack of Mo/AlN/Mo was deposited on the silicon substrate with thicknesses of 0.1/0.5/0.1 µm, respectively. The top Mo layer was patterned to define the top signal electrodes (Fig. 4a), followed by the etching of the AlN layer to provide access to the bottom ground electrode. AlN is also removed from the center portion of the beams and the rigid plate to reduce Q damping (Fig. 4b). Lateral trenches and release holes were then patterned on the Si device layer to delimit the structure geometry (Fig. 4c). Access to the handle layer to define tuning electrodes was also attained in this step. Finally, the device was released in hydrofluoric acid (HF), leaving a capacitive gap between the structure and the handle layer (Fig. 4d).

Figure 5 shows an SEM view of a fabricated 32 kHz resonators with a center plate area of only 250x250 µm^2. Structures with different plate areas where implemented to analyze the trade-offs between performance and area; however, the results presented in this work are only related to the aforementioned structure.

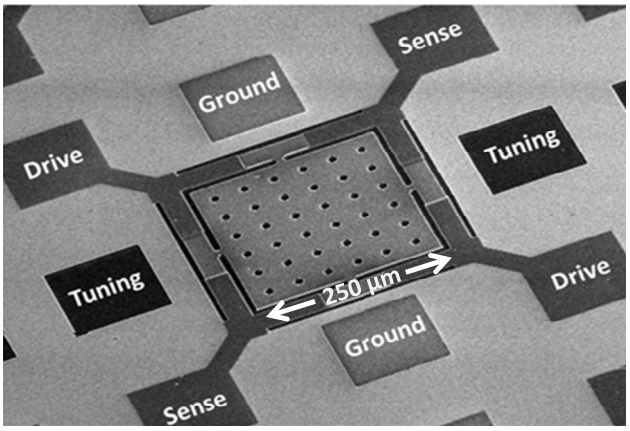

Figure 5. SEM view of 32 kHz tunable piezoelectric MEMS resonator.

IV. Measurement Results

The devices were characterized in an open-loop configuration. Figure 6 shows the frequency response of a resonator after three different tuning potentials were applied. It can be seen that both the motional impedance and the Q remain constant even when the DC voltage changes. This is a clear advantage over most capacitively-transduced resonators since it simplifies the design of the interface circuit required to build up a temperature stable oscillator.

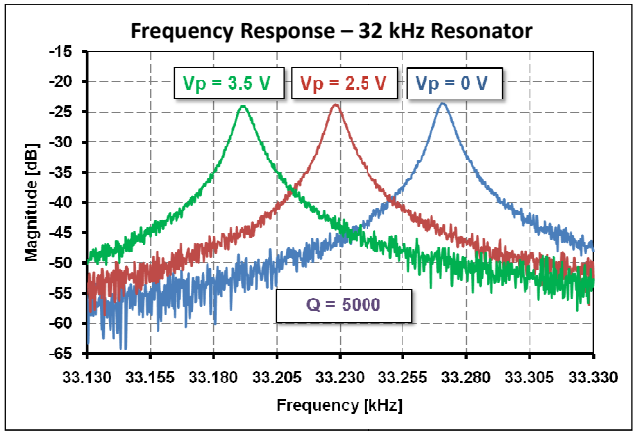

Figure 6. Resonator frequency response. Insertion loss and quality factor are independent of the applied tuning voltage.

To compensate for frequency changes with temperature, the device requires a wide frequency tuning range. Figure 7 shows that by applying voltages no larger than 4 V, this particular design can achieve more than 3100 ppm of tuning. The pull-in voltage of this structure is close to 6 V, meaning that up to 6500 ppm is theoretically achievable if needed. This extra margin can be use to counteract frequency deviations due to process variations.

A linear TCF of -27.8 ppm/ºC was measured for the same device at a constant DC potential. The tuning voltage was then adjusted at each measured temperature point to bring the frequency back to its original value. Full TCF compensation was achieved for temperatures ranging from -25 to 100 ºC. Figure 8 shows the temperature characteristic of the device before and after calibration.

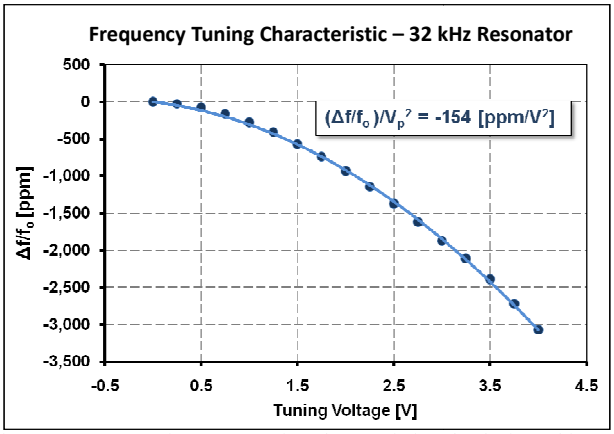

Figure 7. Resonator frequency tuning characteristic. The device achieves 3100 ppm of frequency tuning for voltages no larger than 4 V.

CONCLUSION

This work demonstrates the implementation of tunable piezoelectric MEMS resonators with form factors of at least one order of magnitude smaller than current quartz crystals. The devices operate in an out-of-plane flexural mode, allowing for accurate frequency control during fabrication. 3100 ppm of frequency tuning was achieved for full TCF compensation from -25 to 100 ºC utilizing no more than 4 V. The quality factor and motional impedance of the devices remain constant regardless of the tuning potential, facilitating the implementation of temperature stable oscillators for real-time clock applications.

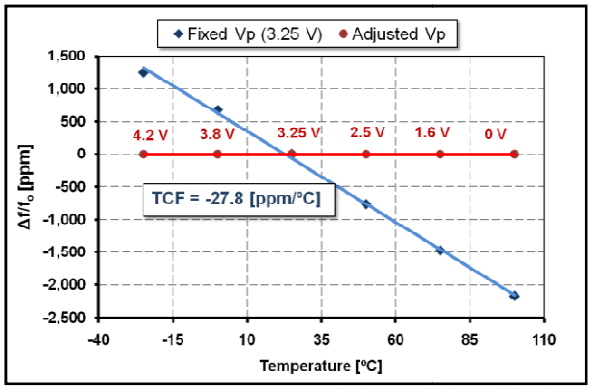

Figure 8. Resonator temperature response before and after calibration. Tuning range is sufficient for full TCF compensation from -25 to 100 ºC.

Linear Acoustic Bandgap Arrays for Spurious Mode Suppression in Piezoelectric MEMS Resonators

Logan Sorenson, Jenna Fu, and Farrokh Ayazi
School of Electrical and Computer Engineering
Georgia Institute of Technology
Atlanta, Georgia, USA
logan.sorenson@gatech.edu

***Abstract*— In this work, we present a technique that utilizes arrays of coupled-ring linear acoustic bandgap (LAB) structures, which exhibit characteristic frequency stop bands, to reduce spurious modes in the wide-band response of AlN-on-Si lateral mode resonators. Aggressive LAB tethering (one support per finger) of high-order modes yields an increase in atmospheric quality factor (*Q*) from 1860 to 2890 for the designed peak at 209 MHz, compared to resonators with traditional tethers. Spurious modes from 0 to 360 MHz are suppressed by at least 30 dB relative to the main peak. The LAB structures presented achieve this goal through a combination of complete acoustic bandgaps and deaf bands.**

I. Introduction

Today's mobile devices are becoming increasingly powerful as a result of the incorporation of multiple wireless frequency standards into a single handheld unit. Applications such as wireless internet, GSM/CDMA voice networks, GPS navigation, and BlueTooth/ZigBee interdevice networking are already included in many mobile phones. Future applications will be enabled by emerging frequency standards (e.g., IEEE 802.15 wireless personal area networks [1]). Mobile phones may soon feature personal health monitoring through body area networks (BANs) [2].

To support integration of these standards into consumer products, microelectromechanical systems (MEMS) resonators, which offer several advantages for RF applications including small size, high mechanical quality factor (*Q*), and low loss, can be configured in the local oscillators of a wireless transceiver. Furthermore, lithographically-defined frequencies of certain MEMS resonators enable multiple frequency standards to be implemented on the same substrate. A typical MEMS oscillator consists of a MEMS resonator connected in the feedback path of a transimpedance amplifier (TIA) (Fig. 1a).

While piezoelectric MEMS resonators can be easily interfaced with low-power electronics, the appearance of sufficiently strong low-*Q* spurious modes near the designed operation frequency can cause degraded oscillator performance. Oscillator phase and gain conditions may cause the spurious mode to become preferred over the desired mode during start-up, causing the oscillator to lock into the spurious mode. Additionally, feedthrough and coupling between the desired and the spurious modes can degrade phase noise

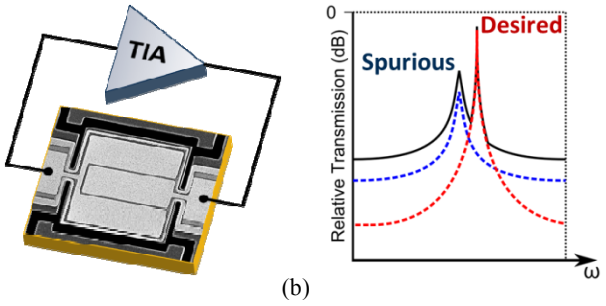

Figure 1. (a) Schematic of MEMS oscillator with resonator in feedback with CMOS TIA; (b) Transmission plot representation showing negative feedthrough and coupling effects of a spurious mode occurring close to the desired resonance peak.

performance and increase frequency instability, depending on the proximity of the spur (Fig. 1b) [3].

Therefore, it is essential to eliminate wide-band spurious modes in piezoelectric micromechanical resonators for use in oscillators [4]. The linear acoustic bandgap (LAB) structures presented in this work may be used to achieve this goal by creating support structures that utilize a combination of complete acoustic bandgaps [5] and deaf bands [6] to suppress the spurious modes without lowering the *Q* of the desired mode.

II. Linear Acoustic Bandgap Structures

LAB structures are one-dimensional phononic crystals (PCs) with small cross-sectional dimensions perpendicular to the axis of the 1D lattice. The coupled-ring LAB structure presented in this work is a linear chain of rings connected by narrow beams, repeated at a characteristic distance *a* known as the lattice constant (Fig. 2). This periodically-repeated section is termed the basis of the 1D PC. The ring inner and outer radii (r_i , r_o), coupling beam width *w*, and layer thicknesses d_i parameterize the basis dimensions.

The periodic nature of the 1D PC combined with large acoustic mismatch at the solid/air interface creates acoustic bandgaps, or frequencies of no allowed acoustic propagation (shaded blue in Fig. 3). In addition to complete acoustic bandgaps, "deaf bands" [6] can also be found in the coupled-ring LAB structure dispersion characteristic. These bands

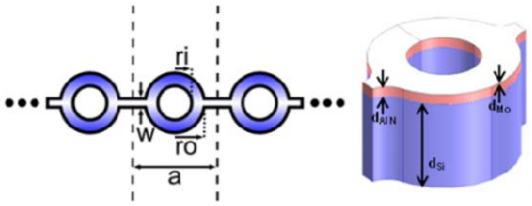

Figure 2. Schematic and 3D view of coupled-ring LAB structure with AlN-on-Si stack (a = 20 µm, r_i = 4 µm, r_o = 8 µm, w = 2 µm, d_{Si} = 10 µm, d_{AlN} = 1 µm, d_{Mo} = 100 nm).

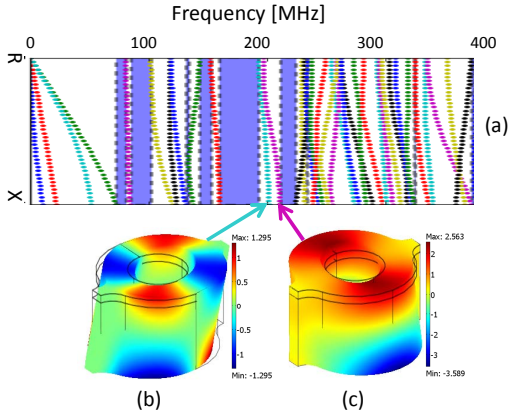

Figure 3. (a) Acoustic dispersion curve for AlN-on-Si coupled-ring linear acoustic bandgap (LAB) structure (bandgaps shaded blue); (b, c) mode shapes of indicated bands showing displacement polarization orthogonal to the axis of the LAB structure.

demonstrate minimal coupling to the LAB structure when waves from the acoustic source exhibit orthogonal polarization to the mode of the LAB structure at the boundary between the two components. The mode shapes of two such deaf bands are depicted in Fig. 3, where the acoustic source is a longitudinal acoustic wave propagating orthogonally to the axis of the coupled-ring LAB structure. For these modes, displacement corresponding to the polarization of the longitudinal wave is effectively zero on the exposed faces of the coupling beam, meaning these bands of the LAB structure are deaf to the longitudinal waves propagating in this direction. Thus, LAB structures and integrated devices must be carefully designed to maximize the attenuation effects provided by complete acoustic bandgaps as well as deaf bands.

III. Device Design and Fabrication

LAB structures can serve as Q-enhancing support elements for MEMS resonators by tailoring bandgaps and deaf bands to confine acoustic energy within the device at the desired operation frequency. This confinement of energy enables an aggressive tethering approach using LAB structures, where one pair of tethers is used for each finger of the interdigitated transducer, to simultaneously improve the support loss component of Q ($Q_{support}$) and provide significant attenuation of spurious modes which lie outside of the designed bandgaps.

A. $Q_{support}$ Enhancement via Aggressive LAB Tethering

The perfectly matched layer (PML) method was employed in COMSOL finite element software to study the effect of aggressive tethering on resonator support loss [7]. PMLs are

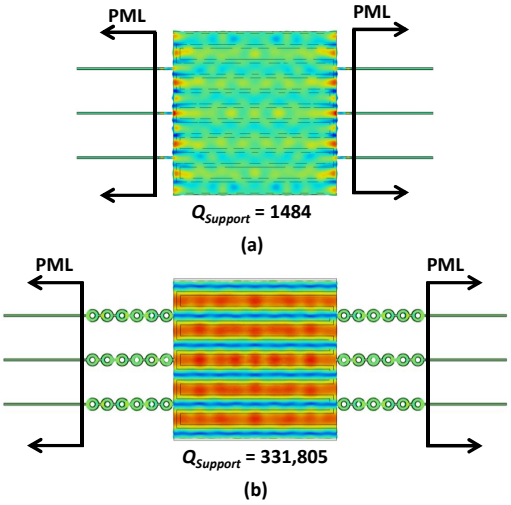

Figure 4. COMSOL PML simulation for a device with three support pairs; (a) simple tethers; (b) LAB tethers.

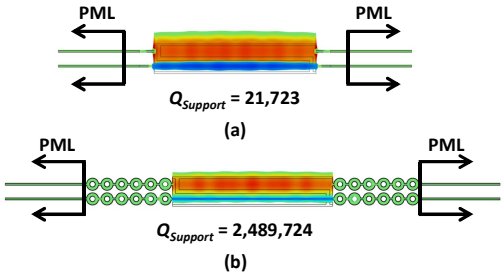

Figure 5. COMSOL PML simulation for an infinite order device; periodic boundary conditions are applied to the appropriate faces of the device to emulate infinite extent; (a) simple tethers; (b) LAB tethers.

additional artificial domains attached to the device which absorb incoming acoustic waves and emulate loss of acoustic energy into the substrate surrounding the device. In this way, PMLs give an estimation of the theoretical lower bound on $Q_{support}$.

Figure 4 shows the results of applying PMLs to an 11th order, 20 µm pitch, 220 µm wide AlN-on-Si resonator, comparing both traditional simple beam support tethers and six periods of coupled-ring LAB supports. For both designs, three pairs of support tethers are used to minimize the number of parallel acoustic leakage paths while maintaining sufficient structural support.

To avoid acoustic mismatch, the PML domains were created by extending the cross-section of the support tethers by a certain distance known as the PML length. In addition to this length, there are several parameters in the PML implementation of COMSOL which must be swept to obtain accurate values for the support loss. Additionally, a sufficiently fine mesh is needed to ensure convergence of the support loss value. Sweeping these parameters enables exploration of the PML design space to determine the lower bound of $Q_{support}$. Because reflections and confinement of acoustic energy due to material mismatch are neglected in simulation, the PML result underestimates the value of $Q_{support}$ (i.e., the values obtained from the PML method are lower than those obtained in reality).

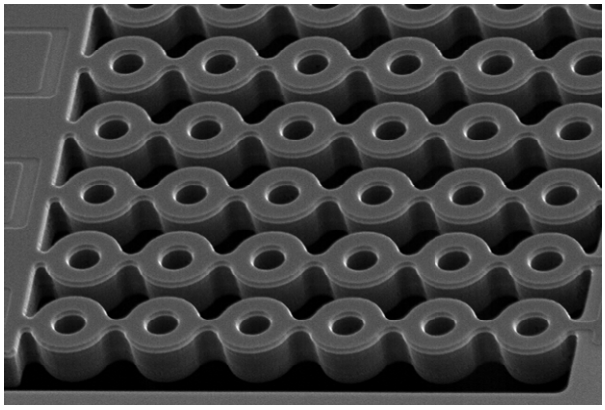

Figure 6. SEM image of fabricated LAB ring tether array.

With these considerations in mind, the $Q_{support}$ for the 11th-order resonator with three pairs of simple tethers is estimated to be 1484 (Fig. 4a), while a $Q_{support}$ of 331,805 is obtained for the same device with LAB tethers, showing over 200-fold improvement of support loss (Fig. 4b). Note that the mode shape in Fig. 4a shows deterioration, and a wave-like pattern develops along the supported edge of the resonator. Comparison of these results with other sets of PML parameters shows that as $Q_{support}$ is increased, the mode shape of the design in Fig. 4a approaches that of Fig. 4b, where the rippling along the supported edge is less apparent, suggesting that the support loss can have localized impact on the resonator mode shape.

Figure 5 studies a device that uses one pair of support tethers per finger of the interdigitated transducer structure. In addition to the PML method, periodic boundary conditions are employed to reduce the number of fingers to two. This effectively models an infinite order resonator and greatly reduces required computation time to calculate $Q_{support}$ (each support contributes a large number of elements). The high number of support tethers confines the mode more closely to the resonator body and nearly eliminates the waves along the supported edge. The confinement also reduces the number of possible resonance modes in the vicinity of the desired mode, which translates into higher $Q_{support}$, even in the traditional tether case. Over 100-fold improvement is obtained in simulation by employing aggressive LAB tethers, boosting the estimated $Q_{support}$ from 21,723 to 2,489,724 (Fig. 5).

B. Fabrication Process Flow

Devices were fabricated on a silicon-on-insulator (SOI) substrate with 10-µm device layer thickness (d_{Si}). The piezoelectric stack, which consists of 100-nm Mo electrodes and 1-µm thick AlN, was deposited directly on the silicon device layer and subsequently patterned to define the top Mo and provide access to the bottom Mo for grounding. The resonator shape, including LAB ring tethers, was defined by RIE etching the piezoelectric stack and Bosch etching the device layer to maintain straight sidewalls. The devices were released by etching the handle silicon layer and removing the buried oxide (BOX) layer. A close-up SEM image of an aggressive LAB tether array is shown in Fig. 6. SEM images of fabricated devices with simple tethers and LAB tether arrays are shown in Fig. 7. The LAB-supported resonators have six periods per support tether. Because the LAB support array provides Q enhancement of insertion loss (IL), the width of the resonator body was decreased.

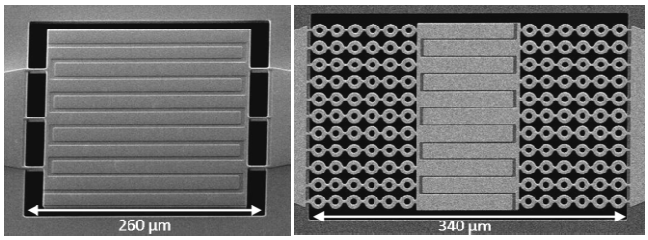

Figure 7. SEM images of 11th-order, 20 µm pitch AlN-on-Si resonators fabricated on 10 µm SOI wafers: (left) 3 pairs of traditional beam supports (20 µm x 2 µm); (right) 11 pairs of 6 period coupled-ring LAB supports.

IV. Experimental Results

To quantify the impact of the LAB support array, the devices of Fig. 7 were measured on a Cascade Microtech Summit 12000 M probe station at atmospheric pressure and room temperature. The data were taken with an Agilent N5241a PNA-X network analyzer in two-port configuration.

A 1 GHz span was measured to observe the wide-spectrum response of both devices (Fig. 8). All spurious modes below 360 MHz are suppressed by at least 30 dB relative to the desired mode, which lies near 209.5 MHz. A few spurs are amplified in the range 150-250 MHz as a result of acoustic confinement introduced by the LAB support array; however, they are not large enough to impact oscillator operation at the desired peak.

In addition to spurious mode suppression in the vicinity of the desired peak, at least 25 dB of suppression is obtained at higher frequencies between 360 MHz and 680 MHz. The cluster of spurious modes near 370 MHz is well-suppressed in IL compared to the reference device. There is also an acoustically quiet section of the frequency spectrum from 380 MHz to 480 MHz in the LAB-supported resonator, when compared to several spurious modes in the reference response. A spurious mode is found at 680 MHz in the LAB-supported case. It is not clear if a relationship exists between this mode and the reference spurious modes in that vicinity; however, it may indicate a bandgap or deaf band introduced by LAB structures at that frequency.

Figure 9 shows a 50 MHz span centered about the desired mode. The LAB array has completely removed a spur on the high-frequency side of the reference device peak. Underlying modes are boosted by the LAB tethers but remain near the noise floor and will have minimal effect on oscillator performance. Finally, Figure 10 gives a narrow-span (2 MHz) measurement of the main peaks for both reference and LAB array devices. The LAB array is found to improve the device Q by almost 60% from 1860 to 2890.

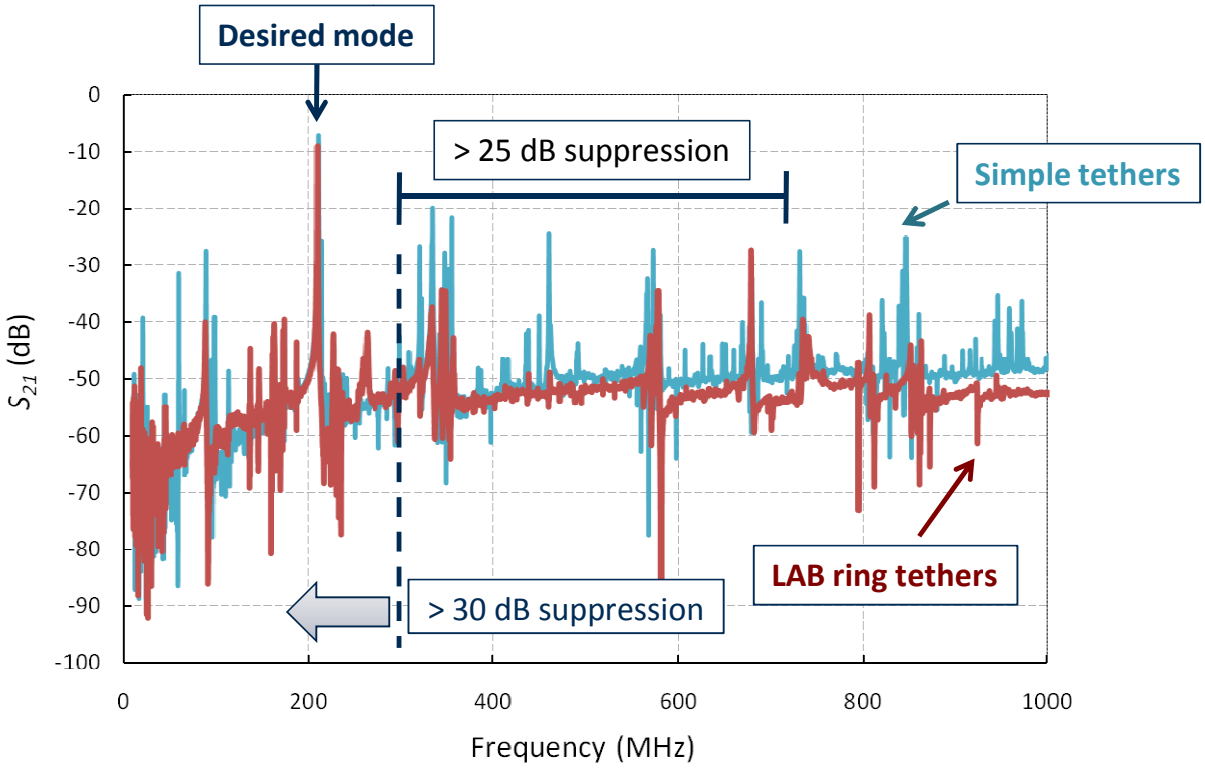

Figure 8. Measured S_{21} response showing wide-band spurious suppression. Below 360 MHz, spurious modes are suppressed at least 30 dB relative to the desired mode. Between 360 MHz and 680 MHz, spurious modes are suppressed at least 25 dB.

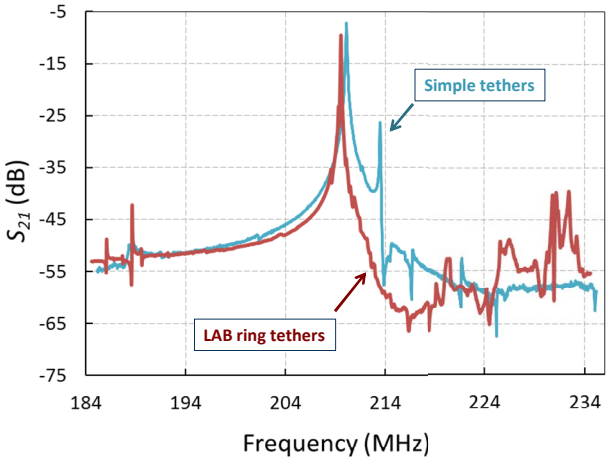

Figure 9. Medium-span (50 MHz) response for both devices at 210 MHz.

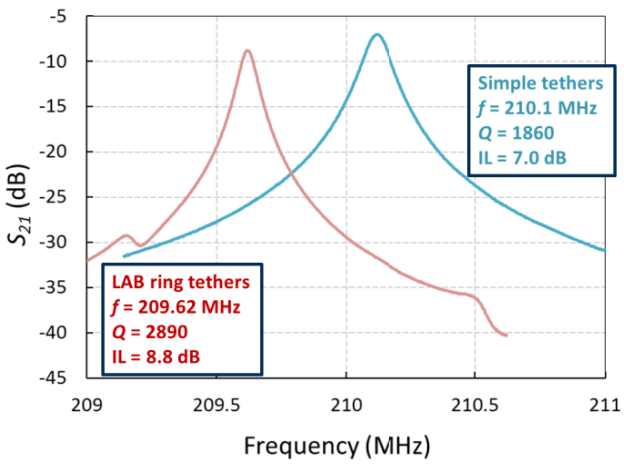

Figure 10. Narrow-span (2 MHz) response for both devices at 210 MHz.

V. Discussion

Comparison of the measured Q value with the $Q_{Support}$ value predicted by COMSOL finite element PML simulations for the simple tether case (Fig. 10 vs. Fig. 4a) yields the conclusion that support loss simulations are accurate to about 20%. However, this particular case ignores reflections back into the resonator body from material and geometry mismatches in the support structure. In that context, COMSOL PML simulations predict the lower bound of the Q value, which is accurate for support loss limited resonators.

However, the predicted $Q_{Support}$ for the LAB-enhanced resonator was in the millions, whereas the measured value was still limited to a few thousand (Fig. 10 vs. Fig. 5b). In high-order piezoelectric MEMS resonators, a large component of the dissipation can be attributed to the piezoelectric transduction stack [8]. LAB array supports nearly eliminate support loss, which causes other factors to become dominant in the expression of the overall Q:

$$Q = \left[\frac{1}{Q_{Support}} + \frac{1}{Q_{Other}}\right]^{-1} \quad (1)$$

Finally, the enhanced Q of the LAB supported device also improves the device IL, enabling a reduced transduction area for similar levels of IL. Thus, LAB structures can be incorporated into MEMS resonators without significantly increasing device area.

VI. Conclusion

In this work, we have presented aggressive tethering of MEMS resonators with LAB arrays to control and suppress spurious modes which negatively impact MEMS oscillator performance. We have also used the PML method to predict the lower bound of support loss contribution to overall resonator Q, and demonstrated that this approach agrees well with measured experimental values when the resonator is support-loss limited.

Reduced Kalman Filters for Clock Ensembles

***Abstract*— This paper summarizes the author's work on timescales based on Kalman filters that act upon the clock comparisons. The natural Kalman timescale algorithm tends to optimize long-term timescale stability at the expense of short-term stability. By subjecting each post-measurement error covariance matrix to a non-transparent reduction operation, one obtains corrected clocks with improved short-term stability and little sacrifice of long-term stability.**

I. Free-Running Timescales

This paper is a summary of work on the formation of timescales, or composite clocks, that the author has carried out over the last ten years, with the goal of surpassing the performance of a previous timescale algorithm [1] that uses a Kalman filter to estimate what the clocks are actually doing.

Let us describe briefly the notion of a timescale derived from an "ensemble" of clocks. One has a set of n free-running clocks with "phase" (i.e, time) residuals $x_1^1(t), \ldots, x_1^n(t)$ at the nominal time t. One cannot read the values $x_1^i(t)$ directly (to the desired precision) but can only measure the phase differences $x_1^{ij}(t) := x_1^i(t) - x_1^j(t)$ at a set of measurement times t. A timescale algorithm, which uses these data and a mathematical model for the clocks, calculates numerical phase estimates $\hat{x}_1^i(t)$ to be subtracted from the clock phases, whether logically or physically, to give corrected clock phases

$$\tilde{x}_1^i(t) = x_1^i(t) - \hat{x}_1^i(t). \tag{1}$$

One hopes to produce corrected clocks with better stability[1] than the physical clocks over a range of averaging times. Since a motion common to all the clock phases is transparent to their differences, one cannot expect the corrected clocks to stay close to a physical clock. Improved timekeeping accuracy is not to be expected from combining clock readings in this way.

Section II describes the most common clock model. Section III sets up an ensemble of these clocks and describes the natural Kalman filter algorithm for calculating the phase estimates. The existing results motivate the author's work to reduce the short-term noise of the corrected clocks. Sections IV and V describe the author's improved Kalman filter algorithms for the case of noiseless measurements, as for a local ensemble. Section VI describes Davis's improvements. Section VII extends the method to remote sets of clocks with significant time-transfer noise. Section VIII gives a recent result on the reduced Kalman covariance matrices of a clock ensemble.

[1]Stability of a phase $x_1(t)$ for an averaging time τ is defined by the Allan deviation $\sigma_A(\tau)$ or Hadamard deviation $\sigma_H(\tau)$, where $\sigma_A^2(\tau) = (2\tau^2)^{-1} \mathrm{E}\left[\Delta_\tau^2 x_1(t)\right]^2$, $\sigma_H^2(\tau) = (6\tau^2)^{-1} \mathrm{E}\left[\Delta_\tau^3 x_1(t)\right]^2$.

II. A Clock Model

Much work in this area has been based on a clock model [2][3] with three independent process-noise components, called white FM (WFM), random-walk FM (RWFM), and random-run FM (RRFM), with phase spectra $S(f)$ proportional to f^{-2}, f^{-4}, and f^{-6}, and Hadamard deviations $\sigma_H(\tau)$ proportional to $\tau^{-1/2}$, $\tau^{1/2}$, and $\tau^{3/2}$, respectively. Missing are the odd-powered models, in particular flicker FM (FFM), for which $S(f) \propto f^{-3}$, $\sigma_H(\tau) = \text{const}$.

The state of one clock at time t is represented as a column vector, $x(t) = \begin{bmatrix} x_1(t) & x_2(t) & x_3(t) \end{bmatrix}^{\mathrm{T}}$, whose components are called phase, frequency state, and drift state. The state evolves according to the stochastic differential equations

$$\frac{dx_1}{dt} = x_2 + w_1, \quad \frac{dx_2}{dt} = x_3 + w_2, \quad \frac{dx_3}{dt} = w_3 \tag{2}$$

where $w_i(t)$ are independent mean-zero white noises with known two-sided spectral densities q_i. One may set $q_3 = 0$, for example, to simulate a constant drift $x_3(t) = c$, in which case $x_1(t)$ contains a quadratic component $\frac{1}{2}ct^2$.

III. Natural Kalman Timescale

The state of an ensemble of n clocks is a $3n$-vector $X(t)$, a stack of n clock vectors $x^i(t)$. The measurements performed on the state consist of noisy phase comparisons, $x_1^{ij}(t) + v_{ij}(t)$, at a sequence of times $t = t_k$, where the measurement noise variances, $\mathrm{E}\, v_{ij}^2(t) = r_{ij}$, are known. Even in the absence of noise, the measurements do not determine the clock states, since all clock phases could conceivably move in the same way together.

To set up a Kalman filter to estimate the state from the measurements, the differential equations (2) for each clock are integrated between two measurement times, call them $t-\delta$ and t, to give a stochastic difference equation. For one clock this takes the form

$$x(t) = \phi(\delta)\, x(t-\delta) + w(t,\delta) \tag{3}$$

where

$$\phi(\delta) = \begin{bmatrix} 1 & \delta & \delta^2/2 \\ 0 & 1 & \delta \\ 0 & 0 & 1 \end{bmatrix} \tag{4}$$

978-1-61284-110-6/11/$26.00 ©2011 IEEE

and the process noise $w(t,\delta)$ is a mean-zero 3-vector with covariance matrix

$$\mathrm{E}\, ww^{\mathrm{T}} = q(\delta) = \begin{bmatrix} q_1\delta + q_2\frac{\delta^3}{3} + q_3\frac{\delta^5}{20} & * & * \\ q_2\frac{\delta^2}{2} + q_3\frac{\delta^4}{8} & q_2\delta + q_3\frac{\delta^3}{3} & * \\ q_3\frac{\delta^3}{6} & q_3\frac{\delta^2}{2} & q_3\delta \end{bmatrix} \tag{5}$$

where the $*$ entries are determined by symmetry. The difference equation for the whole ensemble is written

$$X(t) = \Phi(\delta) X(t-\delta) + W(t,\delta)$$

where Φ has n copies of ϕ down the diagonal and W is a stack of n uncorrelated noises w^i; consequently $\mathrm{E}\, WW^{\mathrm{T}} = Q(\delta)$, which has n 3×3 matrices $q^i(\delta)$ down the diagonal.

The phase comparison measurements at time t take the form $y(t) = H(t) X(t) + v(t)$, where H is a matrix of ± 1's and 0's such that each row takes the difference of two phase components of X. The mean-zero measurement noise v satisfies $\mathrm{E}\, vv^{\mathrm{T}} = R(t)$, a known matrix, usually diagonal. For a local ensemble one sets $R = 0$.

Let $\hat{X}(t)$ be an unbiased estimate of $X(t)$; its quality is specified by an error covariance matrix

$$C(t) = \mathrm{E}\left[X(t) - \hat{X}(t)\right]\left[X(t) - \hat{X}(t)\right]^{\mathrm{T}}.$$

Given $\hat{X}(t-\delta)$, $C(t-\delta)$, and $y(t)$, the Kalman filter equations propagate $\hat{X}(t)$ and $C(t)$ as follows. For clarity, some dependencies on δ and t are suppressed.

$$\begin{aligned} \hat{X}^-(t) &= \Phi\hat{X}(t-\delta) \quad \text{(prediction of } X(t)\text{)} \\ C^- &= \Phi C(t-\delta)\Phi^{\mathrm{T}} + Q \quad \text{(error cov. of } \hat{X}^-(t)\text{)} \\ K &= C^- H^{\mathrm{T}}\left(HC^- H^{\mathrm{T}} + R\right)^{-1} \quad \text{(Kalman gain)} \\ \hat{X}(t) &= \hat{X}^-(t) + K\left[y(t) - H\hat{X}^-(t)\right] \\ C(t) &= (I - KH)C^- \end{aligned}$$

Evidently $\hat{X}(t)$ is a linear function of $\hat{X}(t-\delta)$ and $y(t)$. In fact, $\hat{X}(t)$ is unbiased for $X(t)$ and has the minimal error covariance matrix $C(t)$ of any unbiased linear function in the sense that $C_1 - C(t)$ is non-negative definite if C_1 is the error covariance matrix of any other unbiased linear function. Initialization of this scheme is not treated here.

The natural Kalman corrected clock states are defined by $\tilde{X}(t) = X(t) - \hat{X}(t)$. The corrected phase $\tilde{x}_1^i(t)$ represents the timescale at clock i. The corrected phases need not coincide for remote clocks with noisy phase comparisons, but they do coincide for a set of local clocks being compared with one another with negligible measurement noises ($R = 0$). In this case the common corrected phase constitutes the unique timescale, which may be called $\tilde{x}_1(t)$.

A natural Kalman timescale was implemented at NIST during the 1980's as the local timescale TA(NIST). The GPS Kalman filter [4] also incorporates a natural Kalman timescale. When applied to a simulated ensemble of dissimilar clocks, the NIST timescale was observed to be quiet in long term but noisier in short term than some of the clocks in the ensemble. Weiss and Weissert [5] suggested that the Kalman filter is optimizing accuracy at the expense of stability. This author confirmed their observations with his own simulations and set out to find an improved method of using a Kalman filter to make a timescale that is more stable than any clock in its ensemble over a wide range of averaging times. Stein [6][7] had already accomplished this goal with the KAS-2 algorithm and had described some of its principles, but a full description remains proprietary.

In searching for improved Kalman timescales, the author has held to one fixed principle: the natural Kalman filter does a good job of estimating the underlying frequency and drift states, which, in the author's opinion, reflect the physics of the frequency standards driving the clocks. The author's filter modifications preserve the frequency and drift state estimates but modify the phase estimates to improve the stability of the corrected phases.

IV. Kalman Plus Weights

The author's first successful timescale algorithm [8][9] applies to a local ensemble with negligible measurement noise. The natural Kalman phase estimates are not used at all, but the Kalman frequency and drift estimates, $\hat{x}_2^i$ and $\hat{x}_3^i$, are used in a version of the "basic timescale" iteration. The propagation of the timescale, call it x_1^e, from $t-\delta$ to t can be expressed by

$$\begin{aligned} x_1^e(t) - x_1^e(t-\delta) &= \sum_{i=1}^{n} \lambda_i(t) \\ \cdot \left[x_1^i(t) - x_1^i(t-\delta) - \delta\hat{x}_2^i(t-\delta) - \tfrac{1}{2}\delta^2\hat{x}_3^i(t-\delta)\right], \end{aligned} \tag{6}$$

which says that the increment of x_1^e is a weighted average of the true phases $x_1^i(t)$ minus their predicted values. The weights λ_i are to be chosen subject to $\sum\lambda_i = 1$. The true phases are unknown, of course. To turn this into something that depends only on known quantities, subtract $x_1^j(t) - x_1^j(t-\delta)$ from both sides to give

$$\begin{aligned} x_1^{ej}(t) - x_1^{ej}(t-\delta) &= \sum_{i=1}^{n} \lambda_i(t) \\ \cdot \left[x_1^{ij}(t) - x_1^{ij}(t-\delta) - \delta\hat{x}_2^i(t-\delta) - \tfrac{1}{2}\delta^2\hat{x}_3^i(t-\delta)\right], \end{aligned} \tag{7}$$

which is now a computable iteration for $x_1^{ej}(t) := x_1^e(t) - x_1^j(t)$, the offset of the timescale from physical clock j.

To set the weights λ_i one tries to minimize the variance of $x_1^e(t) - x_1^e(t-\delta)$ in (7). From (3) one can argue for the approximation that $1/\lambda_i$ should be made proportional to the matrix element $q_{11}^i(\delta)$ of clock i (see (5)). As a further approximation, one can make the weights inversely proportional to the white FM noise levels q_1^i of the clocks.

Figure 1 [9] shows the performance of the natural Kalman and KPW timescales on a simulated ensemble of 8 clocks. The odd-numbered clocks have a combination of the three noise types WFM, RWFM, and RRFM. The KPW scale is much quieter than the natural Kalman scale at short averaging times; the natural Kalman scale is slightly quieter around $\tau = 10^6$ s.

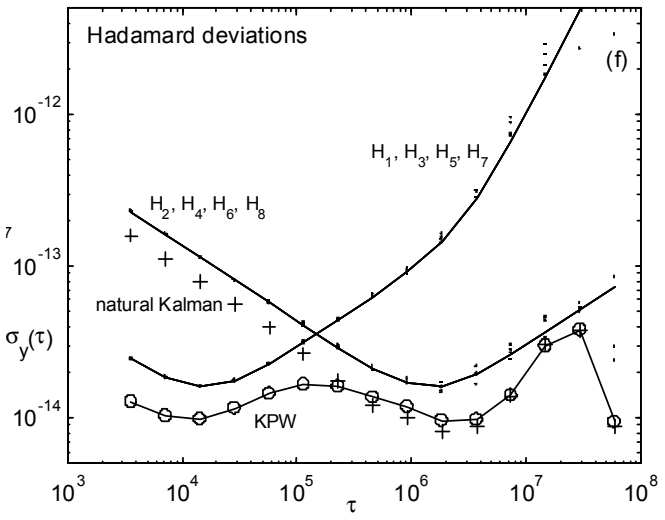

Fig. 1. Hadamard deviation of 8 simulated clocks and two timescales.

V. Reduced Kalman Timescale

For the KPW scale the Kalman phase estimates are irrelevant, but those state components are still carried along by the Kalman filter. Because only the phase differences are measured, the phase rows and columns of the covariance matrix $C(t)$ grow fast. After a processing a set of noiseless measurements, C is singular, however; in fact, the phase rows and columns are all the same vector. The author proved that setting all these matrix elements to zero after each measurement leaves unchanged the future Kalman frequency and drift estimates and their covariances, thus giving a more stable calculation. The author was fortunate to discover, just before giving the paper [9] at BIPM, that this crude operation of covariance reduction, called the "guillotine", also causes the ignored phase estimates $\hat{x}_1^i(t)$, when used as in (1), to yield automatically a different "reduced" timescale $\tilde{x}_1(t)$ that equals a KPW timescale $x_1^e(t)$ with the exact weights λ_i that minimize the mean squared value of the timescale increment $x_1^e(t) - x_1^e(t-\delta)$ [10]. These implicit optimal weights, which can easily be obtained from the Kalman gain matrix, are usually not far from the explicit weights chosen previously for KPW, and the two timescales differ little in practice. The natural Kalman timescale is also a KPW scale with implicit weights [11], but these can differ greatly from the optimal weights.

A Kalman filter that modifies its future estimates by using a reduced covariance matrix is called a reduced Kalman filter. The covariance matrix becomes an operational tool instead of a measure of the actual uncertainty of the phase estimates.

VI. Work with J. Davis

During 2003–5 John Davis of NPL and the author worked together on the reduced Kalman timescale of a local ensemble. Two of his improvements of the art [12] are summarized here.

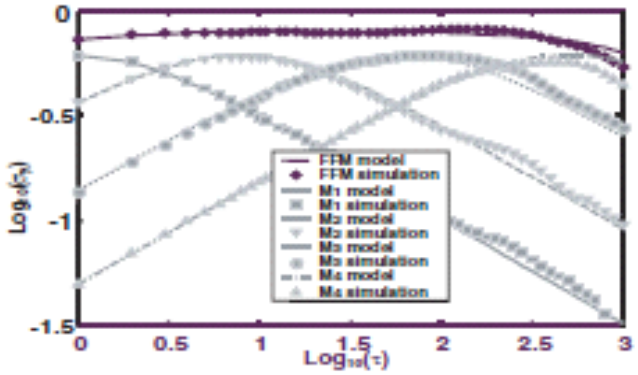

Fig. 2. Approximating flicker FM noise by a sum of independent Markov frequency processes.

First, an approximation of FFM noise can be added to the 3-state clock model by including a sum of independent Markov frequency processes (white noise through a single-pole lowpass filter). One such process is described by

$$\frac{dx_1}{dt} = x_2, \quad \frac{dx_2}{dt} + Rx_2 = w$$

where x_1 is phase, x_2 is frequency, and w is a white noise with spectral density S_w. Integrating this from $t-\delta$ to t gives the stochastic difference equation

$$\begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} = \begin{bmatrix} 1 & \frac{1}{R}\left(1-e^{-R\delta}\right) \\ 0 & e^{-R\delta} \end{bmatrix} \begin{bmatrix} x_1(t-\delta) \\ x_2(t-\delta) \end{bmatrix} + \begin{bmatrix} w_1(t,\delta) \\ w_2(t,\delta) \end{bmatrix}$$

where the covariance matrix of the w_i depends on S_w, R, and δ. One can include several such components in each clock with values of S_w and R chosen so that their sum approximates FFM noise over a range of time scales, as shown in figure 2, which plots the Allan deviation of the components and their sum. One can vary the parameters of the Markov components to produce a more complex frequency stability profile between regions of short and long averaging times.

Second, Davis devised a numerical calculation of the theoretical stability of the reduced Kalman timescale. This is done by calculating the true covariance matrix in a separate iteration that runs alongside the iteration for the operational reduced covariance matrix. One can also calculate the theoretical stability of each clock phase minus the timescale, and the results can be compared with the measured stability of the estimated phases $\hat{x}_1^i(t)$ calculated by the operational filter.

VII. Time-Transfer Noise and IEM

When noise is admitted to the clock phase comparisons, the corrected clocks need not coincide, but the ith corrected phase $\bar{x}_1^i$ can be said to represent the timescale at clock i. In his implementation of the natural Kalman timescale, Brown [4] devised a so-called implicit ensemble mean (IEM), a 3-vector $\bar{x}^B = \begin{bmatrix} \bar{x}_1^B & \bar{x}_2^B & \bar{x}_3^B \end{bmatrix}^{\mathrm{T}}$. This is a weighted average $W_{IE}\tilde{X}$ of the n corrected clock states $\tilde{x}^i$, using a $3\times 3n$ weight matrix W_{IE} that is calculated by solving a least-squares problem

whose noise covariance matrix is just the Kalman filter matrix C. The corrected states tend to cluster about the IEM, and the covariance matrix C_B of the n "representation errors" $\tilde{x}^i - \bar{x}^B$ is Brown's reduced form of C. The representation errors tend to be smaller than the corrected clock states, and C_B grows more slowly than C does. The use of C_B in the Kalman filter is transparent to the future state estimates, and the $\tilde{x}^i$ still represent the natural Kalman timescale. For the case of noiseless measurements, when all the corrected phases coincide, Galleani and Tavella [13] showed that the IEM phase component $\bar{x}_1^B$ does not reduce to the common timescale phase $\tilde{x}_1$. This happens because $\bar{x}_1^B$ depends on the corrected frequency and drift states [15].

By modifying Brown's ideas, the author was able to devise an extension of the reduced Kalman timescale that works well in the presence of measurement noise [14]. The IEM is now a one-dimensional phase $\bar{x}_1^G$, a weighted average $w_{IE}\tilde{X}_1$ of the n corrected clock phases $\tilde{x}_1^i$, where w_{IE} is a row of weights calculated from a 1-parameter least-squares problem with noise covariance matrix C_{11}, the phase-phase submatrix of C. After processing the measurements, one replaces the error covariance matrix C by the reduced version $C_G := SCS^{\mathrm{T}}$, where

$$S = \begin{bmatrix} I_n - 1_n w_{IE} & 0 \\ 0 & I_{2n} \end{bmatrix}$$

and 1_n is a column vector of n 1's. (The state vector has been rearranged so that all n phases come first.) It can be shown that C_G is the true covariance matrix of the corrected states with each $\tilde{x}_1^i$ replaced by its representation error $\tilde{x}_1^i - \bar{x}_1^G$.

The new covariance reduction is not transparent to the future phase estimates. When it is carried out after each set of measurements, the mean squared values of the following increments are minimized:

- $\tilde{x}_1^i(t) - \bar{x}_1^G(t-\delta)$, $i = 1$ to n, the corrected phases minus the previous IEM;
- $\bar{x}_1^G(t) - \bar{x}_1^G(t-\delta)$, the IEM increment.

In the absence of measurement noise, the covariance reduction reduces to the simple guillotine reduction of section V, the IEM $\bar{x}_1^G$ and all $\tilde{x}_1^i$ reduce to $\tilde{x}_1$, and the optimized increments reduce to $\tilde{x}_1(t) - \tilde{x}_1(t-\delta)$.

Figure 3 shows how this works for a simulated two-clock ensemble with measurement noise. For the natural Kalman scale, the corrected phases and Brown's IEM phase component all have the stability of the green clock, which is noisy in short term and quiet in long term. For the reduced Kalman scale, the IEM and corrected blue clock have essentially the same stabilities, while the corrected green clock overcomes the noise and joins the IEM for $\tau \geq 8$.

VIII. A Recent Result on Covariance Reduction

In a further comparison of the natural and reduced Kalman timescales [16], the author's colleagues M. Süß and D. Matsakis discovered that the covariance reductions of Brown (B) and the author (G) can be concatenated in either order to give a further reduced covariance matrix. Afterwards the author was

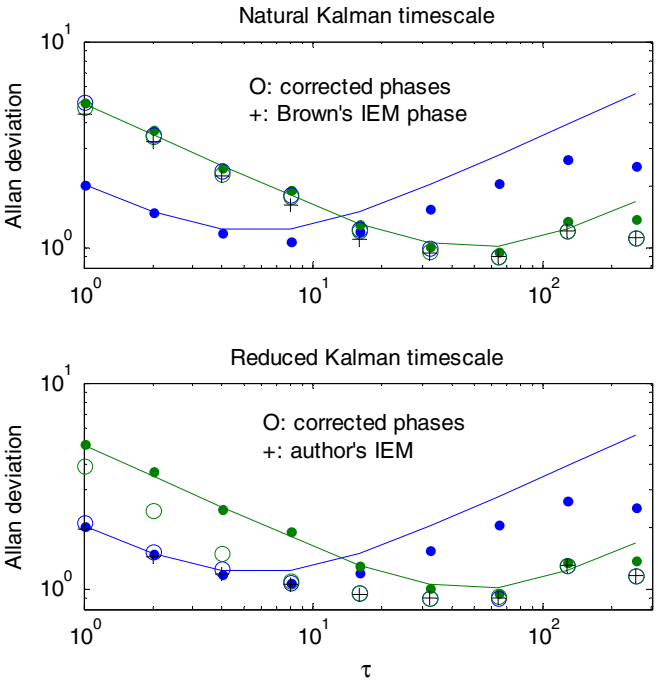

Fig. 3. A two-clock ensemble with measurement noise, showing the stability of the clocks, corrected clocks, Brown's IEM (phase component) and the author's IEM.

able to prove this result mathematically. The reductions are illustrated in fig. 4, in which the matrices are rearranged so that all the phase components come first. For a starting covariance matrix C, the final matrix, $B(G(C)) = G(B(C))$ has the phase border of $G(C)$ and the frequency-drift submatrix of $B(C)$. The final matrix can be used in place of $G(C)$ for operating the reduced Kalman timescale.

IX. Concluding Remarks

By running simulated clock models, the author has found that that the natural method of constructing a timescale from a Kalman filter can be improved by a suitable reduction of the Kalman error covariance matrix, different from the transparent reduction of Brown. The natural Kalman timescale, when applied to dissimilar clocks, tends to minimize the long-term stability of the corrected clocks without regard to their short-term stability. The reduced Kalman timescale, which is designed to minimize the mean squared increments of the corrected clocks instead of their values at one time, seems to produce good results for stability over all available averaging times. So far, though, this is only an empirical observation from experiments in simulation playpens. One needs to gain experience with these algorithms on real clock ensembles while solving practical problems such as noise parameter estimation, clock dropouts, and changes of clock behavior.

The author thanks P. Tavella for inviting him to give this paper. This work was carried out by the Jet Propulsion Laboratory, California Institute of Technology, under a contract

***Abstract*— A clock prediction and steering algorithm has been developed to produce a UTC(k) timescale that may be maintained close to UTC. The algorithm is based on predicting individual (UTC – C_l) clock offsets which are then combined to form a physical UTC(k) timescale. The algorithm is designed to use data from all the available laboratory clocks without the use of a clock ensemble algorithm. The performance of the underlying Kalman filter predictor is examined in depth, along with initial results using three years of historical NPL clock and UTC data combined with a simulated steering process.**

I. INTRODUCTION

The uncertainty in synchronising a UTC(k) timescale to UTC, and the resulting stability of the UTC(k) timescale, are limited by the latency in computation and publication of Circular T by BIPM. This latency is normally 40 days but may be as large as 45 days. To maintain a highly stable UTC(k) timescale, several laboratories have used clock ensemble algorithms to generate a highly predictable free running ensemble timescale. The prediction properties of this ensemble timescale are used to steer a physical timescale UTC(k) which is then maintained close to UTC.

In this paper an alternative and potentially simpler approach is used to generate a simulated UTC(k) timescale that may be maintained close to UTC, without the requirement to compute an ensemble timescale. An algorithm has been designed that is based on the use of individual (UTC – C_l) clock predictions. A Kalman filter-based clock predictor forms the core of this algorithm. The design and performance of the predictor is presented, using both simulated and real NPL clock and UTC data. Initial results from the generation of a simulated UTC(k) timescale are presented using three years of historical NPL clock and Circular T data and simulating the physical clock steering process.

II. OVERVIEW OF THE ALGORITHM

The UTC(k) predicting and steering algorithm consists of several components. The core of the algorithm is a (UTC(k) – C_l) Kalman filter clock predictor, which is designed to provide close to optimal predictions in the presence of standard clock noise types, including Flicker Frequency Modulation (FFM), and also in the presence of linear frequency drift. An algorithm has been developed to weight the individual clock predictions to provide regular (UTC – UTC(k)) estimates. Finally, a steering component is required in order to maintain the UTC(k) timescale close to UTC using the (UTC – UTC(k)) estimates.

III. EVALUATING THE (UTC – C_l) KALMAN FILTER CLOCK PREDICTOR PERFORMANCE

The Kalman filter clock predictor is an extension of the clock predictor described in [1]. The main components of the algorithm are given below.

The state vector at iteration n is given by:

$$x_n = \left(\xi_n,\ \eta_n,\ \zeta_n,\ m_{1n}\ \cdots\ m_{jn},\ p_{1n}\ \cdots\ p_{kn}\right)^T \qquad (1)$$

where ξ_n, η_n and ζ_n represent the (UTC – C_l) time, normalized frequency and linear frequency drift offsets, respectively; $p_{1n} \cdots p_{kn}$ are a group of integrated Markov noise parameters, typically five, used to model FFM noise processes; $m_{1n} \cdots m_{jn}$ are a second group of Markov noise parameters, typically five, used to model non-white measurement noise. The measurement noise is modeled as elements within the state vector, and the measurement covariance matrix R is not used. The components of the parameter covariance matrix P, process covariance matrix Q, and state propagation matrix Φ are described in depth in [1] and [2], as is the initialization of the Kalman filter.

To test the correct operation of the Kalman filter under close to ideal conditions, a data set was simulated using the same constructions of state vector, process covariance matrix and parameter covariance matrix as are used in the filter. The simulated state estimates x_{Sn} evolve from iteration n–1 to n as:

$$x_{Sn} = \Phi(\tau) x_{S(n-1)} + L_Q(\tau) e_n \qquad (2)$$

where $Q(\tau) = L_Q(\tau) L_Q^T(\tau)$, τ is the data spacing, and e_n is a vector of uncorrelated Gaussian noise values of unit variance. The covariance matrix of the simulated data sets at iteration n is given by P_{Sn} where:

$$P_{Sn} = \Phi(\tau) P_{S(n-1)} \Phi^T(\tau) + Q(\tau)\ . \qquad (3)$$

Figure 1 shows the characterization of a simulated data set in terms of Allan deviation (ADEV), modified Allan deviation (MDEV) and Hadamard deviation (HDEV). The simulation plots are obtained by applying ADEV, MDEV and TDEV statistics to the simulated data sets. The theory plots are obtained by computing the ADEV, MDEV and TDEV expectation values directly from the elements of P_{Sn} using a method similar to that described in section 5 of [2]. The two sets of plots agree well.

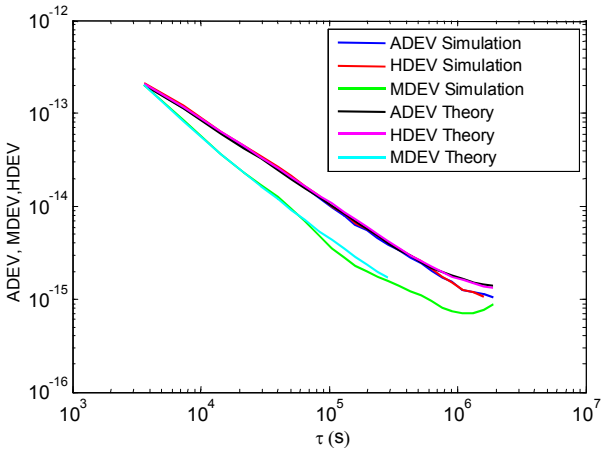

Figure 1. Plots of ADEV, MDEV and HDEV against τ obtained from simulated clock data

The noise process shown in figure 1 is part way between White Phase Modulation (WPM) and Flicker Phase Modulation (FPM), and has characteristics similar to typical time transfer noise.

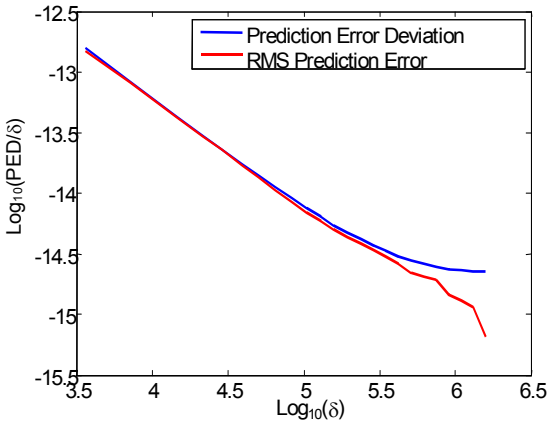

Figure 2. Plots of $Log_{10}(PED/\delta)$ against $Log_{10}(\delta)$ obtained from the Kalman filter predictor operated using the simulated clock data and δ represents the prediction length

In the presence of White Frequency Modulation (WFM) and Random Walk Frequency Modulation (RWFM) the Prediction Error Deviation (PED) is related to ADEV by [3, 4]:

$$PED = ADEV\tau \tag{4}$$

where τ represents the Allan deviation averaging time and is equal to the prediction length δ. This formula is a reasonable first approximation for other power law noise processes. In figure 2 the Root Mean Square (RMS) prediction error has been determined from operating the Kalman filter predictor on the simulated data set used to produce figure 1. The prediction errors are computed from the output data sets, and RMS statistics are then applied. The prediction error deviation is obtained from the post prediction Kalman filter parameter covariance matrix. The plots of $Log_{10}(PED/\delta)$ against $Log_{10}(\delta)$ in figure 2 agree well with the plots of ADEV against τ in figure 1.

The optimal Prediction Error Deviation (PED) obtained in the presence of a FFM noise process is given by [3, 4]:

$$PED = \frac{ADEV\tau}{(\ln(2))^{0.5}} \tag{5}$$

where τ again represents the Allan deviation averaging time and is equal to the prediction length δ.

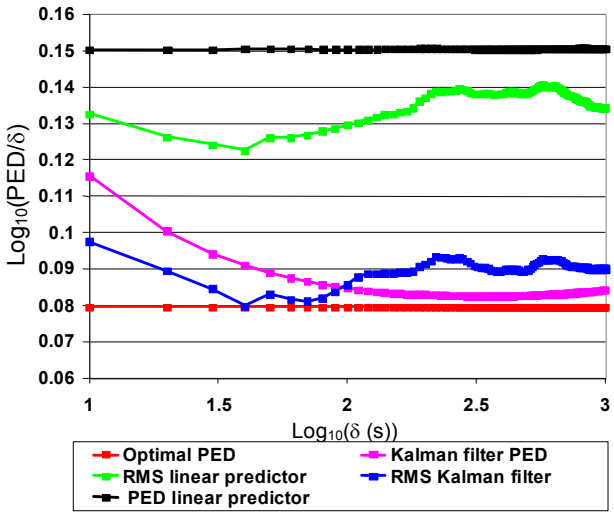

Figure 3. (PED/ δ) estimates obtained from using both the Kalman filter predictor and simple linear predictor on a FFM noise data set

In figure 3 the performance of the Kalman filter predictor is compared against that of a simple linear predictor [1], using a new simulated data set that was dominated by FFM noise. The red line shows the optimal (PED/δ) values obtained from equation 5. Equation 5 assumes a data length and data density prior to prediction that are both tending towards infinity. The pink curves give the theoretical values of (PED/δ) obtained from the Kalman filter covariance matrix. The pink curve deviates from the red line at short prediction lengths when the density of data points relative to prediction length is low, and at large prediction lengths where the total length of the data set is at its smallest multiple of the prediction length. In these two conditions equation 5 is likely to be too optimistic. The black line shows the theoretical performance limit of the simple linear predictor. The blue and green curves are the RMS prediction errors obtained from operating the Kalman filter and simple linear predictor respectively using the same

simulated data set, and then computing the prediction errors from the output data sets. It is concluded that the Kalman filter predictor performs very close to optimal in the presence of FFM noise. There is a significant improvement over using a simple linear predictor.

Figure 4 shows the results of using the Kalman filter clock predictor to predict the time offsets between a pair of NPL's active hydrogen masers. To facilitate direct comparison with the use of a simple linear predictor, the linear frequency drift between the pair of masers was removed before undertaking the analysis.

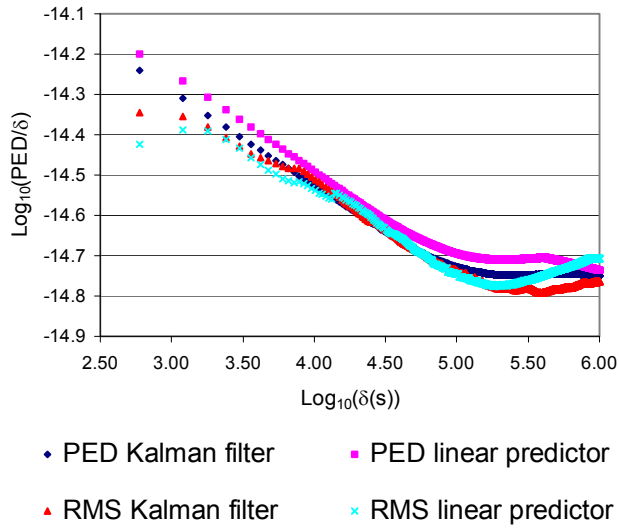

Figure 4. Plots of $Log_{10}(PED/\delta)$ against $Log_{10}(\delta)$ obtained from two of NPLs active hydrogen masers, HM1 and HM2, using both the Kalman filter predictor and a simple linear predictor.

The RMS curves obtained from error statistics agree well with the PED curved obtained from theory, suggesting that the noise models used in the Kalman filter match reality reasonably well. The results obtained from the Kalman filter predictor are better than those from the simple linear predictor, particularly in the long-term where FFM noise dominates.

Active hydrogen masers display significant linear frequency drift. A key advantage of the Kalman filter predictor is that it should be almost insensitive to the presence of linear frequency drift. To demonstrate this characteristic a relatively large linear frequency drift was added to the simulated data sets. The resulting plots of ADEV, MDEV and HDEV against τ are shown in figure 5. The linear frequency drift is clearly identified in the ADEV and MDEV but not HDEV curves obtained from the simulated data sets. The theory values only compute the stochastic component of ADEV, MDEV and HDEV and so are insensitive to linear frequency drift

The resulting plots of $Log_{10}(PED/\delta)$ against $Log_{10}(\delta)$ are shown in figure 6. Comparing figure 6 with figure 2 shows that the theoretical PED values obtained from the Kalman filter remain unchanged and that the linear frequency drift has had only a very slight impact on the RMS prediction errors at averaging times of around one day, the minimum averaging time at which the linear frequency drift dominates the statistics. The ability of the Kalman filter to give close to optimal performance in the presence of linear frequency drift is its main advantage over using a simple linear predictor.

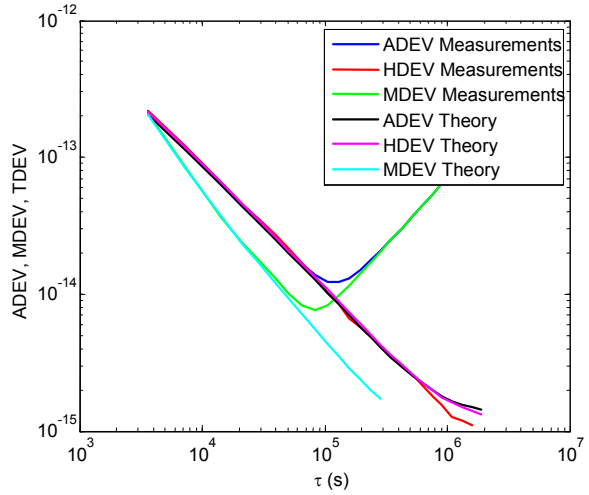

Figure 5. Plots of ADEV, MDEV and HDEV against τ obtained from a simulated data set in the presence of significant linear frequency drift

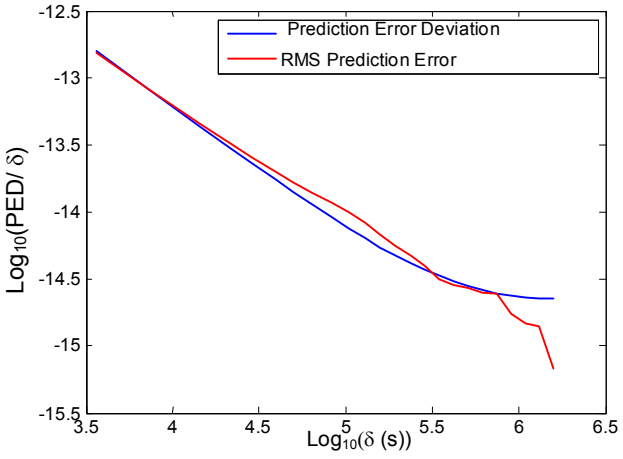

Figure 6. Plots of $Log_{10}(PED/\delta)$ against $Log_{10}(\delta)$ obtained from the Kalman filter predictor operated using the simulated clock data in the presence of strong linear frequency drift

IV. ESTIMATING THE (UTC – UTC(K)) OFFSET

A physical realization of a UTC(k) timescale may be obtained by taking the output signal from an active hydrogen maser and steering the frequency of the output signal using a phase micro-stepper. A counter timer or phase comparator logging system may then be used to make measurements of $(UTC(k) - C_I)$ for each individual free-running laboratory clock C_I.

Circular T data from BIPM contains historical estimates of (UTC – C_l) for each free-running laboratory clock C_l with five-day data spacing. The (UTC – UTC(k)) timescale offsets may then be estimated on an hourly basis using :

$$UTC - UTC(k) = \sum_{l=1}^{r} w_l[(UTC - C_l)_P + (C_l - UTC(k))] \quad (6)$$

where w_l is the weight of individual clock C_l, and r is the number of local free-running laboratory clocks.

Using the Kalman filter clock predictor we are able to predict $(UTC - C_l)_P$ up to 45 or more days ahead and with a much smaller data spacing, e.g. hourly. On receiving the monthly update of (UTC – C_l) the next set of $(UTC - C_l)_P$ predictions will be computed using a whole months additional (UTC – C_l) data. This may result in a discrete change in the estimate of (UTC – UTC(k)). To prevent the algorithm from applying large steers to the UTC(k) timescale to correct these steps, a paper timescale $UTC(k)_S$ is constructed. This timescale has the properties that there is no "step" in $UTC(k)_S$ following the monthly update of BIPM data and that the $(UTC\text{-}UTC(k)_S)$ offset decays exponentially between successive monthly updates. This is achieved by computing the $(UTC\text{-}UTC(k)_S)$ offset up to 50 days ahead at the time the monthly (UTC – C_l) data is being incorporated into the algorithm, and including the latest published value (UTC – UTC(k)) by BIPM. Equation 6 becomes:

$$UTC(k)_S - UTC(k) = \sum_{l=1}^{r} w_l[(UTC(k)_s - C_l)_P + (C_l - UTC(k))] \quad (7).$$

The $(UTC(k)_S - C_l)_P$ individual clock predictions are computed from the $(UTC - C_l)_P$ output of the Kalman filter predictor using:

$$(UTC(k)_S - C_l)_P = (UTC - C_l)_P - (UTC - UTC(k)_S) \quad (8)$$

In the short term e.g. hourly, the physical timescale UTC(k) may be regularly steered to minimize the $(UTC(k)_S - UTC(k))$ offset. Making the assumption that $UTC(k)_S$ may be maintained close to UTC using regular steering it is possible to use historical UTC(k) clock data to determine how well UTC(k) would have been maintained close to UTC assuming that the above weighting algorithm had been applied.

The weights w_l are determined by using the historical prediction RMS prediction errors obtained at the prediction length currently under use. Because the prediction length of the $(UTC - C_l)_P$ predictions will change during each monthly cycle of the algorithm, so do the corresponding clock weights. This is because the optimal clock weight is a function of the prediction length.

V. Results using historical NPL UTC(k) data and simulated rapid steering

Assuming that the physical realization of the UTC(k) timescale may be maintained close to $UTC(k)_S$ then we may use historical UTC(k) data to determine the effectiveness of this UTC(k) prediction and steering algorithm. The errors in the $(UTC - C_l)_P$ individual clock predictions for individual clocks are shown in figures 7 and 8.

Figures 7 and 8 show very sharp changes in the magnitude of the prediction errors on the inclusion of the next month's Circular T data. The prediction errors of active hydrogen masers HM1 and HM2 are generally higher during the first half of the graph. This was a period when NPL was not operating its Two-Way Satellite Time and Frequency Transfer (TWSTFT) earth station. The degraded time transfer using single-frequency GPS measurements resulted in an increased prediction error. The RMS prediction error of the second half of the graph is around 5 ns (1 σ). At a mean prediction length of 30 days this would result in a corresponding approximate ADEV of 2×10^{-15} at an averaging time of 30 days, based on the use of equation 1. This indicates that the Kalman filter predictor is working well and that the two masers are intrinsically predictable in the long term. The results from NPL's high performance (CsHp) and standard tube (CsStd) caesium clocks were as expected. However the prediction errors observed using active hydrogen maser HM4 were far greater than expected and heavily biased, with the sign of the prediction errors changing part way through the run. These effects were caused by a relatively rapid change, followed by a discrete change, in the underlying linear frequency drift of the maser. Such behavior was not accounted for in the clock model.

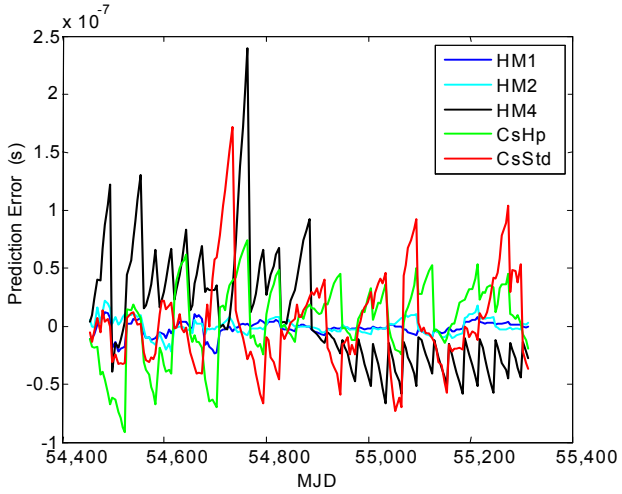

Figure 7. $(UTC - C_l)_P$ prediction errors of each of NPL's clocks

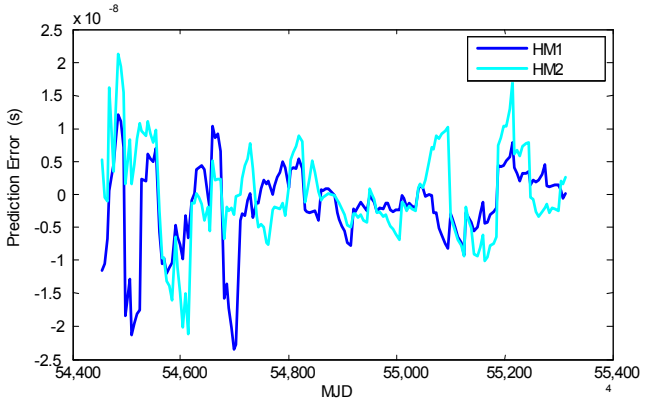

Figure 8. $(UTC - C_l)_P$ prediction errors of NPL's active hydrogen masers HM1 and HM2

Figures 9 and 10 show the resulting (UTC – UTC(k)) timescale offsets obtained using three years of historical UTC clock data. Each offset is computed using a single clock. Again the results obtained from HM1 and HM2 are encouraging, with the offsets being significantly lower during the second half of the period when NPL's TWSTFT system was operational. The (UTC- UTC(k)) offsets obtained using each of the clocks mirrored the prediction errors closely.

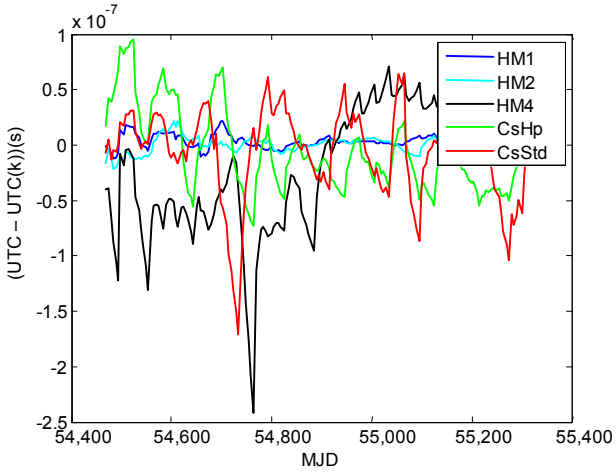

Figure 9. (UTC – UTC(k)) time scale offsets calculated using only one of NPL's clocks

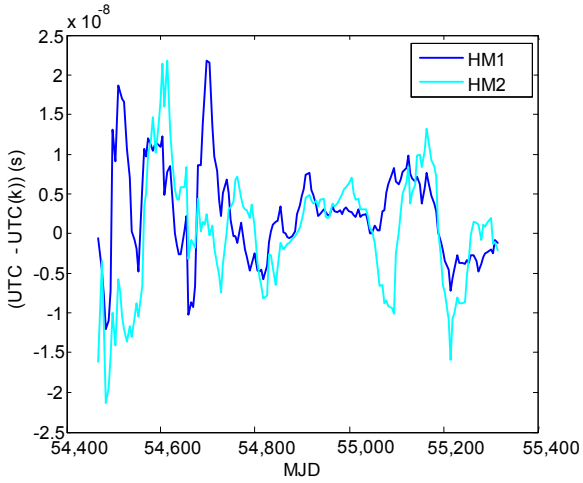

Figure 10. (UTC – UTC(k)) time scale offsets calculated using only NPL's active hydrogen masers HM1 and HM2

Figure 11 shows the (UTC- UTC(k)) timescale offsets again obtained using three years of historical data but computed from a weighted mean of all the (UTC – C_I) clock offset predictions computed as discussed in section IV. The RMS of the (UTC- UTC(k)) offset is significantly lower than was obtained by using any single clock, although the improvement is not dramatic. This is explained by the weighting that attributes well over half of the clock weights to HM2 and the vast majority of the remainder to HM1. This however is a reasonable reflection of the current performance of NPL's commercial atomic clocks. There is also significant GPS and TWSTFT time transfer noise that will be common to all the individual clock measurements. The results are significantly better than is currently achieved using relatively infrequent manual steering of a single active hydrogen maser. Much work is still required in constructing a physical implementation for this algorithm, which has so far only been demonstrated through the post processing of historical NPL clock data and Circular T results.

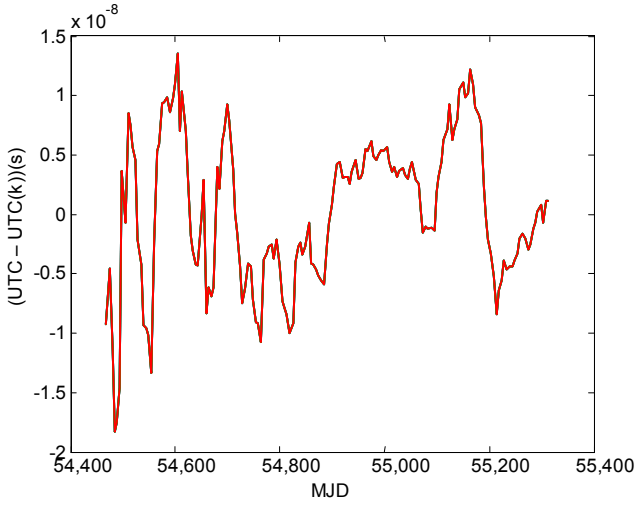

Figure 11. (UTC – UTC(k)) time scale offsets calculated using a weighted mean of all of NPL's clocks

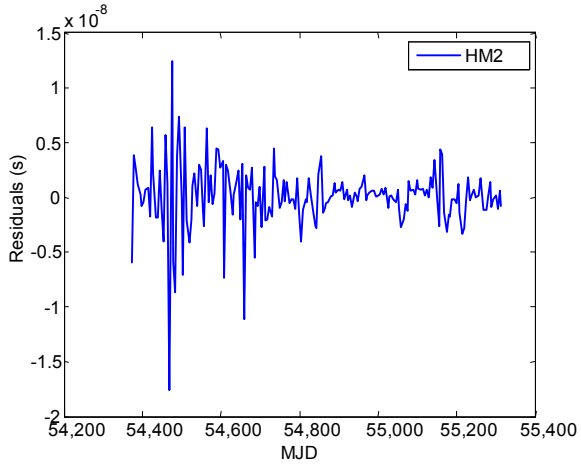

Figure 12. (UTC –C_I) Kalman filter residuals obtained from NPL's active hydrogen maser HM2

Examination of the Kalman filter residuals often provides useful information on the quality of the clock and time transfer noise models used in the Kalman filter. Figures 12 and 13 show the residuals obtained from HM2 and HM4 respectively. In both plots the magnitude of the residuals is lower in the second half of the plots when TWSTFT time transfer was operational. During this period the magnitude of the residuals is very similar despite the resulting prediction errors being very different. In both plots the residuals are close to being white; however, some residual structure may be observed. The key difference is that in the case of HM2 the residuals are

unbiased but in the case of HM4 there is a significant bias that reverses part way through the plot. This is due to a mis-modeling of the linear frequency drift changes occurring with HM4. Either an improved model needs to be developed or a mechanism for detecting significant linear frequency drift changes needs to be incorporated within the Kalman filter.

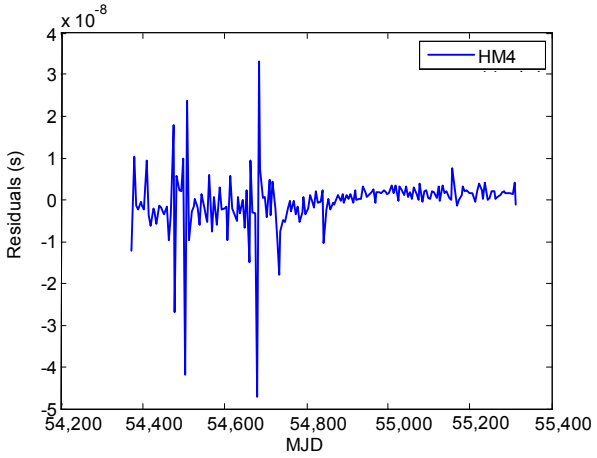

Figure 13. (UTC –C_l) Kalman Filter residuals obtained from NPL's active hydrogen maser HM4

VI. CONCLUSIONS

NPL has developed a prediction and steering algorithm that may be used to maintain a UTC(k) timescale close to UTC. The algorithm operates by weighting individual (UTC – C_l) clock predictions and avoids the requirement to use a clock ensemble algorithm. The core of the algorithm consists of a Kalman filter clock predictor that is shown to produce close to optimal predictions in the presence of FFM clock noise and to be almost insensitive to linear frequency drift. The performance of the algorithm has been demonstrated through the post-processing of three years of historical NPL clock and Circular T data, where the implementation of a rapid steering process has been assumed. Initial results are encouraging. The use of multiple clocks in the algorithm is demonstrated to improve the quality of the resulting UTC(k) timescale and is consistent with the relative weightings given to individual clocks.

Significant work is still required to set up a real-time rapid steering mechanism based on the use of a phase micro-stepper and a suitable algorithm. The prediction algorithm also needs to be improved, to either model better changes in linear frequency drift or detect rapidly the resulting anomalies.

Synchronizing Computer Clocks Using Kalman Filters

Judah Levine

jlevine@boulder.nist.gov

Abstract -- I have used the Kalman Filter algorithm to improve the link between the Internet Time Servers operated by the National Institute of Standards and Technology (NIST) and the primary atomic clock ensemble in Boulder, which realizes UTC(NIST) and which is used as the reference for the time servers. The Kalman algorithm is better able to separate the contributions of multiple noise sources such as the fluctuations in the asymmetry of the channel delay and the statistical fluctuations in the clock used as the internal reference for the time server. This improved separation has made it possible to compensate to some extent for the lower-quality telephone circuits that are often used as the links for synchronizing the time servers to the atomic clock ensemble.

INTRODUCTION

The National Institute of Standards and Technology (NIST) currently operates 35 public network time servers that are located at 21 different sites in the United States. The servers provide time over the public Internet in a number of different formats. All of the servers are synchronized to UTC(NIST). The time servers are linked to the atomic clock ensemble in Boulder, Colorado by the use of a hard-wired connection for the systems that are located at the NIST Boulder laboratories and by dial-up telephone lines, which implement the ACTS protocol [1] which will be described below, for the other systems that are located at remote locations.

THE ORIGINAL ACTS SYSTEM

The ACTS system transmits time using standard dial-up telephone lines and modems. It is a two-way protocol, in which the one-way transmission delay between the server and the user is modeled as one-half of the round-trip value. The message from the server to the client contains a time stamp and an on-time marker character, which the client echoes back to the server with as little delay as possible. The internal system latency is on the order of microseconds, whereas the channel delay is typically tens of milliseconds, so that the system latency is small enough to be ignored. (Both the server and the client have operating system software that has been modified to guarantee that the system latency will be not larger than 15 microseconds even when the client is handling many requests for time from the network.) The round-trip delay is measured by the server as the time that has elapsed from when it transmitted the on-time marker to when it receives the echo from the remote system. The one-way delay is estimated as one-half of this value, and the next on-time marker is advanced using this one-way delay estimate so that it will arrive at the client on-time. The server inserts this one-way delay estimate into each message, so that the client can see the advance that was used. When the client receives the on-time marker, it uses the time stamp of that message to compute the difference between its clock and the clock on the server. This process is repeated every second until the telephone connection is broken. The client can break the connection at any time, and the server will automatically break the connection after 40 s if the client has not done so before this.

There are two important aspects to the design of the ACTS system. The first is that the advance that is applied to any on-time marker is derived from the previous round-trip measurement, so that fluctuations in the delay with a period close to the one-second interval between messages will not be handled correctly. The second aspect, which has more subtle consequences, is that the delay is measured by the server and not by the client. Neither of these was important when ACTS was first designed in 1988, but changes in the telephone system since that time have made both of them significant.

The advance used by the ACTS servers will be accurate and unbiased on the average if the asymmetry in the delay is close to 0 (so that the one-way delay is accurately estimated as one-half of the round-trip value) and if both the delay itself and its asymmetry are well characterized as white noise processes, so that the advance that is used by the server is an accurate estimate of the one-way delay on the average. When these conditions are satisfied, an average of the time differences between the client and the server measured using consecutive ACTS transmissions converges to the true time difference between the two systems. The standard-deviation of the mean is improved by the square root of the number of measurements that are used to compute it, and it was relatively easy to realize sub-millisecond timing accuracy using telephone calls that lasted 15 or 20 seconds.

THE EFFECT OF NEWER TELEPHONE CIRCUITS

The original ACTS servers had no way of evaluating the accuracy of the one-way delay estimate, since they could not estimate the asymmetry of the delay. If we define a symmetry parameter, k, where k= 0.5 indicates that the inbound and outbound delays are exactly equal, then the error in the time-difference measurement, Δt, resulting from an asymmetry in the measured round-trip delay, D, is given by,

$$\Delta t = (k - 0.5)D. \quad (1)$$

The limiting values k= 0 and k= 1 indicate that the inbound or outbound delays (with respect to the server), respectively, are negligibly small compared to the delay in the opposite direction. That is, when k= 0 the transit time from the server to the client dominates the round trip value, so that the clock on the client appears slow.

The measured round-trip delay on analog voice circuits was typically about 0.08 s and the delay asymmetry was typically less than 1%, so that the timing accuracy was of order 0.001 s. These values were realized using the same brand of modem on both ends of the connection and by using a signaling speed of 9600 baud, which has the minimum asymmetry for the modems that we used.[2]

Both the asymmetry and the delay are larger on newer telephone circuits, which are often implemented as a combination of conventional analog and digital packet-switched technologies. This combination is increasingly common even on local subscriber loops – the circuit that links the end user to the local telephone exchange. These circuits often have round-trip delays as larger as 0.25 s, with a varying delay asymmetry that can reach 5% or even more. From eq. 1, the timing error in this case exceeds 0.01 s – about a factor of 10 poorer than the original design. As a practical matter, many users of the Internet Time Services do not need even this level of accuracy and the degraded service may still be adequate for their needs. Nevertheless, I have designed software to try and ameliorate this degradation as much as possible, and I describe the initial tests of these improvements in this paper.

A NEW ACTS CLIENT

In the original ACTS design, the client only had to echo the on-time marker back to the server with negligible delay – all the real work of the protocol was done by the server. However, the client can measure the apparent time difference between the time of the local clock and the time stamp in the ACTS message every second – information that is not available to the server. In order to make use of this information, we must construct a model of the clock in the client system. We use the typical iterative model, in which the time difference at the current epoch, t, is estimated based on a clock model computed at a previous time t-τ. The parameters of the model are the time difference as a function of epoch, x, measured in s and the dimensionless frequency offset, y. The parameters ξ and η are the stochastic noise contributions to the measurement process and the frequency of the local clock, respectively. We assume that the measurement noise, ξ, is approximately stationary white phase noise, so that it does not depend on t or τ. The frequency noise, η, is typically estimated using the Allan deviation for an averaging time of τ. We assume that the Allan deviation is stationary as so does not depend on t.

$$x(t) = x(t-\tau) + y(t-\tau)\tau + \xi \quad (2)$$

$$y(t) = y(t-\tau) + \eta(\tau) \quad (3)$$

Although clock models often include a frequency aging parameter, *d*, whose units are s^{-1}, this parameter is not very useful in this application for several reasons. The frequency aging parameter would add terms $0.5d\tau^2$ to eq. 2 and $d\tau$ to eq. 3. In both cases, the contribution of the aging parameter is masked by the stochastic contributions to the corresponding estimates, so that it is difficult to compute a robust estimate of the aging parameter unless relatively large values of τ are used. Unfortunately, the aging parameter is usually not a constant over these longer averaging times, since the frequency of the oscillator is usually affected in a quasi-random manner by temperature fluctuations and other local environmental perturbations.

The quartz-crystal oscillators used in computer systems typically have y= 2×10^{-5}, η(1)= 10^{-7}, and η(30)= 1.8×10^{-8}. (These parameters characterize the oscillator as seen through the operating system software, and therefore include system latency and jitter. It is almost always impossible to measure the characteristics of the actual "bare" oscillator itself, which is probably considerably more stable than these values of η for almost all averaging times.) If we take 30 s as the maximum duration of a typical connection between a client system and the ACTS server, the stochastic frequency variations contribute about 0.1 μs to the estimates of consecutive time differences spaced 1 s apart, and about 0.5 μs to the dispersion of the time differences over the entire connection. In contrast, the measurement noise, ξ, is typically at least 80 μs even on a very good telephone connection, so that the contribution of the stochastic frequency fluctuations plays no role over the duration of a telephone call. The measurement noise is larger than the system latency because of the quasi-synchronous operation of the message interchange over the telephone line between the two modems. Therefore, the measured time dispersion of the clock in the client system over the duration of the telephone connection can be modeled as white noise superimposed on a simple linear variation. The linear variation can be ignored relative to the measurement noise for short telephone connections lasting less than about 4 s, but must be considered for the 30 s connections that we use for the synchronization of the time servers.

DETAILS OF THE MEASUREMENT ALGORITHM

The client system connects to the ACTS server and receives *N* time messages. Each message contains a time stamp and the advance applied to the on-time marker of that transmission. As described above, the advance parameter was actually computed by the server using the previous measurement that it made of the round-trip delay. The client measures the time difference between its clock and the time stamp of each of the messages, and also records the associated advance parameter. These values are T_i and A_i, respectively.

The algorithm models each of the advance values as the sum of a constant value that is a characteristic of that telephone connection and an additional stochastic value that has some unknown statistical distribution. We explicitly *do not* assume that the distribution of the advance values about the constant value has any particular form. However, we do assume that the variations in the advance have a mean of 0. That is, the mean of the advance values over the entire telephone connection is an unbiased estimate of the true transmission delay. (This assumption is basic to all two-way methods. There is no way of detecting a static bias in the asymmetry.) Thus, the algorithm assumes that the true advance for this telephone connection is given by

$$\overline{A} = \frac{\sum_{i=1}^{N} A_i}{N} \tag{4}$$

and that the additional stochastic contribution to the advance in each message is given by

$$a_i = A_i - \overline{A} \quad . \tag{5}$$

We model the measured time differences (by the use of eq. 2) with a constant time offset, a linear time variation due to a deterministic, constant frequency offset and a measurement noise parameter, which we assume to be stationary. We assume that the measurement noise has a random distribution with a mean of 0 that can be characterized as white phase noise. Therefore, the measured time differences should be accurately modeled using a least-squares straight line, and the measurements should scatter about that line with a random distribution that is characterized by the measurement noise of the process. We ascribe statistically significant deviations from the straight line assumption (relative to the estimate of the measurement noise) as due to an error in the advance parameter for that measurement. The error can be due either to a change in the asymmetry of the telephone connection or to a rapid change in the actual round-trip delay between one-second measurements. Our experience is that rapid changes in the round-trip delay are much less likely after the first few seconds of the connection, and changes in the asymmetry are much more common. See fig. 2 of [2], which shows that the advance varies by less than 1 ms P-P after the first few seconds of the connection.

I can illustrate the basis of the method with a simple example. The client system connects to the ACTS server and receives *N* messages, each of which has a time tag, an advance parameter and an on-time marker. When the on-time marker is received, the client measures the time difference between the time tag and the time of its clock. It also records the advance value that was used.

The first step of the analysis is to fit the time differences to a least-squares line and examine the residuals. In the simplest case, the RMS magnitude of the residuals is of order 1 ms, and the maximum deviation is not greater than 3 ms. The time difference is taken as the intercept of the fitted line (with the appropriate time tag), the frequency is the slope of the line, and the algorithm continues with the next step as described below.

If any residual exceeds the threshold of 3× the RMS value, the algorithm examines the advance values to see if the residual could be due to an error in the advance calculation. The algorithm calculates the mean advance and the deviation of each individual advance from that mean as in eq. 4 and 5. The time difference associated with each message is corrected by the difference between the advance used for that message and the average of all of the advances. This operation models statistically large time differences as due to errors in the advance calculation by the server – most often a result of a change in the asymmetry of the connection, which the server cannot detect. The sign of the correction depends on the direction of the asymmetry – whether the inbound or outbound paths were affected, as shown in eq. 1. Therefore, the algorithm must investigate both possibilities and choose the one that reduces the magnitude of the residuals. In most cases, this calculation reduces the scatter in the time differences, confirming the assumption that fluctuations in the advance are really the cause of the apparent fluctuations in the time differences. Any time difference that still exceeds 3× the standard deviation of the residuals of a least squares straight-line fit to the modified time differences is taken to be an error due to some other unknown reason. It is dropped from the estimate and the least-squares line is re-calculated. When no further outliers are detected, the time difference and frequency offset are estimated as the intercept and slope, respectively, of the fitted line, and the algorithm continues with the next step. If more than 5 points are discarded in this process, the estimate does not proceed. Either the RMS deviation of the model is too optimistic for the real data or the system has failed. The algorithm waits a short time and tries again; the time server is declared unhealthy as a precaution, since the time difference calculation did not complete successfully. The time server will continue to be set to an unhealthy state as long as the problem continues. This condition will trigger an operator alarm.

In the more general case, we use the standard Kalman formalism to estimate average values of each of the parameters over the duration of the telephone connection. In other words, the Kalman algorithm partitions the variance of the time differences measured during a single telephone connection as

due to fluctuations in the advance parameter, which have some unknown statistical distribution with a mean of 0 and a linear time variation with a slope and intercept that are constant during the connection. This calculation is considerably more complicated than the simpler algorithm described above, but it is more general and able to handle more complex noise types. For example, we have experimented with adding a diurnal term to the Kalman model, which could be helpful in estimating the effect of the nearly-diurnal fluctuations in ambient temperature on the frequency of the oscillator in the client. This term must be incorporated into the covariance matrix, since we do not know the amplitude or phase of the admittance to the temperature. This process is often described as "state vector augmentation." [3]

When the computation is completed, we have an estimate of the time offset of the system clock, the average frequency over the time of the connection, and the measurement noise parameter, ξ, which is essentially the RMS value of the residuals of the computation.

We cannot determine the stochastic frequency variation, η, in this way, since its contribution to the time differences is too small over the duration of the telephone call. For averaging times less than a few hours, the frequency fluctuations are well modeled as white frequency modulation. Therefore, we estimate the frequency of the oscillator by

$$y(t) = \frac{y(t-\tau) + T_y \dfrac{x(t) - x(t-\tau)}{\tau}}{1 + T_y} \quad . \tag{6}$$

The first term in the numerator on the right side is the estimate of the frequency on the previous measurement cycle, and the second term is the current average frequency estimated as the evolution of the time difference over the interval since the last measurement cycle. When the time server is operating in steady state, the control software drives the time difference to zero on every measurement cycle, so that $x(t-\tau)= 0$ in this mode. The estimate of the current frequency is then simply the time difference that has accumulated divided by the interval between measurments. The weighting factor T_y implements an exponential filter with a time constant derived from the assumption that the frequency variations can be characterized as white frequency modulation. For most of the computers that we have tested, this assumption is valid for averaging times up to about 12 000 s, so that

$$T_y = \frac{\tau}{12000} \quad . \tag{7}$$

For averaging times shorter than τ, the value of η, the stochastic variation in the frequency of the local clock oscillator is measured using special-purpose hardware that connects directly to the computer bus.

The value of τ, the time interval between measurement cycles is determined as a compromise among several competing considerations. If the interval between measurements is too short, it is difficult to estimate the deterministic frequency, y, in the presence of the measurement noise, ξ and the stochastic fluctuations in the estimate of the delay. Using a conservative value of 1 ms for the noise term, the interval between measurements should be at least

$$\tau \geq \frac{0.001}{2 \times 10^{-5}} = 50\,s \quad . \tag{7}$$

In the limit of a very short measurement interval, the measurement noise dominates the calculation, and the performance is dominated by the characteristics of the noisy channel. The local clock is more stable than the remote clock seen through the noisy channel, and the inherent frequency stability of the local clock oscillator is not being exploited in an optimum way. On the other hand, the interval cannot be made too long without violating the assumption that the evolution of the time difference over the measurement interval satisfies the model equations. The algorithm must also consider the possibility of non-statistical glitches in the clock oscillator, and decreasing the interval between measurements would decrease the impact of these glitches because they would be detected (and removed) more rapidly. Finally, the cost of the telephone connections varies as $1/\tau$. Using the interval between calibrations based on the minimum value in eq. 7 would be too expensive and therefore impractical for this reason.

The value of τ was initially about 3 000 s – 4 000 s, but this value is generally too large for some of the poorer telephone connections, and a value of 2 000 s is often needed to realize an acceptable level of timing accuracy at the server of no worse than 5 ms P-P.

DISCUSSION AND CONCLUSIONS

The algorithm I have developed has made it possible to continue to operate the NIST Internet time servers with the telephone circuits that are becoming increasingly common both for the local connection to the telephone central office and for long-distance links. Maintaining a network of time servers synchronized in this way is important for two reasons. In the first place, the time service provided by these systems is independent of satellite signals in general and the global positioning satellites in particular, so that the systems are not compromised by a denial of service attack on satellite signals. In addition, the servers do not need external antennas and can be installed at any location that has telephone connections. This is a significant advantage, since many of our systems are installed in underground or windowless, secure locations with no access to the outside. On the hand, the servers depend on periodic long-distance connections to the ACTS serves in the NIST Boulder laboratories, and this is an expense that would

not be needed for a system that was synchronized using a satellite timing receiver.

As with all two-way methods, the algorithm cannot detect a static asymmetry in the measurement of the round-trip delay of the telephone circuit. We can estimate the magnitude of this effect by comparing the times of different servers to each other, but these comparisons introduce possible asymmetries in the delay of the Internet path between them. As a practical matter, the asymmetries of the Internet paths are typically at least as large or even larger than the values for the telephone system, so that the results of these comparisons are not definitive.

The method I have described here cannot cope with every type of asymmetry. At one of our sites, the asymmetry had a bimodal character. That is, the asymmetry was constant for some period and then abruptly changed to a different value. The change in the asymmetry resulted in time steps of order 20 ms with an irregular period of a few hours. I had no basis for eliminating these steps, since I didn't know the actual time offset of the client system. Both of the time offsets satisfied the usual statistical tests within a single telephone connection, and the asymmetry was constant over several telephone connections, suggesting that the routing of the telephone calls changed periodically in an unpredictable manner.

The problem of a bi-model asymmetry is not very common on telephone connections – we have only one example on 35 connections. However, a slowly varying asymmetry is common, and it also arises quite often in time synchronization applications that use the Internet as the communications medium. A nearly bimodal asymmetry on the Internet can arise for a system, such as a web server, that often has very different inbound and outbound network activity. The "Huff-'n-Puff" [4] filter is an attempt to deal with both of these cases. The procedure assumes that the minimum delay will also have the minimum asymmetry, which is often true for web servers and similar systems because the asymmetry is a strong function of the load on the client or on the server and not a fundamental characteristic of the intervening path itself, which is assumed to have better symmetry. We do not have a good idea of the source of the varying asymmetry in our configuration, and it is less clear that assuming that the minimum delay also has the minimum asymmetry is appropriate. Nevertheless, there could be an advantage to using only the time differences with the minimum delay in the computation of the estimate of the time of the client. From eq. 1, the time error due to any asymmetry is bounded by one-half of the round-trip delay, so that a smaller delay will have a smaller time error, even if the asymmetry fraction is the same. However, even the shortest delay is many tens of milliseconds, so that this limit is not very useful, since the goal of the time service is to synchronize the servers with an uncertainty of 1 ms RMS. Unfortunately, we also do not have an independent estimate of the true time difference between the two systems, so that we have no basis for choosing one time difference over the other one.

One way to address this asymmetry problem would be to improve the frequency stability of the oscillator in the time server so that much longer averaging times could be supported. The easiest way to do this would be to add an external atomic frequency standard or even a high-quality quartz oscillator and then lock the computer oscillator to the external device. Some of our time servers have external rubidium oscillators interfaced to the system through an interrupt line on the serial port for this purpose. Both the frequency offset and the frequency stability of the clock oscillator are improved by several orders of magnitude using this technique.

When an external oscillator is present, the time-varying asymmetry (and similar slowly-varying perturbations) can be averaged for much longer periods – at least 1 day and probably longer than this, since the frequency stability of the enhanced local oscillator will now support these longer intervals between measurements. Since the variations in the asymmetry are bounded, it can always be divided into two components: a static value and a bounded variation about that value that has a mean of 0 for sufficiently long averaging times. A long averaging time would attenuate the time variations in the asymmetry and convert a static asymmetry into a time offset. This time offset would have a slow variation in time if the static value of the asymmetry was not stationary. (This would be true if the asymmetry had a random-walk spectrum, for example, since such a spectrum has no robust mean value.) The time offset could be estimated through comparisons with the NIST time servers that are located at NIST facilities and are synchronized by direct connection to the NIST clock ensemble. These directly-connected time servers would serve as the constraints on the ensemble of network servers, so that the ensemble would provide a stable source of time messages that would be less affected by the asymmetry of any single network path. To the extent that the network paths are disjoint, an ensemble of network paths might also have an overall asymmetry smaller than the asymmetry of any one of them.

***Abstract*— We propose an algorithm for the detection of frequency jumps in atomic frequency standards. The algorithm is based on the innovation generated by the Kalman filter. When the magnitude of the innovation is larger than a given threshold, an anomaly is detected. We characterize the performance of our method for the case of a Rubidium clock by estimating, through numerical simulations, the probability of false alarm, the probability of detection, and the latency time on a large number of numerical simulations.**

I. Introduction

The fast detection of anomalous behaviors of atomic frequency standards is becoming a very urgent issue in the most demanding technological applications, such as navigation systems. The capability to identify an anomalous behavior of a frequency standard is a need in timekeeping and in several other metrological applications, but the peculiarity of navigation systems is that any anomaly which can impact the user positioning has to be detected and signaled in short times and with very low probability of false alarm. These requirements ask for an extremely fast and efficient algorithm, whose design is challenging. Several algorithms have been proposed in the last years [1]-[6], and the research is still very active. In [3] anomalies are detected by analyzing the variations of the clock stability with time, represented by the dynamic Allan variance [7], [8].

In this article we propose a detection algorithm based on the Kalman filter. The Kalman filter [9] estimates the state by a two-step procedure: first, the current state is predicted, based on the previous estimate; then, when the new measurement is available, the prediction and the measurement are properly averaged by taking into account their variance. Therefore, the Kalman filter can be seen as a weighted average of the prediction (based on the knowledge of the dynamical evolution of the system) and of the new measurement. We now note that the prediction should be close, on the average, to the new measurement. A large deviation of the difference between the new measurement and the prediction, known as innovation, can hence be used as an anomaly detector. This idea is the key point of our method and, even though this use of the innovation is already known [10], to the best of our knowledge it has never been applied to atomic clocks.

First, the paper describes the clock model and the proposed implementation of the Kalman filter. Then, the evaluation of the innovation as a test on possible anomalies is introduced. Finally, the detector is characterized for the case of a space Rubidium Atomic Frequency Standard, and the probability of false alarm, the probability of detection, as well as the latency time are estimated by numerical simulations.

II. Kalman Filter Detector

We first define the model of the clock noise and then we describe the Kalman filter detector.

A. The clock noise model

We assume that the frequency deviation $y(t)$ is made by the sum of a white frequency noise (WFN) $\xi_{WFN}(t)$, of a random walk frequency noise (RWFN) $W_{RWFN}(t)$, and of a slowly varying deterministic drift $d(t)$

$$y(t) = \xi_{WFN}(t) + W_{RWFN}(t) + d(t) \tag{1}$$

The autocorrelation function of $\xi_{WFN}(t)$ is given by

$$R_{WFN}(t_1, t_2) = E\left[y(t_1)y(t_2)\right] = \sigma_1^2 \delta(t_1 - t_2) \tag{2}$$

where E is the expected value and $\delta(t)$ is the Dirac delta function. The RWFN noise component is a Wiener process defined as

$$W_{RWFN}(t) = \int_0^t \xi_{RWFN}(t')dt' \tag{3}$$

where

$$R_{RWFN}(t_1, t_2) = \sigma_2^2 \delta(t_1 - t_2) \tag{4}$$

In discrete-time, we model RWFN and the drift as [11], [12]

$$\mathbf{x}[n] = \mathbf{\Phi}\mathbf{x}[n-1] + \eta[n-1] + d[n] \tag{5}$$

where $n = t/T_s$ is the (dimensionless) discrete time, T_s is the sampling time, $\mathbf{x}[n]$ is the two-component vector

$$\mathbf{x}[n] = \begin{bmatrix} x_1[n] \\ x_2[n] \end{bmatrix}, \tag{6}$$

$\mathbf{\Phi}$ is the transition matrix given by

$$\Phi = \begin{bmatrix} 1 & T_s \\ 0 & 1 \end{bmatrix}, \tag{7}$$

978-1-61284-110-6/11/$26.00 ©2011 IEEE

$\eta[n-1]$ is a two-component vector of Gaussian random variables with zero mean and covariance

$$Q = \begin{bmatrix} \sigma_2^2 & 0 \\ 0 & 0 \end{bmatrix}, \tag{8}$$

and $d[n] = d(nT_s)$ is the deterministic drift. We take the initial conditions

$$\mathbf{x}[n] = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{9}$$

We now add WFN by making believe that it is an additive measurement noise $v[n]$, obtaining

$$z[n] = H\mathbf{x}[n] + v[n] \tag{10}$$

where

$$H = \begin{bmatrix} 1 & 0 \end{bmatrix} \tag{11}$$

is the measurement matrix, $v[n]$ is a Gaussian random variable with zero mean and variance $R = \sigma_1^2$. Therefore, $z[n]$ represents the discrete-time average frequency deviation corresponding to the frequency deviation $y(t)$ of Eq. (1), and it is given by

$$z[n] = \frac{1}{T_s} \int_{(n-1)T_s}^{nT_s} y(t')dt' \tag{12}$$

B. Kalman filter detector

The system model equation of the Kalman filter detector is given by

$$\mathbf{x}[\mathbf{n}] = \mathbf{\Phi}\mathbf{x}[n-1] + \bar{\eta}[n-1] \tag{13}$$

where $\bar{\eta}[n-1]$ is a two-component vector of Gaussian random variables with zero mean and covariance matrix

$$\bar{Q} = \begin{bmatrix} \bar{\sigma}_2^2 & 0 \\ 0 & 0 \end{bmatrix} \tag{14}$$

We take $\bar{\sigma}_2$ to be larger than σ_2 to accelerate the transient phase that arises when a frequency jump occurs. The measurement equation of the Kalman filter is identical to Eq. (10).

At time n, we first obtain the extrapolated version of the previous estimate as

$$\hat{\mathbf{x}}[n|n-1] = \mathbf{\Phi}\hat{\mathbf{x}}[n-1|n-1] \tag{15}$$

Then, we build the innovation

$$\nu[n] = z[n] - H\hat{\mathbf{x}}[n|n-1] \tag{16}$$

whose variance is given by

$$\sigma_\nu[n] = HP[n|n-1]H^T + R \tag{17}$$

where $P[n|n-1]$ is the extrapolated error covariance matrix. Finally, we detect an anomaly when

$$|\nu[n]| > k\sigma_\nu[n] \tag{18}$$

where k is a parameter which influences the performance of the detector.

III. EXAMPLE

In Fig. 1 we show the simulated average frequency deviation (blue line) of a Rubidium clock experiencing a frequency jump, and the estimate $\hat{x}_1[n]$ generated by the Kalman filter (black line). The red vertical bars are located at the time instants corresponding to a detection. We see that the detector quickly reveals the frequency jump. After the frequency jump, the estimate $\hat{x}_1[n]$ experiences a transient phase and then adapts to the time-varying drift. The Rubidium clock is simulated by using the following values of the parameters

$$\sigma_1 = 5 \times 10^{-12} \tag{19}$$
$$\sigma_2 = 5.2 \times 10^{-16} \tag{20}$$
$$d = 1 \times 10^{-12}/\text{day} \tag{21}$$
$$T_s = 1\text{s} \tag{22}$$

The detection threshold is obtained by using $k = 5$.

Performance analysis. We describe a preliminary statistical characterization of the detector obtained by Monte Carlo simulations. When $k = 5$, the probability of false alarm (PFA) estimated on 10^8 realizations is given by

$$PFA = 5 \times 10^{-7} \tag{23}$$

The probability of detection (PD) estimated on 10^4 realizations of the frequency jump with size

$$\Delta_f = 2.5 \times 10^{-11} \tag{24}$$

is given by

$$PD = 0.967, \tag{25}$$

and the corresponding latency time is

$$\Delta n = 1.31 \text{ s} \tag{26}$$

Smaller jumps can be detected by increasing the latency time. This problem is currently under study.

IV. CONCLUSIONS

An anomaly detector based on the evaluation of the innovation, which is a quantity embedded in the Kalman filter, is presented and applied to atomic clocks. The developed detector seems to have several advantages. First, it is fast, in that it can detect anomalies with a very short latency time. Second, due to the recursive nature of the Kalman filter, the algorithm has low computational cost and requires the storage of a small and fixed amount of data. Therefore, being fast and light, the detector can be used in real time applications and onboard satellites, where low computational power is available.

We are currently working on several improvements to our method, such as the detection of slow frequency jumps.

***Abstract*— We report the characterization of Coherent Population Trapping (CPT) resonances in Cs vapor microcells filled with Neon (Ne) buffer gas. The impact on the atomic hyperfine resonance of some external parameters such as laser intensity and cell temperature is studied. We show the suppression of the first-order light shift by proper choice of the microwave power. The temperature dependence of the Cs ground state hyperfine resonance frequency is shown to be canceled in the 77-80°C range for various Ne buffer gas pressures. We preliminary demonstrate a 852 nm VCSEL-modulated based CPT atomic clock exhibiting a short term fractional frequency instability $\sigma_y(\tau) = 1.5 \times 10^{-10}\ \tau^{-1/2}$ until 200 s.**

I. Introduction

Coherent Population Trapping physics [1] combined with the progress of micro-fabrication techniques and semiconductor laser technologies allows the realization of highly miniaturized battery-powered chip scale atomic clocks (CSAC). These references can be used in a wide-range of electronics-based systems such as global positioning, synchronization of telecommunication networks or military applications. The first microfabricated CPT clock was demonstrated at NIST in 2004 [2] while such sources now become commercially available [3]. Nevertheless, leading research remain to be done in this field to further improve the performances of these clocks in terms of frequency stability, power consumption or size or to propose simpler and original architectures.

A CSAC is based on the combination of a high-frequency modulated Vertical-Cavity Surface Emitted Light (VCSEL) laser, micro-optics to shape and circularly polarize the laser beam, a mm-scale alkali (Cs or Rb) vapor cell in which CPT interaction takes place, a photodiode to detect transmitted light through the cell and packaged electronics including a local oscillator (LO) and various low-frequency servo loop electronics to stabilize experimental parameters. The microcell is currently filled with a buffer gas or mixture of buffer gases in order to operate in the Dicke regime [4]. A buffer gas mixture is often prefered to cancel the temperature-dependent collisional shift [5], [6] at a pre-determined inversion temperature [7]. However, the partial and total buffer gas pressure is very difficult to control in microfabricated cells because of high temperatures required to operate the anodic bonding process. In the frame of the challenging european MAC-TFC project, this paper reports a detailed characterization of CPT resonances measured in Cs-Ne microcells. These novel-technology cells are fabricated by following the technology process described in [8], [9], [10]. We recently reported the observation of a quadratic temperature dependence of the Cs 0-0 ground state hyperfine resonance frequency in such cells [11], [12]. The inversion temperature, expected to be independent of the buffer gas pressure, has been measured to be in the 77-80°C range. This paper aims to further prove the potential of our cells for microclocks applications.

Section II describes the experimental set-up. Section III is devoted to present the characterization of CPT resonances obtained in our Cs-Ne microcells. Section IV presents the dependence on laser intensity and cell temperature of the CPT resonance frequency. The last section V shows preliminary frequency stability measurements of a Cs-Ne microcell-based CPT clock.

II. EXPERIMENTAL SET-UP

Figure 1(a) describes the experimental set-up of the Cs CPT clock.

The Cs-Ne vapor cell is 2-mm in diameter and 1.4 mm-long. The microcell is filled with a Ne buffer gas pressure using an original two-step anodic bonding procedure recently described in [10]. The microcell temperature is stabilized to within 1 mK. A static magnetic field is applied around the cell in order to split the Zeeman components and isolate the $|F=3, mF=0\rangle \rightarrow |F=4, mF=0\rangle$ hyperfine clock transition. The ensemble is inserted into a cylindrical mu-metal magnetic shield in order to reduce spurious environmental magnetic fields.

The laser source is a VCSEL resonant with the Cs D2 line at 852 nm. The VCSEL injection current is directly modulated at 4.596 GHz (half of the Cs clock frequency) to produce two phase-coherent sidebands with a frequency splitting of 9.192 GHz. The 4.596 GHz signal is generated using a commercial microwave synthesizer driven by a 10 MHz quartz crystal local oscillator.

The linearly polarized output beam from the laser is collimated using a cylindrical lens in a 1-mm diameter beam and converted into circular polarization using a quarter-wave plate

978-1-61284-110-6/11/$26.00 ©2011 IEEE

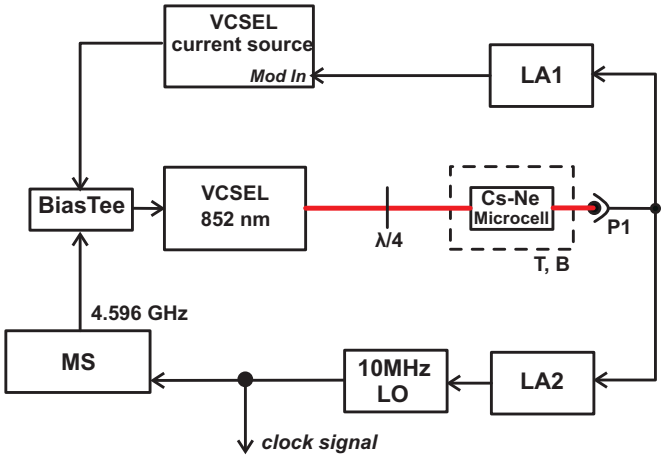

Fig. 1. *Experimental SetUp. Cs atoms with Ne buffer gas in the mm-scale cell interact with the microwave-modulated light from a VCSEL. The optical power transmitted through the cell is detected by the photodiode P1. The lockin amplifier LA1 is used to lock the VCSEL to the Cs optical resonance. The lockin amplifier LA2 is used to lock a quartz local oscillator (LO) driving a microwave synthesizer (MS) that generates the 4.596 GHz signal.*

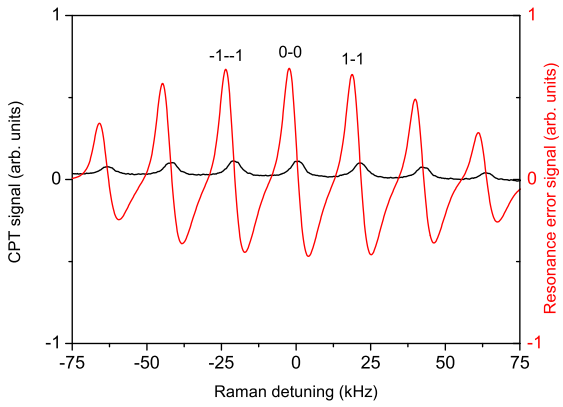

Fig. 2. *Zeeman spectrum obtained in a Cs-Ne microcell (dark line) and the corresponding error signal (red line) at the output of the lockin amplifier LA2. A longitudinal magnetic field of 2.9 μT flux density is applied.*

inserted in front of the cell. A neutral-density filter is used to adjust the laser intensity. The optical power transmitted through the Cs-Ne microcell is detected by a low noise Si photodiode (P1).

With the microwave modulation applied, the VCSEL frequency is locked on the position of maximum optical absorption by modulating the laser DC current at 65 kHz and demodulating the absorption signal on the photodiode with the lockin amplifier LA1. An error signal is then fed back to the VCSEL current driver to correct the laser injection current. The CPT resonance is detected by scanning the 4.596 GHz microwave signal frequency. The signal-to-noise (SNR) ratio of the resonance is increased by utilizing a similar frequency modulation-demodulation spectroscopy technique at 1-3 kHz with the lockin amplifier LA2. A voltage error signal can then be sent to the electric tuning port of the local quartz oscillator to lock the microwave synthesized signal on the atomic transition frequency.

III. CHARACTERIZATION OF CPT RESONANCES IN CS-NE MICROCELLS

In this section, we report the characterization of CPT resonances obtained in Cs-Ne microcells with various buffer gas pressures as a function of several experimental parameters such as the laser intensity I, the cell temperature T and the microwave power P_μ injected in the VCSEL.

Figure 2 shows a typical experimental Zeeman spectrum obtained in a Cs-Ne microcell as well as the corresponding error signal obtained at the direct output of the lockin amplifier LA2.

The 0-0 CPT resonance linewidth and height are extracted by fitting the CPT resonance error signal with the FM lineshape of a Lorentzian function [13]. The resonance contrast C is considered here as the ratio between the height of the resonance error signal and the background DC voltage at the direct output of the photodiode. The clock frequency stability can be measured by comparing the 10 MHz quartz local oscillator with a signal coming from a reference hydrogen maser. Frequency shifts measurements are performed by calculating the offset between the measured 0-0 resonance frequency and the unperturbed Cs atom frequency (9.192 631 770 GHz).

Cs-Ne microcells with different buffer gas pressures are tested. Cells 1, 2, 3 and 4 are filled with a Ne buffer pressure of 8.1, 6.7, 6.7 and 4.4 kPa respectively. All of them have the same dimensions. The static magnetic field B is 16 μT for all the following experiments.

A. Laser Intensity

Figure 3 shows the linewidth of the CPT resonance versus the total laser intensity for two different Cs-Ne microcells (cell 1 and cell 2).

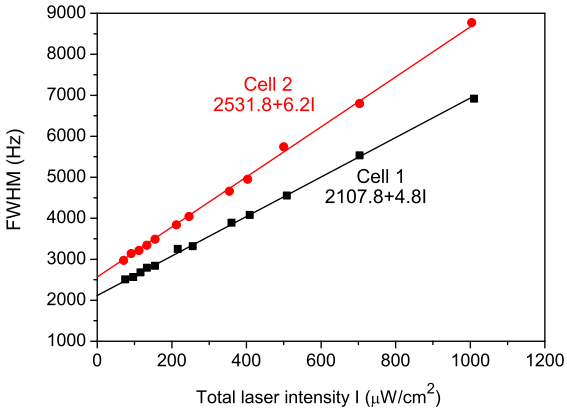

Fig. 3. *Linewidth of the dark resonance signal as a function of the total laser intensity for two Cs-Ne microcells with different Ne pressure (squares: cell 1, circles: cell 2). Solid lines are linear fit. Experimental parameters are: T=62.1°C, P_μ= 2.5 dBm.*

The CPT linewidth linearly increases with laser intensity

due to power broadening. The slope of the increase is lower for the cell with higher buffer gas pressure because of the increase of the optical linewidth $\Gamma^{\star}$. The zero-intensity linewidth is measured to be lower for the cell with higher buffer gas pressure. In this experimental set-up, the linewidth is limited by time-of-flight broadening because the laser beam is only 1-mm diameter [12]. The zero-intensity linewidth is expected to decrease with higher buffer gas pressures until the contribution of Cs-Ne collisions dominates. This only happens around 100 kPa in millimeter-scale cells.

We report in Fig. 4 the evolution of the ratio between the CPT resonance linewidth and contrast as a function of the total laser intensity for both cells 1 and 2.

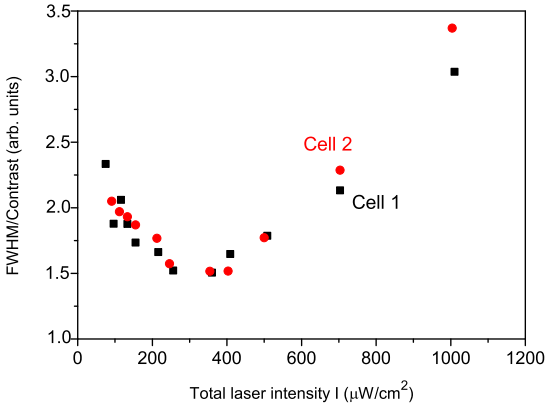

Fig. 4. *Ratio FWHM/contrast of the dark resonance as a function of the total laser intensity for two Cs-Ne microcells with different Ne pressure (squares: cell 1, circles: cell 2). Experimental parameters are: T=62.1°C, P_{μ}= 2.5 dBm.*

The ratio FWHM/contrast is minimized for both cells for intensities around 300-350 μW/cm^2. We observed that the noise on the detector increases strongly with increasing laser power W_i. This is due to the increase of the shot noise associated to the background signal, the increase of the laser AM noise that presents a $1/f$ slope at the modulation frequency but also due to the increase of the laser FM noise through a FM-AM conversion process in the vapor cell. In [14], it is claimed that the FM laser noise is the main limit to the short term frequency stability of a CSAC.

B. Cell Temperature

Fig. 5 shows the height of the dark resonance error signal versus the cell temperature for cells 1, 2 and 4.

For the three cells, we obtain a bell-shaped curve where the CPT resonance height is maximized in the 55-60°C range. A similar behavior has already been observed in cm-scale cells [15], [17], [16]. We see that the use of a higher buffer gas pressure gets the bell-shaped curve broader, reduces the CPT line height and shifts the temperature where the dark resonance height is maximum to higher temperatures. The signal is degraded by a factor 4-5 at 80°C compared to 60°C.

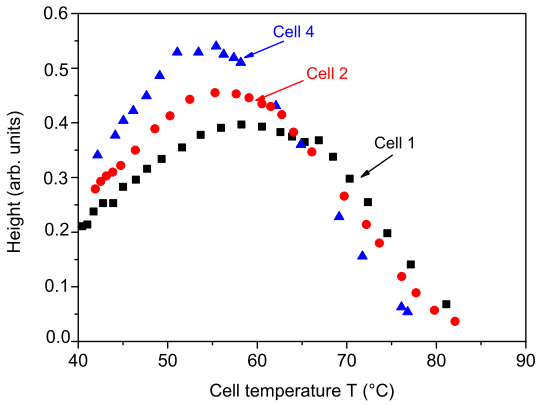

Fig. 5. *Height of the dark resonance error signal as a function of the vapor microcell temperature for three Cs-Ne microcells with different Ne pressure (squares: cell 1, circles: cell 2, triangles: cell 4). Experimental parameters are: I= 500 μW/cm^2, P_{μ}=2.5 dBm.*

It means that the clock short term frequency stability should be optimized at 60°C and degraded at 80°C.
The CPT linewidth is measured to decrease with higher buffer gas pressure and to slightly decrease with the cell temperature until about 80°C where the linewidth seems to rise poorly again.
We measured that the ratio FWHM/contrast is reduced when the buffer gas pressure is increased and is optimized in a temperature range between 58 and 66 °C for the three cells. The optimum temperature point increases when the buffer gas pressure is increased. Due to the reduction of the CPT signal height, this ratio is degraded around 78°C by a factor decreasing with higher buffer gas pressure. Note that no significant variation of the detected noise on the CPT resonance at the modulation frequency has been measured by changing the cell temperature.

IV. FREQUENCY SHIFTS

A. Light Shift

Light shift is known as a major limitation in the frequency stability of vapor cell frequency standards. We realized measurements of light shift in our Cs-Ne microcells. Figure 6 plots the frequency shift of the 0-0 resonance from the unperturbed Cs frequency as a function of the total laser intensity for three different microwave powers P_{μ} with the cell 2.

We show the possibility to cancel the first-order light shift by proper choice of the microwave power. For P_{μ} = 3.5 dBm, the light shift slope is measured to be only − 0.08 Hz/(μW/cm^2). In both other cases (2.5 dBm and 4 dBm), the slope is increased by a factor 6.1 but with opposite signs. Also, note that a slight frequency difference of 4.2 Hz between fitted curves extrapolated at zero-intensity is obtained validating our experimental measurements.

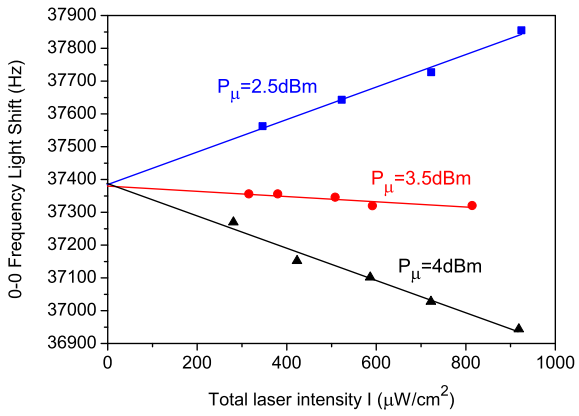

Fig. 6. *Light shift of the CPT resonance in the cell 2 for three different microwave power P_μ: 2.5 dBm (squares), 3.5 dBm (circles) and 4 dBm (triangles). Experimental parameters are: T=62°C. The solid lines are linear data fits.*

B. Collisional Frequency Shift

The 0-0 resonance frequency is measured for different temperatures for two Cs-Ne buffer gas microcells (cells 1 and 3) on Fig. 7. The measured frequencies are corrected for the Zeeman quadratic shift and for the light shift. The points are the experimental data. Data are fitted by a second order polynomial function.

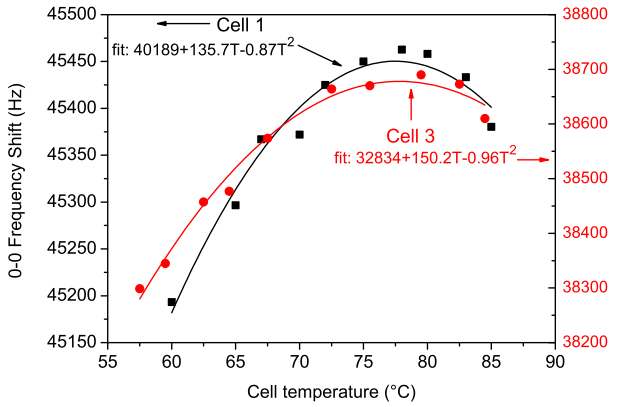

Fig. 7. *Frequency shift of the CPT resonance in cell 1 (squares) and cell 3 (circles) as a function of the cell temperature. The solid lines are data fits.*

The temperature dependence of the clock frequency is found to be cancelled for both cells around an inversion temperature of 78°C. These results agree well with those presented in [11] and confirm that the inversion temperature does not depend on the Ne buffer gas pressure. The fit of experimental points, with the gas pressure as fitting parameter and using coefficients given in [6], gives a Ne pressure of 8.1 kPa and 6.7 kPa for the cell 1 and cell 3 respectively at a temperature of 0°C. For the cell 1, the curvature is measured to be 1.7×10^{-10} K^{-2}. Assuming that the temperature control system allows to set the cell temperature T_c at $T_{inv} \pm 100$ mK with rms temperatures fluctuations dT =10mK around T_c, the clock frequency stability limit due to temperature variations is expected to be about 1.7×10^{-13}. These results are of great importance in view of the development of high long-term frequency stability miniature Cs atomic clocks with a unique Ne buffer gas cell. In this case, no suitable and well-controlled buffer gas mixture is required.

V. FREQUENCY STABILITY MEASUREMENTS

Fig. 8 shows preliminary measurements of the clock short term fractional frequency stability. For this purpose, the frequency stability of the 10 MHz output signal of the quartz local oscillator is measured using a digital 5120A Allan deviation test set [18] referenced by a hydrogen maser and plotted in Fig. 8.

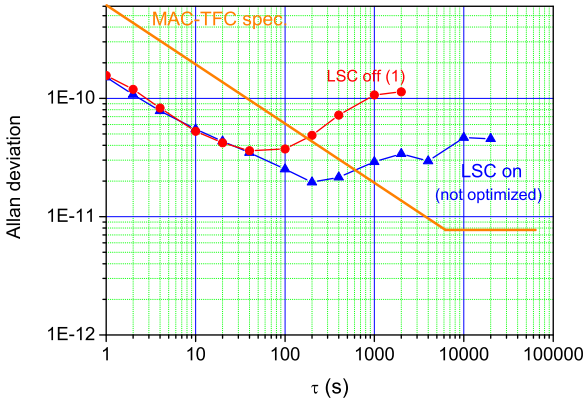

Fig. 8. *Allan standard deviation of the D_2 line VCSEL-based CPT clock using a Cs-Ne microcell. Experimental parameters are: T=60°C, P_μ=2.5 dBm. A measurement with or without light shift correction is shown.*

In a first measurement, the short-term frequency stability is given to be 1.5×10^{-10} $\tau^{-1/2}$ for averaging times between 1 and 30 s [12]. For short integration times, this result is comparable to those previously published [2] for miniature clocks using a VCSEL resonant with the Cs D_2 line and a mm-scale cell. The short-term frequency stability is expected to be significantly improved by the use of a laser resonant with the Cs D1 line [19] and was measured to be degraded by a factor 4 at 80°C. For integration times longer than 30 s, we observe a frequency random walk mainly attributed to huge temperature variations in the laboratory as well as laser intensity fluctuations.

Later, we started to investigate the possibility to implement a light shift correction (LSC) to improve the long-term frequency stability performances. Several advanced techniques, described in [20], [21], [22], were tested and allowed us to detect a zero-light shift point. In a first solution inspired from [20], the microwave power amplitude is modulated. This AM modulation is detected on the LA2 lockin amplifier output and can be minimized by adjusting the 4.596 GHz signal power.

The RF power for which the AM modulation vanishes is the zero-light shift point. This AM modulation can then be demodulated with a third lockin amplifier to generate a dispersive error signal crossing zero when the light shift is minimized and actively stabilize this point with an additional PI controller. We observed that this optimum point coincides well with the microwave power for which the CPT signal is maximized, i.e the point where the optical power contained in both first-order optical sidebands is maximum. In a second solution inspired from [22], the same lockin amplifier (LA2) is simultaneously used to lock the LO frequency to the clock transition and reduce the light shift. Indeed, it was observed that in presence of light shift, there are different zero-crossing frequencies for the in-phase and out-of-phase quadrature channels of the lock-in amplifier. When the in-phase channel is used to lock the local oscillator, the quadrature channel is proportional to the light shift near a zero-shift frequency. Note that both methods gave about the same optimum zero-light shift point. Figure 8 shows the improved frequency stability with LSC technique inspired from [20]. Despite the lack of optimization of the PI servo loop, the clock frequency stability is found to be 3×10^{-11} at 1000s and better than 5×10^{-11} at 20.000s. Further optimization remains to be done. Note also that the clock frequency should be better stabilized around 78°C where the temperature dependence of the clock frequency is greatly reduced.

VI. Conclusion

Cs-Ne microcells can be used for high performance miniature atomic clocks. For optimized clock frequency stability performances on the short term term, the clock should operate preferably with a VCSEL resonant on the Cs D1 line. For long term operation, the cell should operate at a temperature around 78°C to reduce greatly the Cs clock frequency temperature dependence. Moreover, advanced noise reduction techniques should be implemented to reduce frequency variations due to light shift effects. We preliminary investigated in this article a solution consisting in stabilizing the microwave power at a point where the light shift is cancelled.

***Abstract*— We report on progress in the development of an All-Optical Integrated Micro-Primary Atomic Clock (AO-IMPAC). The operattion of the clock is based on an inhomogeneously broadened rubidium optical transition used for stabilization of a Kerr optical frequency comb generated in a high-Q whispering gallery mode (WGM) microresonator. We have demonstrated the initial operation of this clock built in a physics package with dimensions $5 \times 6 \times 1.2$ cm. The clock's long term stability approaches 3×10^{-13} at about 2×10^4 s integration time. The measured value is limited by the noise floor of the measurement setup.**

I. Introduction

We introduced the concept and a preliminary design of an All-Optical Integrated Micro-Primary Atomic Clock (AO-IMPAC) at IFCS'2010 [1]. In this paper we report on progress towards implementing the design and evaluating the first demonstration of the clock operation. We have realized a bread-board model of this clock that is based on an optical frequency comb generated in a high-Q whispering gallery mode (WGM) microresonator, stabilized to an inhomogeneously broadened rubidium optical transition. The clock utilizes a low power single-mode DFB diode laser, self-injection locked to a mode of the microresonator. The optical frequency comb is generated in the resonator as a result of Kerr effect and four wave mixing process. The comb mode spacing effectively determines the RF output signal. Since the center frequency of a comb line and the comb's mode spacing both are determined by the refractive index and geometry of the microresonator, stabilizing the center frequency of a comb line stabilizes the clock frequency. In other words, locking a single frequency point of the comb is enough to stabilize the frequency spacing of the comb.

We have demonstrated the initial operation of this clock built in a $5\times6\times1.2$ cm physics package. The clock's long term stability approaches 3×10^{-13} at about 2×10^4 s integration time. The measured value is limited by the noise floor of the measurement setup locked to a commercial Rb clock. The maximum spectral width of the observed frequency comb was 4 nm, and the 24 GHz repetition frequency was generated with the vertical (not the basic) mode family of the WGM microresonator.

The comb was stabilized by locking it to the inhomogeneously broadened D1 line of Rb^{87} by means of a semiconductor laser. The lock quality and the frequency drift of the rubidium transition ultimately determine the performance of the system. The stability goal for this clock is to keep the time loss at the level of 32 ns over a period of one month. To achieve this timekeeping performance, the clock's random-walk frequency noise coefficient must be below 10^{-17} $s^{-1/2}$, and it must have a frequency aging rate below 10^{-15}/day. We found that a Doppler-broadening-induced shift mechanism is the most important parameter for stability, since it can lead to a temperature sensitivity of $4\times10^{-11}/^o$C, if the laser is locked to the peak of the absorption line. To reduce the temperature sensitivity by two orders of magnitude, we locked the laser to the so called isoclinic point of the D_1 line.

II. Operation principle and scheme of the clocks

Schematic of the clock setup is shown in Fig. (1). The goal of the set up is to stabilize the temperature of the resonator. Since the frequency drift of the hyper-parametric oscillation is primarily caused by temperature drift in the system, removing the temperature drift results in long term stabilization of the hyper-parametric oscillator.

Stabilization of the resonator temperature is realized via locking the frequency of a selected WGM to a Rb^{87} optical transition. We use the fact that the ratio of frequency of a high order optical mode and the free spectral range (FSR) of a monolithic WGM resonator does not depend on the resonator temperature or any resonator strain, to first approximation. The long term drift of the optical frequency is correlated with the drift of the FSR. Therefore, by stabilizing the optical frequency the FSR is also fixed.

The linewidth of the free running semiconductor distributed feedback (DFB) laser used in the experiment is on the order of a few megahertz. The bandwidth of the WGM is less than a hundred kHz. To pump the optical mode efficiently, we use the self-injection locking mechanism to lock the laser to the WGM, resulting is more than a thousand fold reduction of the laser linewidth. As a result, more than 30% of the power emitted by the laser is coupled to the mode.

It was shown that the frequency of hyper-parametric oscillation is determined by the FSR only, and does not depend on the parameters of the pumping laser light, if the optical absorption and corresponding heating of the resonator annulus is neglected. Thus drift of the laser frequency and the laser intensity noise do not influence the performance of the oscillator based on an ideal resonator. In a real system the light absorbed in the mode shifts the optical frequency and

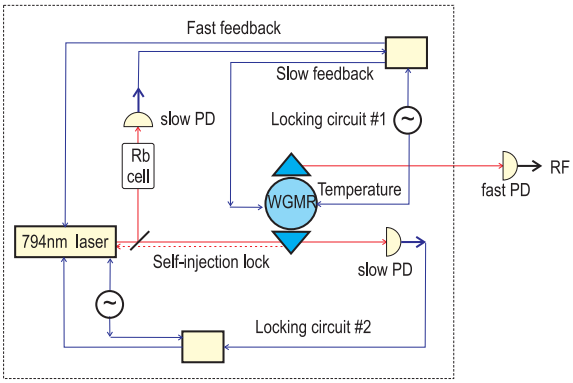

Fig. 1. Schematic of the demonstrated clock. A 794 nm semiconductor DFB laser is self injection-locked to a WGM. A slow PDH lock is used to keep the laser frequency at resonance with the WGM . The locked laser operates as an external cavity semiconductor laser, and can be tuned by tuning the frequency of the resonator. The laser/resonator combination is PDH locked to the ^{87}Rb D1 line. The locking scheme uses modulation of the frequency of the laser via temperature modulation of the WGM resonator, and the error signal is fed back to correct the temperature of the resonator. Since changing the laser current also changes the temperature of the resonator and the oscillation frequency, an additional lock loop is used for the laser.

the FSR frequency. Self-injection locking technique used to reduce the laser linewidth does not fix the value of detuning of the laser and the WGM. Thermal drift and drift of the current feeding the DFB laser result in drift of the detuning, and a corresponding drift of the WGM temperature due to change of the absorption of light in the resonator. Thus, we use a slow PDH-like locking circuit (locking circuit #2 in Fig. 1) to keep the laser frequency tuned to the specific position of the selected WGM.

Once the frequency of the laser follows the specific point of the WGM resonance, we lock the resonator to the atomic transition via the laser (locking circuit #1 in Fig. 1). This is accomplished by modulating the frequency of the optical mode thermally. The temperature modulation results in pure frequency modulation of the light emitted by the laser. The error signal is obtained by sending the modulated light through the atomic cell. The signal is subsequently processed and fed back to the resonator temperature. The modulation of the temperature is not the optimal solution since it also results in the modulation of the clock signal. Insertion of a power efficient phase modulator in front of the atomic cell, instead of modulation of the resonator temperature, would improve performance of the clocks.

The long term stability of the clock is determined by the thermal stability of the atomic transition. Any drift in the rubidium vapor temperature influences the stability of the D1 line in the Doppler-broadened optical absorption spectra, and compromises its frequency stability. We found that there exists a specific thermally insensitive point of the atomic resonance located in the vicinity of the local absorption minimum midway between the $5^2S_{1/2}(F_g = 2) \rightarrow 5^2P_{1/2}(F_e = 1, 2)$ absorption lines of ^{87}Rb vapor [2]. We verified experimentally that the relative frequency stability of the isoclinic point is better than -2×10^{-12} ^{o}K^{-1} while the stability of the point of the maximal absorption is on the order of 4×10^{-11} ^{o}K^{-1}. Therefore, the measured isoclinic point's temperature coefficient was an order of magnitude lower than the resonant transition. The thermal shift of the isoclinic point is probably even smaller since we could not find a difference between the isoclinic points temperature shift and zero at the 95% confidence level. Therefore, by keeping the averaged temperature of the cell stable with 10 mK accuracy the relative frequency drift of the system will be less than 2×10^{-14}.

III. Validation of Self-Injection Locking of a Laser with WGM Resonator

We performed an experiment in which we pumped a crystalline CaF_2 WGM resonator with 794 nm light emitted by a semiconductor laser that was self-injection locked [3] to a selected WGM. The light was sent in and retrieved out of the resonator using a glass coupling prism. The exiting light was collimated and injected into a single mode optical fiber to be further analyzed. The resonator was fabricated out of a z-cut CaF_2 wafer by mechanical polishing. The loaded quality (Q-) factor of the resonator exceeded 3×10^9.

We locked the semiconductor DFB laser to a WGM mode having a frequency in the vicinity of the isoclinic point of the D1 line of ^{87}Rb (Fig. 2). The self-injection locked range is a constant absorption level in the middle of the Rb absorption doublet. The absorption does not change since the frequency of the laser is constant and equal to the WGM frequency, while the current driving the laser changes (locking area). At the same time, the power of the light emitted by the laser decreases within the locking area since some amount of the light scatters back to the laser.

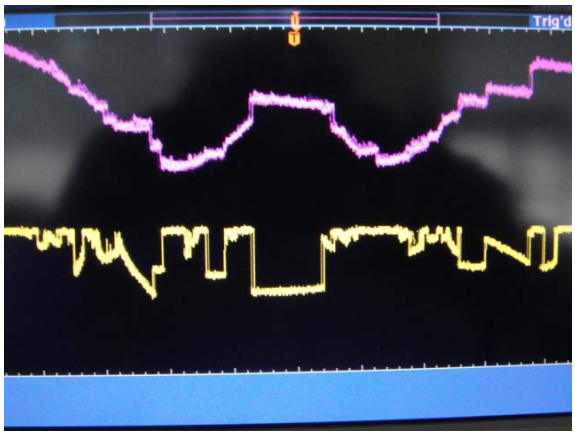

Fig. 2. Spectrum of the D1 transition of the rubidium (top) and the LI curve (optical output power (L) as a function of current that drives the laser (I)) of the DFB laser self-injection locked to the WGM resonator (bottom). The curves are shown on the oscilloscope screen.

IV. Demonstration of Stabilization of the Laser

Initially we demonstrated that the laser itself can be stabilized using the resonator. We then reduced the power of the laser such that the resonator operated in the linear regime, activated all the locking loops, and measured the frequency of

the laser during several hours. To lock the laser to the atomic transition, the laser frequency was modulated at the frequency of 0.23 Hz and a magnitude of about 100 MHz. Then the PDH-type lock scheme was implemented by feeding the signal from a lock-in amplifier back to the resonator temperature. To measure the stability of the laser we used another Rb cell as a frequency discriminator.

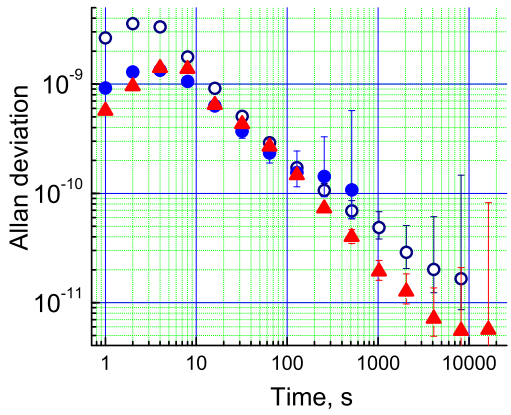

Fig. 3. Allan deviation of the frequency of the DFB laser locked to a WGM resonator and the rubidium cell. Several realizations are shown. All the realizations show averaging proportional to the integration time. Even though further averaging was expected we were unable to continue the measurements since the sensitivity floor of the measurement technique was reached.

V. Hyper-parametric oscillations at 794 nm

A nonlinear frequency conversion within the WGM resonator was used to make the system fully operate as a clock. Four-wave mixing (FWM) [4] and hyperparametric oscillation [5], [6] have been studied with WGM resonators with the generation of recently observed optical frequency (Kerr) combs [7]. Kerr combs have rapidly become the subject of extensive research as simpler alternatives to conventional combs produced with femtosecond mode-lock lasers. [7]-[14]. They have excellent uniformity as well as high repetition rate, which makes them ideal for many practical applications. We used such a comb for the implementation of the clock.

To generate the clock signal the power of the light pumping the resonator was increased so the optical frequency Kerr comb could be generated. The onset of hyperparametric oscillation was observed at 0.1 mW of optical power. Increasing the power to 0.3 mW resulted in the formation of a well pronounced optical frequency comb shown in Fig. (4). The optical spectrum of the comb demonstrates a clear asymmetry [15]. Depending on the position of the collimator collecting the light exiting the resonator, either higher or lower frequency components of the comb are nearly hidden in the noise. By changing the wavelength of the laser and locking it to different transverse modes of the resonator, we obtained the spectra shown in Fig. (4a and 4b). In some cases, the first optical sideband on the comb had higher power than the pump light exiting the resonator.

The observed optical comb spectra had several common features: i) they were asymmetric with respect to the pump frequency, i) the repetition frequency did not correspond to a multiple of the FSR of the resonator, contrary to earlier observations [8], [12]; ii) the envelope of the comb spectrum had unusually sharp edges. These features are novel, yet the comb lines are clearly self-phase locked since they produce a spectrally pure RF signal on a fast photodiode (Figs. 5 and 6), as in previously observed Kerr optical frequency combs [8].

A. Kerr comb on vertical modes

There are two nonlinear processes that result in the generation of a phase locked frequency comb in a WGM resonator possessing $\chi^{(3)}$ nonlinearity: hyper-parametric oscillation (modulational instability [16], [17], [18]) and FWM. The oscillation process involves two pump photons and two sideband photons and starts when the power of a continuous wave laser exciting the mode exceeds some threshold value [19], so that sidebands symmetrical in frequency are generated. Increasing the pump power results in the generation of multiple sidebands, phase locked due to the FWM process. The initial generation of sidebands widely separated by multiple FSR's could have a lower threshold compared with that of closely separated sidebands [8], [14], depending on the dispersion of the WGM spectrum.

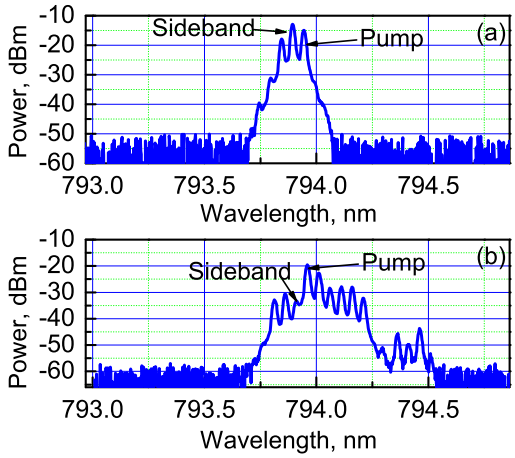

Fig. 4. Kerr optical frequency combs generated in the WGM resonator: (a) the power of the first generated sideband of the comb exceeds the power of the pump signal leaving the resonator; (b) the power of the same sideband is suppressed. To generate spectra (a) and (b) we pumped different WGMs of the same resonator. The spectra also are influenced by the position of the collimator collecting the light. No stimulated Raman scattering is observed. The resonator has 8 GHz free spectral range, while the optical frequency comb has 23.78 GHz repetition rate. The comb harmonics are self-phase locked, so they generate a coherent RF signals on a fast photodiode.

We found that i) the geometrical shape of the WGM resonator determines the frequency envelope as well as the repetition rate of the Kerr comb; ii) the observed components of the comb belong to different WGM families, i.e. have different spatial distribution; iii) the asymmetry of the spectrum

results from the significant spatial spread of the light emitted from the resonator and selectively coupled into the fiber. This novel type of Kerr comb could have, a higher repetition rate as compared with the FSR of the basic WGM sequence, as observed, and also a significantly lower repetition rate. The reason for such a flexibility is in the ability to modify the dispersion of the resonator with respect to the optical modes involved in the comb generation.

While it is generally believed that a Kerr comb is generated in the basic WGM family and has a relatively symmetric envelope, this is not the only option. A spheroidal resonator which has two nearly equidistant mode sequences characterized with FSR_l and $FSR_p = FSR_l(a-b)/b$, where b is the other semiaxis of the spheroid [20], may produce different results. Here, FSR_p can significantly differ from FSR_l depending on the ratio a/b. In our case $a/b \approx 4$, so that $FSR_p \approx 3FSR_l$, which is close to experimentally measured value $FSR_p/FSR_l = 23.78\ GHz/8\ GHz = 2.96$, where 23.78 GHz is the repetition frequency of the comb we observed. Therefore we conclude that the frequency components of the Kerr comb reported here are not generated in the same family of fundamental modes with different orbital momentum. Rather, the components belong to the family of modes with different vertical quantum number p and the same orbital momentum l.

B. The RF spectrum

We verified the spectral purity of the optical frequency comb and measured the repetition frequency using the RF signal produced by demodulation of the comb on a fast photodiode. The resolution of our optical spectrum analyzer did not exceed 8 GHz at 794 nm, so the optical spectrum was not suitable for measuremen. We increased the optical pump power, collected 2.5 mW of light leaving the resonator into a single mode fiber connected to a fast InGaAs photodiode. The photodiode generated several microWatt of 24 GHz RF signal that was analyzed using an RF spectrum analyzer. The recorded RF signal is shown in (Figs. 5 and 6).

The narrow linewidth RF spectrum generated by multiple comb lines suggests that the harmonics of the comb are self-phase locked in the sense of modulation-based combs [21].

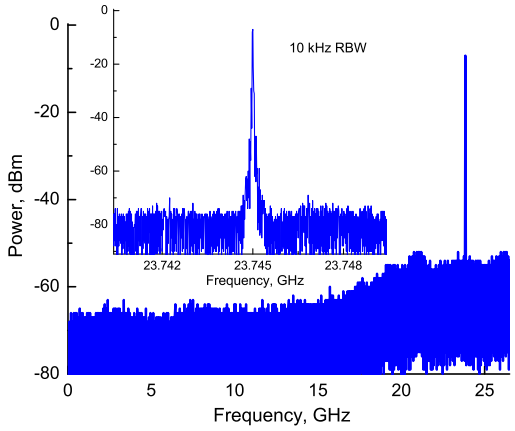

Fig. 5. The RF signal generated by demodulation of the optical frequency comb on a fast photodiode. Only one RF frequency component is generated.

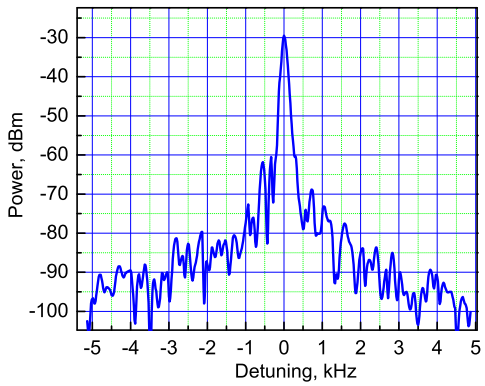

Fig. 6. The RF signal generated by demodulation of the optical frequency comb on a fast photodiode with lower resolution bandwidth than is shown in Fig. 5. Thermal drifts of the RF frequency limit the the resolution bandwidth of the measurement to 10 kHz. The instantaneous linewidth of the RF signal is 10 Hz, since the skirts of the RF signal can fitted with a Lorentzian curve of 10 Hz full width at half maximum.

VI. Locking the comb to the atomic transition

Activating the feedback loops shown in Fig. 1 locked the comb to the atomic transition, and the Allan deviation of the frequency of the locked signal could be measured with a frequency counter locked to a reference rubidium standard. The result of the measurement is shown in Fig. 7. The Allan deviation of the AO-IMPAC clock was averaging inversely proportional to the averaging time until it reached the sensitivity level of the measurement system determined by the Allan deviation of the reference Rb clock.

The observed behavior of the Allan deviation needs an explanation since it averages very fast as τ^{-1}, where τ is the integration time. When the Kerr comb runs freely the frequency drift behaves as $\tau^{1/2}$ (green line in Fig. 7). Such a drift results from the frequency random walk, so the phase noise spectrum is proportional to f^{-4} for $f \to 0$ (f is the spectral frequency). When the feedback is switched on, the phase noise should be divided by the product of the feedback gain and the PDH error function resulting from the lock to the atomic transition. If we assume that the error function goes as f^{-2} (the error-function for a Lorentzian) and the gain is constant at low frequencies (we found that the spectrum of the feedback gain is constant till 0.3 Hz), the phase noise in the closed loop will be proportional to f^{-2} for $f < 0.3$ Hz. This is the white frequency noise resulting in a $\tau^{-1/2}$ averaging of the Alan deviation signal. The expected behavior of the Allan deviation is illustrated by the black line in (Fig. 7). This is not what was observed with both the laser and the comb locked

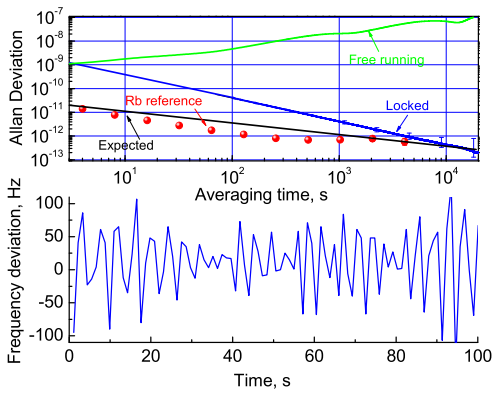

Fig. 7. Top: Allan deviation of the RF signal generated by the free running (green curve) and locked (blue curve) optical frequency comb; the Rb clock used in the measurement system (red dots); and expected averaging resulting from the PDH lock loop used in the experiment (black line). Bottom: Frequency signal from the counter.

to the atomic cell. The averaging apparently behaves as τ^{-1}.

The reason is that the resonator producing the comb is thermally modulated. The thermal modulation produces the frequency modulation of light needed to lock the laser and the resonator frequencies to the atomic transition. But, modulation of the resonator temperature changes the FSR of the resonator, as well, so the clock signal is also modulated with the same frequency (see the picture at the bottom of Fig. 7). The modulation frequency is approximately $f_1 = 0.238$ Hz. The averaged measured modulation magnitude of the 24 GHz signal is ± 70 Hz. The frequency counter sampling time is 1.1 s. Taking these values into account w the Allan deviation of a 24 GHz signal can be calculated, the frequency of which is modulated as $70\cos(2\pi f_1 t)$. The Allan deviation estimated in this way coincides with the Alan deviation measured in our experiment, which behaves as τ^{-1}. Hence, the measured result is determined by the imperfectness of the measurement system we used. The actual performance of the clock is likely better than what is measured.

VII. Conclusion

We have shown that a Kerr frequency comb excited in a WGM resonator can be used in the realization of a new type of optical atomic clock. The clock features an architecture using an optical transition in an atom or molecule, making it suitable for miniaturization with small power for operation. This is the goal of the AO-IMPAC clock, which will be further developed in the next phases of the DARPA IMPACT program.

***Abstract*— We present the development, testing and characterization of a low-power chip-scale Rubidium (Rb) plasma light source designed to serve for optical pumping in miniature atomic clocks. The technique used is electrodeless capacitively coupled plasma (CCP) discharge, driven in a micro-fabricated Rb vapor cell. The device is electrically driven at frequencies between 1 and 36 MHz to emit 140 µW of stable optical power while coupling < 6 mW of electrical power to the discharge cell. To our knowledge this is the first reported Rb plasma emitted from a chip-scale device.**

I. INTRODUCTION

Compact Rb atomic clocks (overall volumes of 100-1000 cm^3), are widely used in many applications including navigation systems, network synchronizations and digital communications [1]. A common commercial implementation of such an atomic clock is the compact (~100 cm^3) Rubidium microwave frequency standard based on the Double-Resonance (DR) technique, using a glass-blown Rb plasma discharge lamp to achieve optical pumping. With the advent of microtechnology there has been an upsurge in portable devices (GPS receivers, for example) leading to a growing need for smaller, lower-cost, chip-scale atomic clocks with reduced power consumption, that show better frequency stability than the currently used quartz crystal oscillators. This has led to research towards miniaturizing atomic clocks to reach volumes of few cm^3 or below [2, 3], mostly based on the Coherent Population Trapping (CPT) approach that has been preferred over the traditional DR technique [4].

The majority of Rb DR clocks use Rb plasma discharge lamps as the light source for optical pumping due to the lamp's intrinsically correct frequency (Rb lines), technical simplicity, very slow frequency drift (aging), and long lifetime. However, because these glass-blown lamps usually consume several watts of electrical power and are not easily integrable with an ideal chip-stack configuration, chip-scale Rb DR clocks had been deemed a challenge and are relatively unexplored. The CPT technique was preferred for chip-scale clocks by using a laser diode (VCSEL) as the light source for atomic resonance [2, 3] because of their easy integration, good power efficiency, planarity and compact dimensions (~mm^2). However, the VCSEL approach requires critical temperature control, sophisticated control electronics for laser frequency stabilization, and complicated setup procedures [2].

The goal of this research is to develop a microfabricated planar low-power Rb plasma light source (as shown in operation in Fig. 1) to exploit the inherent advantages of a Rb discharge lamp, avoiding the issues faced by the VCSEL and providing an alternative and innovative design for chip-scale Rb atomic clocks.

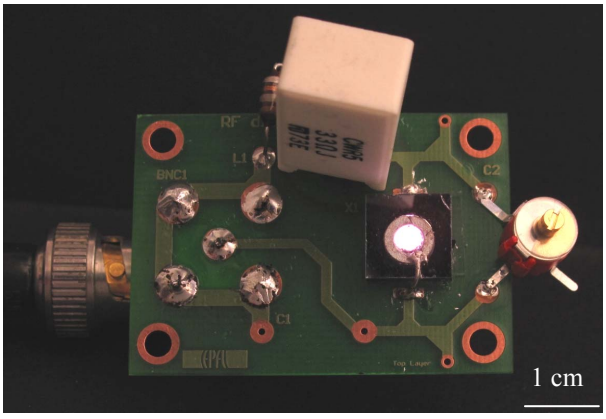

Figure 1. Photographic view of the Rb plasma light source emitting the Rb glow discharge

This project was funded by Swiss National Science Foundation *(SNSF)* Sinergia grant CRSI20_122693.

Microfabrication of hermetically sealed Rb cells with volumes on the order of 1 mm^3 has been a challenge, with several groups reporting different bonding techniques compatible with Rb filling, for instance anodic bonding [3, 5] or soldering [6, 7]. Such cells have been used as the reference cell in miniaturized atomic frequency standards (atomic clocks), but not as light sources – in part due to the additional complexity of igniting a stable plasma. While first studies on micro-cell plasma light sources reported on low-power rare-gas discharges, no Rb light was reported [8, 9].

A. *Double Resonance Rb Atomic Clock*

The fundamental concept behind timekeeping in atomic clocks is to exploit an atomic resonance as reference for stabilizing the frequency of a quartz oscillator. In a Rb atomic clock [6], this resonance is the "clock" transition between the two ground-state hyperfine levels of ^{87}Rb, at a microwave frequency near 6.83 GHz ($5^2S_{1/2}$ state, $|F=2, m_F=0\rangle$ to $|F=1, m_F=0\rangle$), detected on atoms maintained in a small Rb reference cell. In a double-resonance Rb clock, pump light from a lamp or laser resonant with the Rb D1 or D2 line (794.8 nm or 780.2 nm, respectively) irradiates the cell and creates a ground-state polarization in the atoms. The clock transition is then detected by applying a microwave field to the atoms via a microwave-cavity placed around the cell, and the resonance manifests itself as a narrow dip in pump-light power transmitted through the cell. The frequency of a voltage-controlled quartz oscillator is locked to this dip using phase-sensitive detection.

Our envisaged double-resonance Rb atomic clock consists of a micro-fabricated Rb plasma light source, a micro-fabricated Rb^{85} filter, a micro-fabricated Rb reference cell which is enclosed by a miniaturized microwave cavity, and a photodetector (Fig. 2). The Rb plasma light source intrinsically emits at the correct wavelengths, Rb D1 and D2 lines, as required in a Rb clock.

B. *Rb Plasma Glow Discharge*

Sustaining a plasma glow discharge in a Rb cell requires continuous ionization of Rb vapor atoms. A sufficiently strong electric field, when applied across a Rb vapor cell, can ionize the Rb vapor atoms to generate Rb ions and free electrons.

By maintaining a sufficiently strong electric field, the electrons and ions are accelerated towards the electrodes, and many of them collide with more neutral vapor atoms to generate positive ions and electrons through impact ionization before they reach the electrodes. This becomes an avalanche process, eventually initiating an electrical breakdown leading to several possible types of gas discharges [10], including the Rb plasma glow discharge emitted as radiation by Rb atoms during their radioactive decay from the excited state to the ground state.

The Rb vapor density is very low at room temperature (~10^{-6} millibars of vapor pressure at 30 ºC), hence requiring an extremely high field strength to ionize the Rb atoms (Paschen curve) [11]. In order to reduce the field and hence the electrical power to ignite the glow discharge, an inert low-pressure starter gas is added to the cell. The temperature of the cell is also increased to up to 150°C by using a resistive heater, in order to increase the Rb vapor density in the cell. As Rb is highly reactive with many gases, a few ten millibars of an inert gas are used as starter gas – in our case Ar, which has a relatively smaller diameter and high mean free path among noble gases with an ionization potential of 15.75 eV [10].

II. Device Microfabrication and Development

A. *Design and Microfabrication*

The design approach chosen for the Rb plasma light source is the electrodeless capacitively coupled plasma (CCP), sustained in a planar micro-fabricated Rb cell. Capacitive coupling produces stronger field lines in a planar cell cavity and therefore makes it easier to ignite a plasma than the more widely used inductive coupling which is more efficient for spherical cells.

The micro-fabricated Rb cell (outer dimensions of 1 x 1 x 0.3 cm^3), consists of a stack of three layers: Pyrex (500 µm thick), Silicon (2 mm), Pyrex (500 µm) which enclose a Φ = 5 mm, h = 2 mm cylindrical cavity in which few microliters of Rubidium and 70 millibars of Argon are hermetically sealed by a two-step anodic bonding process (Fig. 3). First, the cavity is created by DRIE etching a through-hole in the silicon wafer. Then, the etched silicon wafer is anodically bonded to the bottom Pyrex layer.

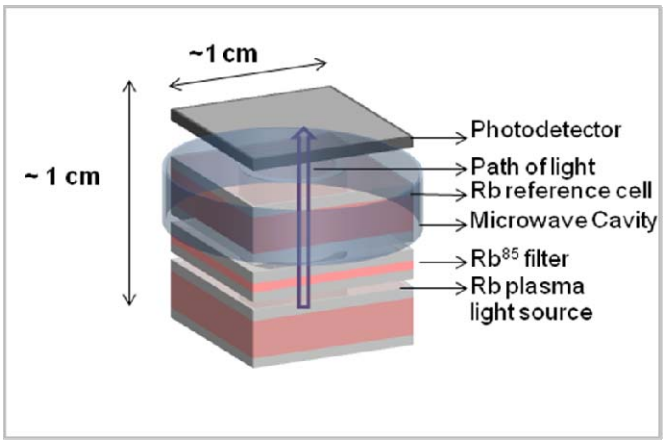

Figure 2. Schematic diagram of the envisioned Rb DR chip-scale atomic clock with the integrated Rb light source

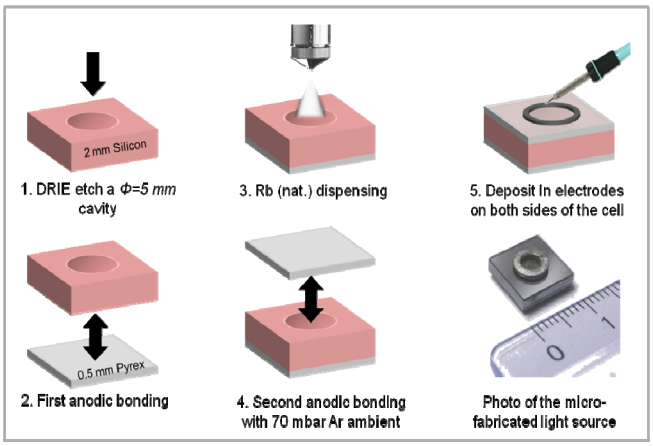

Figure 3. Schematic diagram showing the Rb light source microfabrication process flow

After this first bonding step, the natural Rb is dispensed into the cavity under vacuum by an atomic jet, 70 millibars of Argon are introduced in the chamber, and the top Pyrex layer is anodically bonded to the bottom layers to create the hermetically sealed Rb mini-cell [12].

A 200 µm thick 100% Indium solder ring or film is deposited on top of both sides of the Pyrex layers (i.e., outside the cell) to act as capacitive parallel electrodes to capacitively couple RF power to the cell. 100% Indium wets glass well and is hence a good choice for deposition on the Pyrex walls. The 100% Indium electrodes are deposited by placing and aligning Indium pre-form rings on top of Pyrex layers above the cavity and reflowing using a soldering iron. These external electrodes avoid electrode corrosion and might allow for lower power consumption when compared to the more traditional internal electrode designs [13]. Note that in a future wafer-level production of the plasma light source, the electrodes can be directly integrated onto the Pyrex layers used to close the cell by evaporation or sputtering and micropatterning techniques, and could be made of a suitable metal other than Indium in order to better withstand high temperatures. Our micro discharge cell design is thus compatible with wafer level manufacturing of many devices at a time, potentially allowing for greatly reduced costs per unit.

B. *RF Capacitively Coupled Plasma (CCP) Circuit*

The technique used to power the light source is RF electrodeless CCP. The microfabricated Rb vapor cell has an intrinsic capacitance of ~0.4 pF at low frequencies (<10 MHz) and up to ~1.6 pF at higher frequencies (<36 MHz), and a reactance of ~j85 kΩ at low frequencies (few MHz).

The output impedance of the RF generator used as signal source is (50 + j·0 Ω) hence requiring careful impedance matching of the load to equal the source to (50 + j·0 Ω) using L-C components. This enables high power and voltage amplification across the cell to achieve the required breakdown voltage with the lowest input electrical power.

Fig. 4 shows schematically the RF plasma ignition circuit connected to the impedance-matched load constituting the light source. The two main components in the impedance matching network are (1) a capacitor in parallel to the cell to reduce the overall capacitive reactance and (2) an inductor in series with the above capacitors to cancel out the reactive load to form a purely resistive load. The values and the Equivalent Series Resistance (ESR) of the components are carefully chosen to maximize the power transfer to the cell.

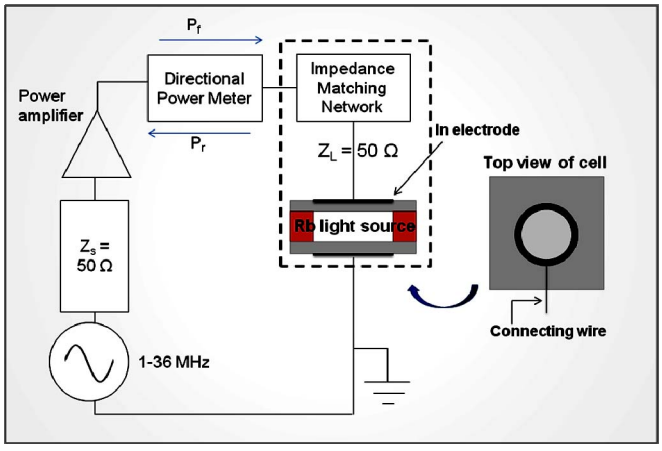

Figure 4. Schematic circuit of the RF electronic circuitry and impedance matching for plasma ignition

III. Device Characterization

The light source was impedance matched and tested at several frequencies over the 1 MHz to 36 MHz frequency range. The results reported in this article were obtained at 4.6 MHz.

A. *Output optical characteristics*

The output optical spectrum of the light source was measured using a spectrometer and is shown in Fig. 5. At cell temperatures above ~90 ºC strong Rb D1 lines (794.8 nm) and D2 lines (780.2 nm) are observed. These lines rapidly rise in intensity with increasing cell temperature, as expected with the rapidly rising Rb vapor pressure inside the cell.

The total optical power of the light source was 140 µW when 6 mW of electrical power was coupled to the cell. The total optical power emitted on the Rb D2 line was 15 µW, at a cell temperature of 150 ºC.

B. *Rb light power stability*

The stability of the output optical power of the Rb lines was recorded over time for the plasma light source operating at a temperature of 100°C. The short-term (seconds) and long term (hours) variation in optical power was measured.

The average short-term fluctuations in optical intensity of the Rb lines was found to be less than 0.1% and the long-term variations were found to be less than 5% (shown in Fig. 6). The primary cause of the long-term variations in optical power is the drift in resistance (2-3%) of the electrical components of the impedance matching network with time, mainly due to thermal effects. These long-term variations can be limited to less than 0.01% using a PID feedback loop that controls the input electrical power and/or the RF drive frequency to maintain a steady output light power level.

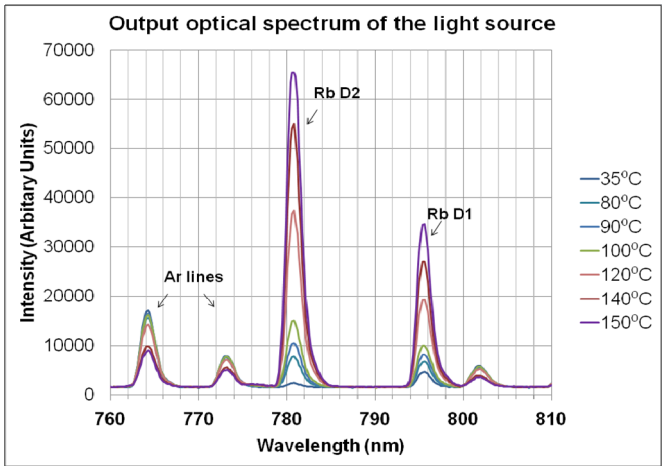

Figure 5. Optical spectrum of the light source at different temperatures between (35-150 ºC). The spectral width of the lines is limited by the resolution of the spectrometer used here.

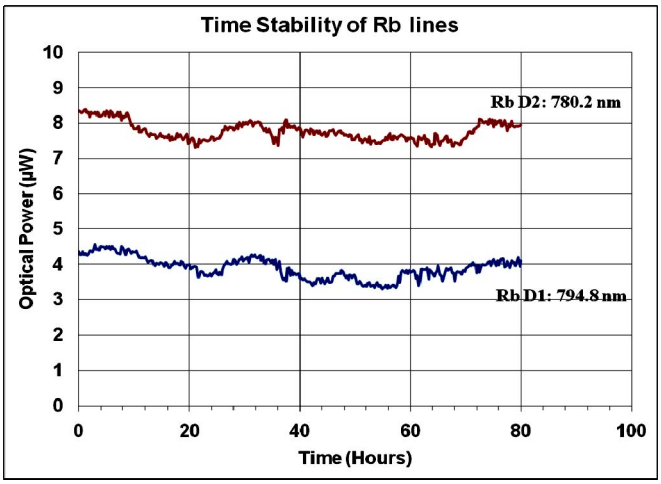

Figure 6. Stability of the Rb lines with time, measured at 100 ^{0}C

IV. Summary and Future Work

A stable and low-power chip-scale Rb plasma light source with potential for wafer-scale fabrication has been demonstrated, intended for use in chip-scale atomic clocks. The light source emits several μW of optical power at the 780.2 and 794.8 nm Rb lines from a 0.3 cm^3 chip stack. A successful Rb hermetic sealing technique through standard microfabrication processes has been demonstrated that withstands the plasma operation. The external electrode design ensures the longevity of the device by avoiding electrode erosion by the plasma.

When combined with a micro-fabricated ^{85}Rb filter cell [9], the presented plasma light source can be used for hyperfine optical pumping of Rb in a novel miniature atomic clock.

Testing of this light source as an optical pump in a test DR atomic clock setup to prove its functionality is planned. In the current circuit design, the efficiency of power coupled to the cell is low, thus current research is geared towards increasing this efficiency. Different starter gases and pressures are to be explored to find the best performance conditions.

MOT Loading Enhancement with Stimulated Light Forces

***Abstract*—We demonstrate atom number enhancement in a magneto-optical trap (MOT) by use of bichromatic cooling to slow an atomic beam that is loaded into a MOT. Bichromatic cooling employs stimulated emission to apply strong cooling forces that are not limited by spontaneous emission. We demonstrate a factor of 3.5 increase in atom number captured from the atomic beam for a 1.5 cm cooling length. For a 1.5 cm effective cooling length, our technique yields MOT atom number enhancement that is about three times higher than the enhancement acheived via spontaneous emission.**

I. Introduction

While atom cooling and trapping have revolutionized atomic clocks and precision measurements, cold atoms are not yet used in commonplace technologies. The ability to create widely disseminated, high-performance compact atomic clocks and sensors based on cold atoms could revolutionize portable frequency standards. A fundamental difficulty in developing compact cold-atom devices is that the number of captured atoms in a conventional magneto-optical trap (MOT) scales as d^4, where d is the laser beam diameter [1]. Experiments performed with microfabricated pyramidal traps have demonstrated an $N \propto d^6$ scaling law, showing that the scaling can be even worse for small systems [2].

The strong dependence of the atom number on beam size is fundamentally set by the maximum spontaneous light force achievable in a MOT, $F_{spont} = \hbar k\gamma/2$ [3], where $\hbar k$ is the photon momentum, γ is the resonance linewidth, and $\gamma/2$ is the maximum spontaneous photon scatter rate. To overcome this limitation, we have employed stimulated emission forces to slow a ^{87}Rb atom beam and increase the atom number density at low velocities. In principle, the stimulated forces are limited only by the available laser power.

The stimulated forces are created by a bichromatic cooling technique. Experiments demonstrating use of the bichromatic force to slow an atomic beam were first done by Söding et al., who slowed a cesium beam over a distance of 10 cm with total laser power exceeding 100 mW [4]. Bichromatic cooling has also been studied for Rb atoms [5] and metastable He atoms [6]. A thorough review of laser cooling and trapping techniques that includes a review of bichromatic cooling can be found in Ref. [3]. To our knowledge, our experiment is the first to use the technique for MOT atom number enhancement.

The concept of bichromatic cooling is presented in Fig. 1, where a sample atom is moving with a velocity v_{atom} to the right. A light beam with two frequency components, $\omega = \omega_0 \pm \Delta - kv_{atom}$, strikes the atom from the right and a light beam with the frequency components, $\omega = \omega_0 \pm \Delta + kv_{atom}$, strikes the atom from the left, where $k = 2\pi/\lambda$ is the photon wavevector for light resonant with a cycling transition in the atom at resonance frequency ω_0. Due to the Doppler shift, the light from both the left and the right has frequency components of $\omega = \omega_0 \pm \Delta$ in the atom's frame of reference. For each bichromatic light beam, the two frequency components interfere to create a beat pattern with period $T = \pi/\Delta$. Tuning the intensity such that each frequency component has the Rabi frequency $\Omega = \Delta/4$ configures the light field into two counterpropagating traveling waves of pi-pulses. When the relative phase difference between the pulse trains is set such that an atom on average first absorbs a photon from the beams propagating opposite to its velocity, and is then de-excited due to stimulated emission into the other pulse train, the atom will be slowed with a $2\hbar k$ momentum loss per stimulated-emission cycle.

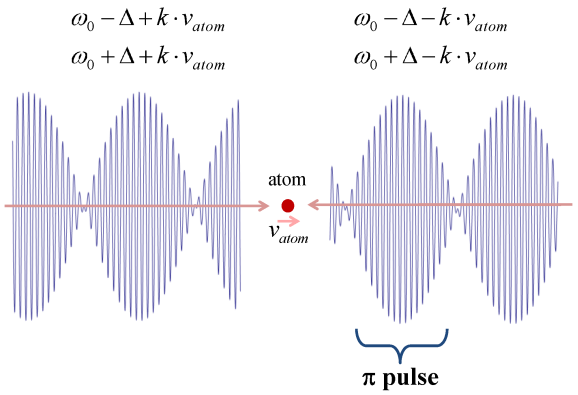

Fig. 1. The π-pulse picture of bichromatic cooling.

The relative phase of the beats from the two beams sets the preferred direction of photon momentum transfer. The optimum relative phase ϕ between the counterpropagating beat signals occurs at about $\phi \simeq \pm\pi/2$ ($+\pi/2$ for cooling, $-\pi/2$ for heating.) Spontaneous emission breaks the symmetry in the system. Since the atoms have more time after the second pulse to undergo spontaneous emission ($3T/4$), they

are preferentially excited by the first pulse and de-excited by the second pulse that arrives a period $T/4$ later. The velocity over which the bichromatic force profile acts extends over a large class, $\delta v = \Delta/k$, centered on the velocity v_{atom}.

II. Experiment

We slow atoms from a thermal beam and then capture them in a MOT. We have deliberately used low cooling powers for the MOT beams to simulate the small capture velocity that would result from the use of small MOT beams. The MOT is formed from three pairs of retro-reflected cooling beams with a 7 mm diameter and approximately 0.9 mW of laser power per beam ($I/I_{sat} = 1.4$). Under these conditions, we calculate a MOT capture velocity of $v_c \simeq 15$ m/s, which is equal to the value for a MOT of 2 mm diameter with fully saturated beams.

To test how bichromatic cooling scales with miniaturization, we performed experiments over short cooling lengths and with low laser powers. We use laser powers of < 2 mW per bichromatic frequency component, which is $\sim 0.05\times$ as large as the powers used in Ref [4]. We achieve the high intensities required for stimulated emission by focussing the light through two apertures of 0.5 mm diameter that collimate the atomic beam ($I/I_{sat} \simeq 600$). Through simulations of the force profile, we calculate a maximum stimulated force $12\times$ larger than the spontaneous force limit, with less than 8 mW of total laser power. We set the central position of the force profile to sit at 70 m/s so that cooling force extends from atoms with velocities of about 15 m/s ($\simeq v_c$) out to about 120 m/s.

We vary the effective slowing distance by changing the total interaction period of the cooling light with the atomic beam. This is accomplished by rapidly chopping the bichromatic cooling light with a radiofrequency (rf) switch that controls the rf power applied to acousto-optic modulators. We switch the cooling light on and off on time scales as short as ten microseconds. To vary the cooling length, we change the duty cycle with which we pulse the light. The full distance that the atomic beam travels in our system before entering the MOT volume is 7.5 cm, and we typically test the cooling methods down to cooling lengths of about 0.4 cm (5 % duty cycle).

To test the effectiveness of bichromatic cooling for loading a small MOT, we compare the number of captured atoms loaded with an atomic beam slowed by spontaneous forces versus one slowed by stimulated forces. For spontaneous slowing, we apply a strongly saturated monochromatic light beam red-detuned from resonance by approximately $2\pi \times 100$ MHz. We optimize the intensity and detuning to maximize the number of captured atoms. We quantify the the effects of the beam slowing in terms of MOT number enhancement, which we define as the ratio of captured atoms in the MOT with and without slowing light applied to the atomic beam.

III. Simple Model

We have performed simple modeling of the bichromatic cooling process with which we compare our experimental results. When the phase and Rabi frequency are optimized for a selected value of Δ, the force profile is nearly rectangular in shape with a width of Δ/k (see, for example, Refs. [4], [5]). The bichromatic force is averaged across the Gaussian beam profile since the Rabi frequency varies with intensity. The force profile is further averaged over the full slowing length of our system, because the relative phase of the π pulse trains varies by about 20 degrees. This averaging broadens the range of velocities over which the force acts by about 50 % and lowers the maximum force by about a factor of 1/2. For simplicity, we have approximated the ideal force profile with a rectangular function of constant force that we fit to the force profile determined via numerical modeling of the optical Bloch equations. For the spatially averaged profile, we have decreased the maximum force and broadened the addressed velocity class to fit the spatially averaged force.

To estimate the fraction of captured atoms in a MOT, we have calculated an approximate "effective capture velocity," v_{max}. To find v_{max}, we set the work done on the atoms by the bichromatic force over the cooling distance L equal to the initial kinetic energy of the atoms with a velocity v_{max} and we solve for v_{max}. This gives $v_{max} = (2R_{scatt}Lv_{rc})^{1/2}$, where R_{scatt} is the photon scatter rate and v_{rc} is the recoil velocity. Note that this is the same equation that is often used for the MOT capture velocity with laser beams of diameter L [1]. For stimulated bichromatic forces, R_{scatt} is determined from numerical modeling to be about $10\times$ greater than what is achieved via spontaneous forces for the powers used in our experiment. To estimate the fraction of the atomic beam captured in the MOT, we integrated a normalized Maxwell-Boltzmann distribution out to v_{max} or the upper edge of the calculated force profile, whichever is smaller.

Fig. 2 is a plot of the simulated fraction of atoms captured in a MOT versus duty cycle for spontaneous and stimulated cooling processes. The fraction captured with the bichromatic cooling method saturates at low duty cycles (effective cooling lengths) because the atoms are cooled very quickly by the strong bichromatic force, and they stop interacting with the cooling light when their velocity is lowered below the edge of the force profile. The strongly saturated spontaneous cooling profile is weaker than the ideal bichromatic force by about an order of magnitude, but it acts over a much larger velocity range, which is why the fraction of captured atoms continues to rise for larger duty cycles, whereas the bichromatic fraction captured saturates.

IV. Results

A detailed paper on our experimental results is currently in preparation [7]. By use of bichromatic forces, we have demonstrated an increase in atom number captured from an un-cooled atomic beam by a factor of about 3.5 for a 1.5 cm effective cooling length, and by up to a factor of 5.5 for longer cooling lengths. Consistent with Fig. 2, the technique yields MOT atom number enhancement that is about $3\times$ higher than the enhancement achieved with spontaneous forces for a 1.5 cm effective cooling length.

Fig. 3 shows example data for MOT number enhancement versus duty cycle achieved with and without an applied

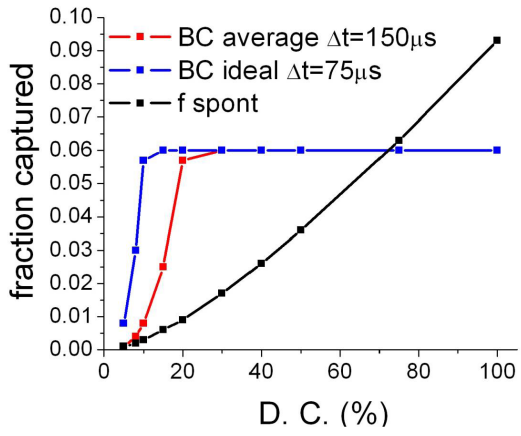

Fig. 2. Simulations of the fraction of captured atoms versus duty cycle for spatially averaged and ideal bichromatic force profiles as well as for a spontaneous force profile. To convert from duty cycle to effective cooling length (in centimeters), multiply the x-axis by 0.075. $\Delta t = m\delta v/F$ is the time required to slow an atom from the upper to the lower limit of the force profile of width $\delta v = \Delta/k$. The fraction captured in the MOT without any slowing of the atomic beam is 0.0002.

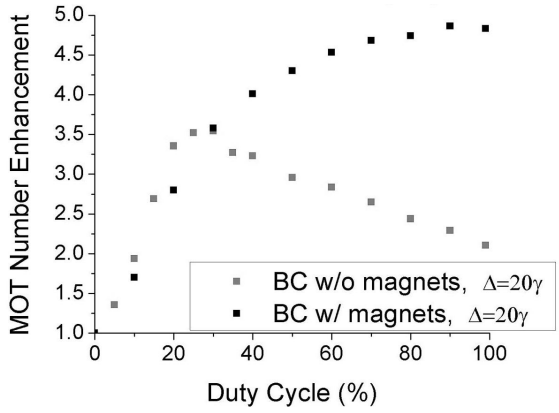

Fig. 3. Measurements of the MOT number enhancement versus duty cycle with (black squares) and without (gray squares) a magnetic guiding potential between the apertures.

magnetic guiding field. The unguided data are qualitatively similar to Fig. 2, but the enhancement actually decreases for the higher duty cycles after a maximum of 3.5× is reached for a 20 % duty cycle (1.5 cm effective cooling length). In other experiments, the MOT number enhancement actually *increased* when the bichromatic force was made *weaker* – particularly for the higher duty cycles (data not shown).

We attribute these dependencies on force magnitude and cooling length to cold-atom loss. Consistent with this, the MOT number enhancement that we observe is about 60 times smaller than what we would expect. We suspect that the main loss channel is transverse spreading of the atomic beam. The divergence angle of the uncooled atomic beam is set by the aperture geometry in the atomic beam collimator to approximately 10 mrad. The divergence angle for a given atom is equal to its transverse velocity divided by its longitudinal velocity. When an atom is slowed, its divergence angle increases and it is less likely to emerge from the second pinhole in the collimator.

One of the data sets in Fig. 3 was measured with a linear quadrupole field applied between the collimator apertures by two permanent magnets. The magnetic field gradient was $\sim$ 20 G/cm, which is strong enough to guide atoms with transverse velocities of up to 0.1 m/s through the second collimator aperture. Since the maximum transverse velocity for the atoms addressed by the cooling light is $\sim$ 1.2 m/s, we would not expect to guide all of the atoms with the quadrupole field, but we would expect to increase the enhancement for the proper cooling-light polarization. With the guiding field, we increased the MOT number enhancement for the higher duty cycles from about 2× to about 5× (Fig. 3). As expected, the increase in MOT atom number enhancement was only observed for the proper cooling-light polarization.

V. Conclusion

By use of bichromatic cooling, with our current experimental parameters we should be able to slow 6 % of the atoms in an atomic beam to MOT capture velocities in distances of under 1 cm.

We are currently working on experimental design changes that will alleviate the problem of cold atom loss, after which we will try the method in a compact system with trapping volumes of order 1 mm^3. Ultimately, we expect to optimize our system to be able to load an optical molasses with 1 mm diameter beams with 100× more atoms than if loaded from a background vapor.

***Abstract*— We report progress in measuring the third order electric polarizability of the Cs ground states using a Ramsey pump-probe experiment on coherent population trapped (CPT) atoms in a thermal atomic beam. We give a short description of the apparatus as well as the Fourier transform method used to monitor the phase and frequency of the Ramsey signal. Analysis of a typical data set is shown, proving the consistency of the method. We show that the motional magnetic field phase shift can be used to test the reliability of the electric field modeling. Finally, we give a preliminary value for the Cs ground state polarizability and compare it to previous published values of the DC Stark shift.**

I. Introduction

The second is defined by the unperturbed ground-state hyperfine frequency splitting in ^{133}Cs (ISO 31–1). Realizing the second requires control and understanding of the systematic effects [1], [2] that perturb that transition. One effect is the AC Stark shift arising from the blackbody radiation spectrum of the finite temperature clock environment. In practice, the blackbody radiation shift can be calculated from the Cs ground state third-order polarizability $\alpha_0^{(3)}(F)$ which we measure in a CPT-based Ramsey pump-probe experiment similar to [3] and [4] on a Cs thermal atomic beam. The polarizability induces a shift in the resulting Ramsey fringe as a function of the DC electric field applied in the free evolution region of the atom's flight.

The energy shift produced by a DC electric field $\mathbb{E}$ is described using the electric polarizability α as $\Delta E(n, L_J, F, m_F) = -\frac{1}{2}\alpha\mathbb{E}^2$. The constant α is traditionally expanded in power series, both in multipole order (subscript) and perturbation order (superscript). Neglecting the (small) quadrupole hyperfine interaction, the lowest order terms (i.e., third) affecting the $\Delta m_F = 0$ ground-state Cs hyperfine transitions, produce a frequency shift $\delta\nu = -\frac{1}{2h}\alpha\mathbb{E}^2$ [5], [6] with

$$\alpha = \frac{16}{7}\alpha_0^{(3)}(F{=}4) + \alpha_2^{(3)}(F{=}4)\frac{3m_F^2-16}{28}f(\theta)\,, \qquad (1)$$

where $\alpha_0^{(3)}$ and $\alpha_2^{(3)}$ are the third order scalar and tensor polarizabilities, m_F is the magnetic quantum number defined by the quantization axis (magnetic field), and $f(\theta) = 3\cos^2(\theta) - 1$ is a function of the relative angle between $\hat{\mathbb{E}}$ and the quantization axis. Note that $f(\theta)$ averages to zero for isotropic blackbody radiation, and that the Ramsey method makes the shift sensitive to the effective average squared field, $\langle\mathbb{E}^2\rangle$. For a 20 kV/cm static electric field, the expected scalar shift in Cs is 830 Hz, and the tensor shift is about 3 Hz.

A. Motional magnetic field

Atoms flying through the electric field $\vec{\mathbb{E}}$ experience an additional magnetic field $\vec{B}_{mot}$ given by

$$\vec{B}_{mot} = -\frac{\vec{v}}{c^2}\times\vec{\mathbb{E}}\,,$$

where $\vec{v}$ is the velocity of the atom. This motional field produces a Zeeman shift of the $\Delta m_F = 0$ hyperfine transitions but due to its linear velocity dependence this shift results in a phase change

$$\Delta\phi = (g_{F=4} - g_{F=3})m_F\mu_B\frac{\langle\mathbb{E}\rangle}{\hbar}\frac{L}{c^2} \qquad (2)$$

of the Ramsey resonance, where g_i is the Landé factor of level i, m_F is the magnetic quantum number of both ground states (our experiment presently probes phase shifts of levels with identical m_F), $\langle\mathbb{E}\rangle$ is the mean electric field seen by the atoms between the pump and the probe zones, separated by L. This phase shift produces a small displacement of the Ramsey resonance center frequency and thus mimics an atomic frequency shift. However, from this measured phase, the mean electric field value can be inferred and then compared to an electric field model prediction to give confidence in the latter.

B. Extracting frequency and phase

The Ramsey resonance lineshape $S(\omega_{RF})$ can be expressed as the integral of the phase accumulated by each velocity class during the interaction with the electric and magnetic fields weighted by the atomic velocity distribution, $\rho(v)$. The accumulated phase is given by a term oscillating at the difference between the microwave ω_{RF} and atomic ω_{at} frequencies and includes a constant offset ϕ.

$$S(\omega_{RF}) = \int_0^\infty \rho(v)\cos\left[(\omega_{RF}-\omega_{at})\frac{L}{v} + \phi\right]dv\,. \qquad (3)$$

Taking the Fourier transform of $S(\omega_{RF})$ yields

$$\mathcal{F}[S(\omega_{RF})] \propto \rho(T)\exp[i(\omega_{at}T + \phi)]\,, \qquad (4)$$

where $\rho(T)$ is the atomic time-of-flight distribution. The argument of the complex exponential contains information on both atomic frequency ω_{at} and phase ϕ of the Ramsey signal $S(\omega_{RF})$ permitting their clear separation and extraction. The

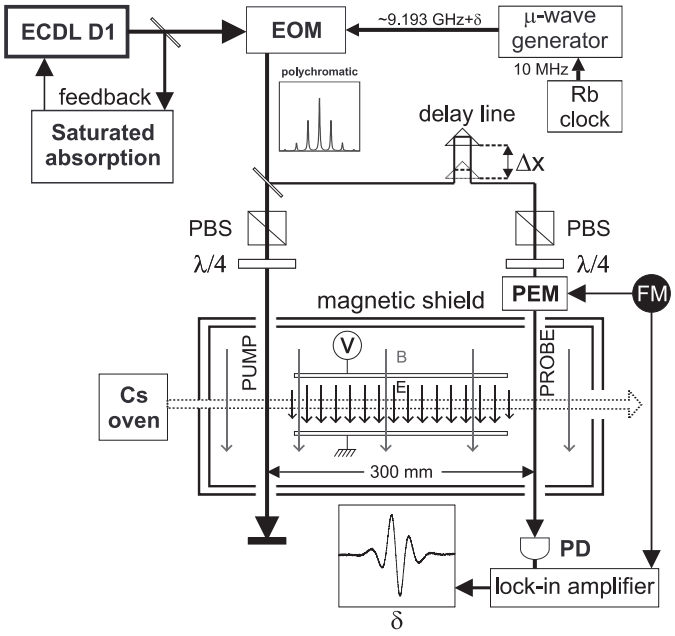

Fig. 1. Experimental setup for the measurement of the Stark shift. In order to produce a phase coherent bichromatic light field, a Cs D_1 extended cavity diode laser beam is phase modulated at the Cs hyperfine frequency using a electro-optic modulator (EOM). The modulated laser beam is split into a strong pump and a weak probe and sent to a Cs atomic beam experiment to perform Ramsey interrogation. The probe-beam transmitted intensity is recorded while scanning the microwave frequency. The DC Stark shift is obtained applying an electric field to the atoms during their flight between the pump and the probe zones.

Fourier transform is therefore a powerful tool to distinguish between Stark frequency shift and motional phase shift: similar techniques have been used in [7], [8].

II. Experimental setup

The main elements of the present experimental scheme have already been described in detail in [9] and here we will focus on the new elements. Figure 1 shows the actual experimental configuration. A Cs D_1 extended cavity diode laser is stabilized to a chosen Cs hyperfine transition (normally the F=3 $\longrightarrow$ F'=3) using saturated absorption in an atomic vapor cell. The light is sent through a commercial lithium niobate electro-optic modulator (EOM), which accepts a microwave signal (whose frequency can be scanned around the Cs ground state hyperfine frequency ~ 9.2 GHz), and produces a frequency modulated spectrum, containing multiple sidebands all separated by the modulation frequency. The resulting spectrum generates coherent population trapping (in this case, the carrier and the $-\omega_{RF}$ bands are used). The modulated beam is split into a strong pump beam and a weak probe beam. The pump and probe beams pass through polarization optics to create the desired circular polarization before being sent to the thermal Cs atomic beam. The interaction between the light and the atoms occurs in a magnetically shielded environment with a 3.6 μT DC magnetic field. The atomic beam first interacts with the pump laser beam creating a coherence between the Cs hyperfine ground states which then evolves

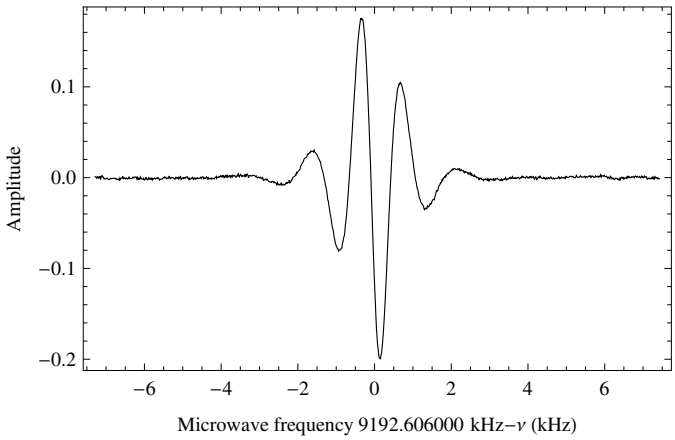

Fig. 2. Averaged Ramsey fringe pattern (15 scans) of the Cs hyperfine transition $m_F = +1 \rightarrow m_F = +1$, with a central fringe period of ~ 1 kHz. The dispersive lineshape is due to the difference of microwave phases between the pump and probe zones and can be controlled by the optical delay line.

over a 300 mm path length during which it passes between two 260 mm long electrodes with given potential difference. The electric field between the plates shifts the atomic coherence oscillation frequency due to the Stark perturbation. Finally the phase of the coherence is probed by recording the transmitted laser intensity of the probe beam in the second interaction zone while scanning the microwave frequency, thus producing typical Ramsey spectra (Fig. 2).

A. Electric field

The electric field is produced by applying a known voltage to one of the two conductive rectangular float glass plates, while the other is grounded. The plate separation is defined by 6.065 mm thick optical flats. Two grounded metal plates, with apertures collimating the Cs beam, are placed at the entrance and exit of the capacitor to shield the light interaction zones from electric fringe fields. The applied high voltage is measured by a calibrated digital voltmeter (with resolution of 10^{-4}), and remains stable to better than that resolution for the typical measurement time of 10 minutes. A technical problem prevented the use of negative voltages exceeding -2000 V. Finite element electric field modeling is used in the data analysis to extract the polarizability [10].

III. Experimental results

A. Ramsey fringe data

Ramsey fringe spectra are recorded for each of the seven $\Delta m_F = 0$ hyperfine transitions, split by the 3.6 μT field. Due to the $\sim$ 1 ms precession time in the fields, the period of the central fringe is about 1 kHz. Each resonance spectrum is obtained ramping the microwave frequency over ± 7.5 kHz around the center of the fringe. The background is removed using a quadratic fit function. The phase of the Ramsey resonance can be accurately controlled by an optical delay line. Figure 2 shows a typical Ramsey fringe spectrum for the $m_F = +1 \rightarrow m_F = +1$ hyperfine ground state transition.

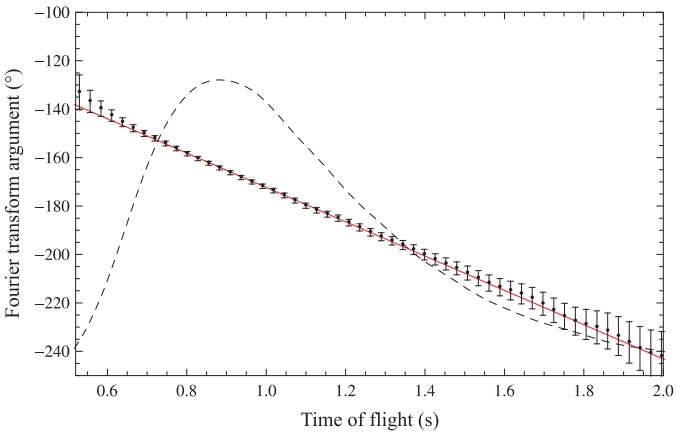

Fig. 3. Fourier transform data of recorded Ramsey signal showing the linear dependence of the argument $\omega_{at}T + \phi$ in Eq. (4) in function of the time of flight. Each data point is weighted proportionally to the time of flight distribution in the beam (dashed line). A weighted linear fit is used to extract both the atomic frequency ω_{at} and the Ramsey fringe phase ϕ.

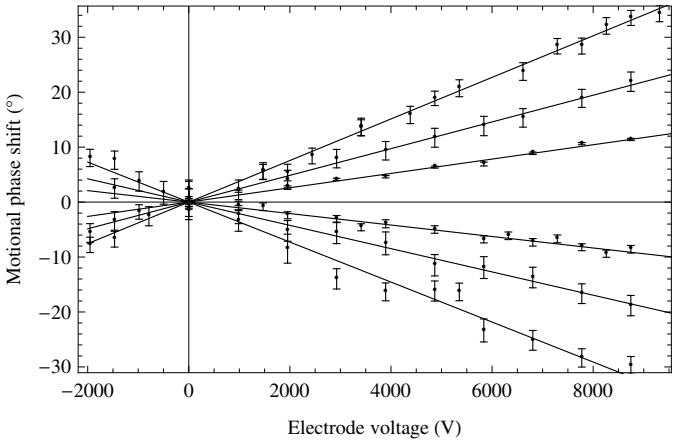

Fig. 4. Measurement of the Ramsey resonance phase as function of the applied electrode voltage for hyperfine transitions with Δm_F=0 and m_F=± 1, ±2, ±3. The linear fit of these data gives access to the mean electric field experienced by the atoms on their flight between the pump and probe interactions.

B. Fourier transform of Ramsey data

A discrete Fourier transform is applied to the Ramsey spectra. To avoid noise coming from asymmetric ends of the spectrum, a Tukey windowing function is applied to the data before transformation. The transformed data become functions of the atomic time-of-flight with a minimal time interval between two data points determined by the microwave scan span. However, since the applied frequency window goes to zero and there is no signal beyond the span limits, the effective span can be arbitrarily extended during the Fourier transform. As consequence, we are not limited in the time resolution of the Fourier transform. Figure 3 shows typical data from the Fourier transform's argument $\omega_{at}T + \phi$ in Eq. (4). Each data point is attributed a weight proportional to the corresponding signal intensity from the time-of-flight distribution $\rho(T)$ (dashed line in Fig. 3). The atomic frequency ω_{at} as well as the Ramsey fringe phase ϕ are extracted by a weighted fit of a straight line.

C. Motional magnetic field

The motional magnetic field produces a phase change of the Ramsey resonance as a function of the applied electric field, as described above. The Fourier transform analysis of the Ramsey spectra for different applied voltages gives access to this phase shift. Figure 4 shows the motional phase shift of the six Δm_F=0 hyperfine transitions with m_F=± 1, ±2, ±3 as fit with a linear function. As expected from Eq. (2) the slope depends linearly on m_F. The linear fits therefore give measurements of $\langle \mathbb{E} \rangle$ which can be compared to the mean electric field value obtained from the field modeling, useful to verify the accuracy of the latter. The quantity compared is the effective electrode separation d_{eff} defined as

$$\langle \mathbb{E} \rangle = \frac{V}{d_{\text{eff}}},$$

where $\langle \mathbb{E} \rangle$ is the mean electric field between the pump and probe interaction and V the applied voltage. Table I shows that the model and measurements agree. We currently work on improving the statistical and systematic uncertainties of the measurement.

	Field modeling	Measurement
d_{eff}	5.90(2) mm	5.83(8) mm

TABLE I

VALUES FOR THE EFFECTIVE DISTANCE BETWEEN THE ELECTRODE PLATES OBTAINED WITH THE ELECTRIC FIELD NUMERICAL MODELING AND FROM THE MOTIONAL MAGNETIC FIELD PHASE SHIFT MEASUREMENT.

D. Stark shift

The Cs ground state Stark shift is obtained by measuring the change of atomic frequency ω_{at} as a function of the applied electrode voltage using the method described above. Figure 5 shows the Stark frequency shift for the m_F=+1 → m_F=+1 Cs ground state hyperfine transition. A second order polynomial is fit to the data for extracting the quadratic coefficient, itself proportional to the electric polarizability of the Cs ground states. The linear coefficient is consistent with zero, as expected. The voltage is converted into the effective mean of the squared electric field $\langle \mathbb{E}^2 \rangle$ seen by the atoms between the pump and probe interactions using numerical modeling of the electric field. A value of the total electric polarizability for each of the seven Cs ground states hyperfine transition is obtained and the polarizability difference of any pair of grounds states can be extracted using Eq. (1). Preliminary data with fit are shown in Fig. 6. The relative orientation of the electric and magnetic field for these measurement is $\theta = 85(1)^{\circ}$. A preliminary value for $\alpha_0^{(3)}$ has been extracted from the fit and is compared, in Table II, with the two latest DC Stark shift measurements (which between themselves showed a discrepancy of more than 5 σ).

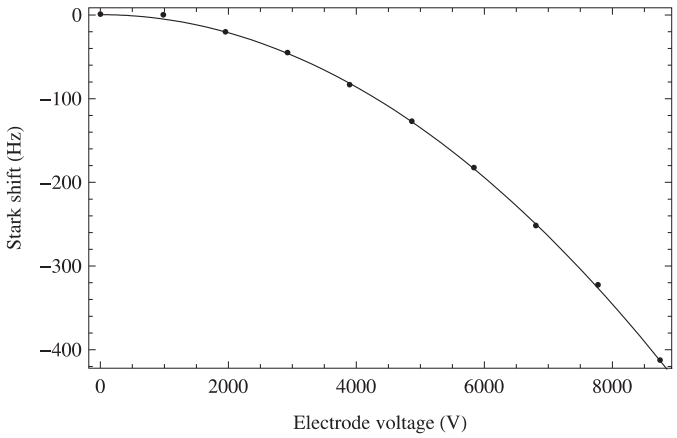

Fig. 5. Cs ground state Stark frequency shift of the $m_F{=}+1 \rightarrow m_F{=}+1$ hyperfine transition. Statistical uncertainties on the points are smaller than the point size. The continuous line is a second degree polynomial fit.

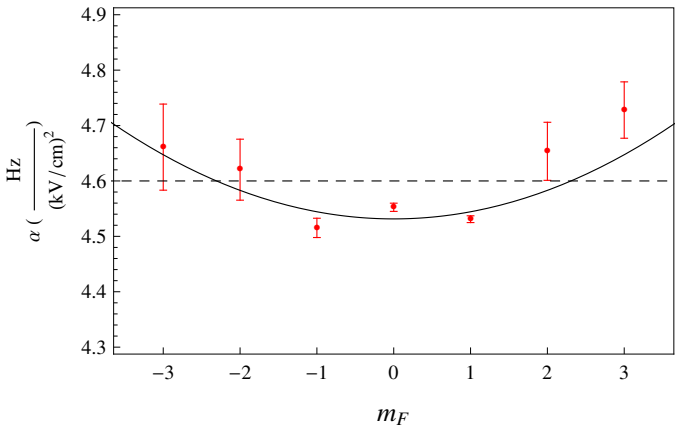

Fig. 6. Cs ground state electric polarizability extracted for each of the seven hyperfine transitions $(4, m_F \leftrightarrow 3, m_F)$. Error bars come from the measurement statistics with sizes depending on the signal to noise ratio of the Ramsey fringe, which is higher for low m_F transitions. The continuous line shows the fit with Eq. (1). The dashed line shows only the scalar contribution in α from Eq. (1).

IV. Conclusion

The Fourier analysis of the Ramsey spectra phase and center frequency has been successfully applied to measured data, extracting the Stark frequency shift, and the motional phase needed to test the electric field model which itself permits the third order Cs ground state polarizability $\alpha_0^{(3)}$ to be inferred. Our preliminary value for $\alpha_0^{(3)}$ was compared to previous measurements of the DC Stark shift. Further work will focus on improving the statistical uncertainties of the measurements and characterize and reduce the systematic effects.

***Abstract*—The work of an efficient design tool for engineers to enhance the frequency stability performance of AT-cut quartz crystal resonator in whole working temperature range is presented. Based on Mindlin's 2D AT-cut plate model, the design tool is a finite element analysis(FEA) program to simulate quartz plate vibration with partial electrodes(mass loading), finite dimensions(free edge), piezoelectric and temperature effects. The simulation and experiment results, including mode chart, electrical response and frequency-temperature characteristics, of a 3.2mm by 2.5mm 40MHz resonator are shown in this study. Finally, an activity-dip-contour-map which locates the high frequency-temperature stability zone is constructed and it guides engineers to do a robust design.**

I. INTRODUCTION

As a key frequency device in almost all electric circuits, AT-cut quartz resonator should be very accurate and high stability, and therefore could not be designed by experiments or trial and error only. Mindlin[1],[2] did a series of work in crystal plate vibration as the base of AT-cut quartz resonator analysis. Lee[3] constructed a FEA program based on Mindlin's 2D model to analyze pure mechanical crystal plate vibration without piezoelectric effects. Yong and Wang[4],[5] extended the work to 3D FEA and some details, like frequency-temperature characteristics and quality factor. Today, some commercial FEA software could also simulate quartz plate vibration. However, it is time consuming to analyze quartz resonator by general commercial FEA programs because of the anisotropic structure and aspect ratio (length/width to thickness) of the quartz plate. Hence, an efficient and accurate enough design tool for modern quartz crystal resonator is always desired.

In this study, a 2D AT-cut quartz plate finite element model based on Mindlin's 2D theory is built. By the weak coupling of quartz, the pure mechanical vibration and piezoelectric effects are considered separately in the FEA to enhance the calculation efficiency. The simulation mode charts by 2D and 1D model show 2D model could contain more complete modes of quartz crystal plate. Due to including piezoelectric effects in the FEA program, the simulation electrical response (at room temperature) and frequency activity dip (in working temperature range) match the experiment results very well.

Today's high volume quartz crystal resonators' business is quite challenging. Cost reduction and maintain high quality is the key for survive. Engineers should take care wide temperature range activity dips of resonators, and this makes argues inside about design and process control. For shortening the development time and saving the cost of frequency temperature stability testing, an activity-dip-contour-map is introduced. The ordinate and abscissa of the map are the length and width of the electrode (or quartz plate), respectively. And the contour level shows the frequency activity dip (in ppm) due to working temperature change. The simulation activity-dip-contour-map is similar to the experiment results and could help engineers to choose a comfortable zone for producing.

II. TWO-DIMENSIONAL AT-CUT QUARTZ PLATE MODEL

Considering a rectangular thin crystal plate shown in Figure 1. the width, length and thickness of the plate are 2c, 2a and 2b, respectively, and it is partially plated by metal as electrodes with 2W by 2L dimension.

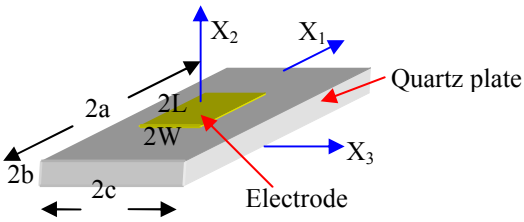

Figure 1. A rectangular crystal plate with electrodes

The equations of motion obtained from Mindlin's 2D plate theory[6]

$$\begin{cases} c_{ijkl}^{(0)}\left(u_{k,li}^{(0)}+\delta_{2l}u_{k,i}^{(1)}\right)+e_{kij}^{(0)}\varphi_{,ki}^{(0)}+T_j^{(0)}=\rho\ddot{u}_j^{(0)} \\ e_{kij}^{(0)}\left(u_{j,ki}^{(0)}+\delta_{2i}u_{j,k}^{(1)}\right)-\varepsilon_{ij}\varphi_{,ij}^{(0)}+D^{(0)}=0 \\ c_{abcd}^{(1)}u_{d,ca}^{(1)}+e_{cab}^{(1)}\varphi_{,ca}^{(1)}-3b^{-2}\left[c_{2bkl}^{(0)}\left(u_{l,k}^{(0)}+\delta_{2k}u_l^{(1)}\right)+e_{a2b}^{(0)}\varphi_{,a}^{(0)}+e_{22b}^{(0)}\varphi^{(1)}\right]+T_b^{(1)}=\rho\ddot{u}_b^{(1)} \\ e_{cab}^{(1)}u_{b,ca}^{(1)}-\varepsilon_{bc}\varphi_{,bc}^{(1)}-3b^{-2}\left[e_{2ijl}^{(0)}\left(u_{j,i}^{(0)}+\delta_{2i}u_j^{(1)}\right)-\varepsilon_{a2}\varphi_{,a}^{(0)}-\varepsilon_{22}\varphi^{(1)}\right]+D^{(1)}=0 \end{cases} \quad (1)$$

where:

$u^{(0)}$, $u^{(1)}$: the zero and first order of mechanical displacement, and $i,j,k,l=1,2,3$; $a,b=1,3$

$\varphi^{(0)}$, $\varphi^{(1)}$: the zero and first order of electrical potential

$T^{(0)}$, $T^{(1)}$: the zero and first order of stress

$D^{(0)}$, $D^{(1)}$: the zero and first order of electrical displacement

c, e, ε: the components of elastics stiffness, piezoelectric stress constant and dielectric permittivity of AT-cut quartz plate, respectively

Defining zero order mechanical strain (ν), mechanical stress (P, Q), electric field (β) and electric stress (P_E, Q_E); and first order mechanical strain (χ), mechanical stress (M), electric field (η) and electric stress (M_E) as shown in Figure 2. and Figure 3.

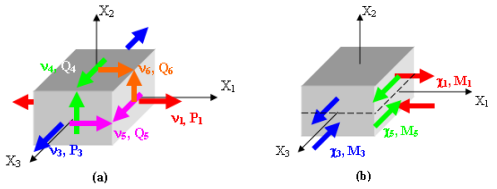

Figure 2. The sketch of strains and stresses: (a)zero order; (b) first order

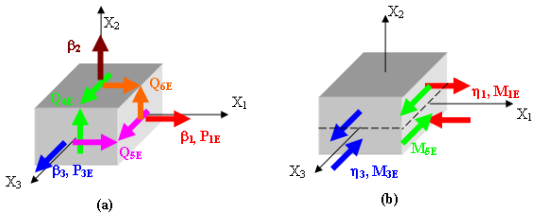

Figure 3. The sketch of electric field and stresses: (a)zero order; (b) first order

equation (2) could be express by these stress items[7]:

$$\begin{cases} P_{1,1}+Q_{5,3} & +P_{1E,1}+Q_{5E,3} & =\rho(1+R)\ddot{u}_1^{(0)} \\ Q_{4,3}+Q_{6,1} & +Q_{4E,3}+Q_{6E,1} & =\rho(1+R)\ddot{u}_2^{(0)} \\ P_{3,3}+Q_{5,1} & +P_{3E,3}+Q_{5E,1} & =\rho(1+R)\ddot{u}_3^{(0)} \\ M_{1,1}+M_{5,3}-Q_6 & +M_{1E,1}+M_{5E,3}-Q_{6E} & =\rho(1+3R)\ddot{u}_1^{(1)} \\ M_{3,3}+M_{5,1}-Q_4 & +M_{3E,3}+M_{5E,1}-Q_{4E} & =\rho(1+3R)\ddot{u}_3^{(1)} \\ D_{1,1}^{(0)}+D_{3,3}^{(0)} & -D_{d1,1}^{(0)}-D_{d3,3}^{(0)} & =-D^{(0)} \\ D_{1,1}^{(1)}+D_{3,3}^{(1)}-D_2^{(0)} & -D_{d1,1}^{(1)}-D_{d3,3}^{(1)}+D_{d2}^{(0)} & =-D^{(1)} \end{cases} \quad (2)$$

introducing a interpolation function for finite element model, and by energy densities in terms of nodal displacement and variational principle, obtained the equations of motion for one element in matrix form:

$$\begin{cases} [M^e][\ddot{U}^e]+[d_m^e][\dot{U}^e]+[K_m^e][U^e]+[K_p^e][\Psi^e]=[\hat{F}^e] \\ [K_p^e]^T[U^e]+[K_d^e][\Psi^e]=[\hat{D}^e] \end{cases} \quad (3)$$

where

$[\mathrm{M}^e]$: element mass matrix; $[\mathrm{M}_m^e]$: element elastic stiffness; $[\mathrm{d}_m^e]$: element damping matrix; $[\mathrm{K}_p^e]$: element piezoelectric coupling matrix; $[\mathrm{K}_d^e]$: element dielectric stress matrix; $[\hat{\mathrm{F}}^e]$ and $[\hat{\mathrm{D}}^e]$ are the element mechanical force and surface electric displacement.

III. FINITE ELEMENT ANALYSIS PROCESS

Assembling all elements of FEM model to obtain the system equations in matrix form are

$$\begin{cases} [M][\ddot{U}]+[d_m][\dot{U}]+[K_m][U]+[K_p][\Psi]=[\hat{F}] \\ [K_p]^T[U]+[K_d][\Psi]=[\hat{D}] \end{cases} \quad (4)$$

Based on weak piezoelectric coupling of quartz, the elastic displacement and electrical potential are solved separately [8] to enhance the calculation efficiency. The FEA process steps are

(i) Free vibration eigenfrequency analysis

$$[M][\ddot{U}]+[K_m][U]=0 \quad (5)$$

Solve (5) as an eigenproblem to get eiengmodes U_1, U_2, … U_n and the natural frequency f_1, f_2, … f_n.

(ii) Static electric potential due to applied voltage

$$[K_d][\Psi]=[\hat{D}'] \quad (6)$$

Give the surface-charge $[\hat{D}']$ as electric excitation signal to solve potential field $[\Psi]$ in the crystal plate.

(iii) Piezoelectric coupling stress due to potential field

$$[K_p][\Psi]=[\hat{F}'] \quad (7)$$

Substituting $[\Psi]$ form step (ii) into (7) to obtain $[\hat{F}']$, where $[\hat{F}']$ is the amplitude of piezoelectric coupling stress due to applied potential. In the next step, $[\hat{F}']$ is the external force to the pure mechanical system.

(iv) Force vibration frequency response analysis

$$[M][\ddot{U}]+[d_m][\dot{U}]+[K_m][U]=[\hat{F}']\cos\omega t \quad (8)$$

where $[\hat{F}']\cos\omega t$ is a harmonic external stress. Equation (8) is solved by mode superposition method to get the harmonic elastic displacement response

$$U=a_1U_1+a_2U_2+\ldots+a_nU_n$$

where U_1, U_2, … U_n are the nature modes in step (i) and a_1, a_2, … a_n are weights of each mode.

(v) Electric displacement and response

$$[K_p]^T[U]+[K_d][\Psi]=[\hat{D}] \quad (9)$$

Substituting U in step (iv) and $[\Psi]$ in step (iii) into (9) to obtain $[\hat{D}]$, the electric displacement response of the system.

(vi) Others

In the post process of the FEA, the admittance curve and equivalent circuit parameters, C_0, C_1, R_1 and L_1 .could be obtained.

IV. Simulation and Experiment Results

A 3.2mm by 2.5mm 40MHz and 7.0mm by 5.0mm 61.44MHz resonator design examples, including mode charts, frequency response verification, temperature stability verification and activity-dip-contour-map, are presented in this section.

A. Mode charts by simulation

The simulation mode charts of a 3.2mm by 2.5mm 40MHz resonator by 2D FEA model and 1D model are shown in Figure 4. and Figure 5. respectively. The former could calculate more complete modes of AT-cut quartz plate and make the simulation more accurate.

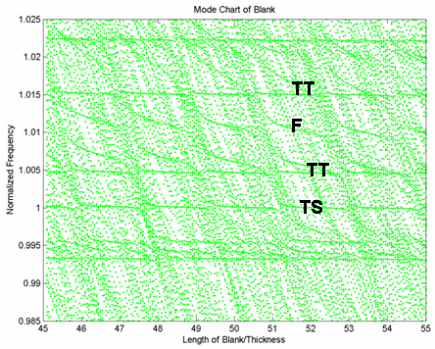

Figure 4. A 3.2mm by 2.5mm 40MHz simulation mode chart by 2D FEA model

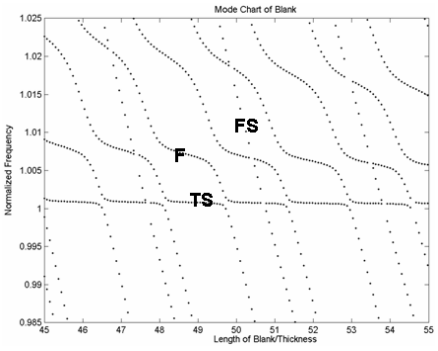

Figure 5. A 3.2mm by 2.5mm 40MHz simulation mode chart by 1D mode

B. Verification in freauency response

Considering the piezoelectric effects as a force excitation in (8), the program calculates the modes "existence obviously". The response Figure 6. shows there are three modes will be measured easily in real products as Figure 6.

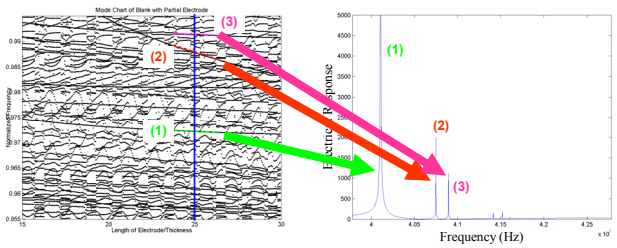

Figure 6. Simulation electrical response

We can plot the mode shape of U1(displacement in X1-axis direction) of modes (1), (2), and (3) in Figure 6. along length and width of the quartz plate, and identify mode (1) is thickness shear and mode (2) and (3) are thickness shear inharmonic overtones. The results were also check by using experiment data. In Figure 7. the left and right chats are the response by simulation and experiment, respectively. The frequency of three strong modes are marked on the simulation charts (the frequency in the parenthesis are experiment data). These two results matched very well.

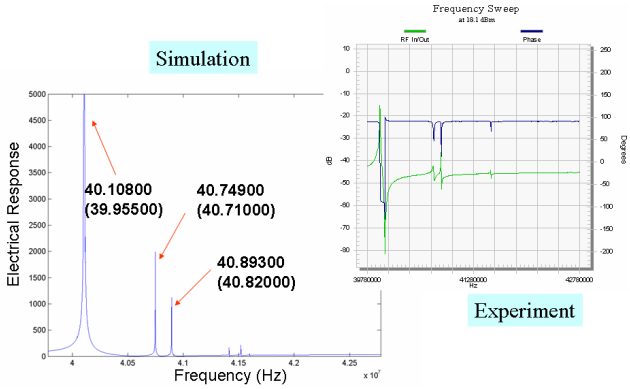

Figure 7. Verification in freauency response

C. Verification in frequency-temperature stability

In Figure 8. the left and right chats are the frequency-temperature stability curves by simulation and experiment, respectively. There are activity dips around 16 °C and 40 °C in both calculating and testing data; that means this FEA design tool could simulate the frequency-temperature characteristics very well in the whole working temperature range.

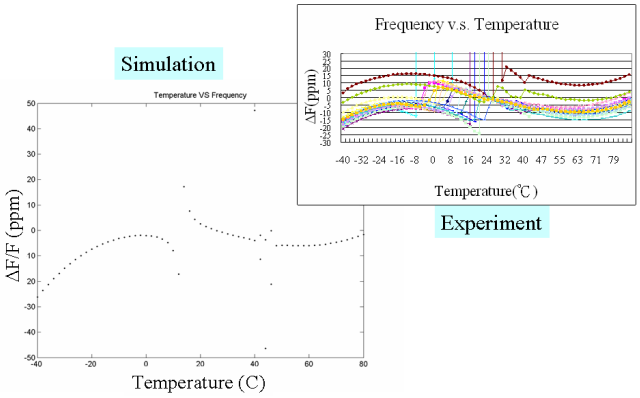

Figure 8. Verification in freauency temperature stability

D. *Activity dip contour map*

Traditionally, a crystal resonator designer should work hard to test many dimension combinations of quartz plate and electrode to verify the frequency-temperature stability performance of each size. These trial and error works make the cost of products development high; however, it spends too much time to simulate temperature characteristics by general commercial FEA program.

The design tool in this study could calculate the activity dip across the whole working temperature fast. Because of its high efficiency, it could finish the simulation for hundreds of different size in a few days with a common PC.

Figure 9 is a sketch of activity-dip-contour-map. The abscissa and ordinate are the length and width of crystal plate or electrode. The vertical axis is the activity dip of each size. The valleys on the map are "good" zones, but the peaks on the map are "bad" zones.

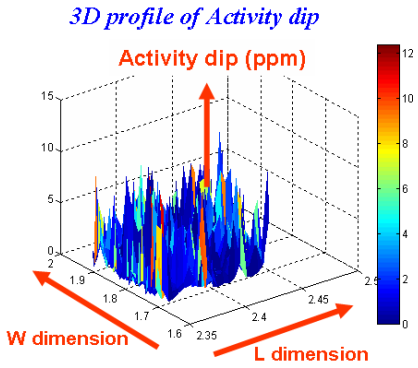

Figure 9. Activity-dip-contour-map

In Figure 10. the left and right chats are the activity-dip-contour-map by simulation and experiment, respectively. It is a 7.0mm by 5.0mm 61.44MHz design example. The main simulation conditions are:

(i) 16 steps in width, 16 steps in length

(ii) -30 ^{o}C to 85^{o}C in 2^{o}C step

(iii) Total simulation time: 5 days by PC 2.4GHz CPU with 4GB memory

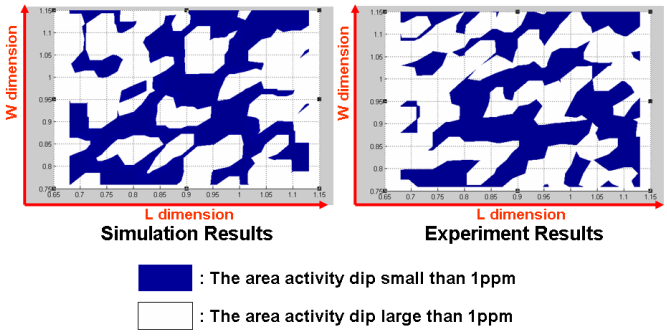

Figure 10. Simulation design map v.s. testing data

Due to some limitation of the FEA model and process variation, the activity-dip-contour-map by calculation and testing does not match very well, but it still could guide engineers to start their work in a better base for robust design.

V. CONCLUSION

A 2D Mindlin plate FEA model considering mechanics, piezoelectrical, and dielectrical effects is constructed. As quartz weak coupling characteristics, the simulation efficiency could be enhanced by calculating the mechanics and electrical response separately. The simulation results of frequency response in room temperature and the activity dip characteristics in working temperature are verified. The simulation tool can provide direct-feeling about design robustness and still need to improve to consider more factors inside model. More study activities between company and academic resources are needed.

***Abstract*— This work presents the results of investigations on different aspects of cryogenic operation of BAW resonators. For the quartz crystal resonators the losses mechanisms, the temperature sensitivity, the amplitude-frequency effect are described for liquid helium temperatures. The corresponding problems are discussed. To overcome some of these problems, the possible solution of operation at higher modes is considered. Some of these higher modes exhibit outstanding quality factors. The highest (for BAW resonators) quality factor value and quality factor-frequency product are measured for the 11th and 13th overtones respectively. In addition, two LGT resonators have been characterized in a wide temperature range. Finally, some preliminary results on utilization of cryogenic quartz resonators as a part of a frequency stabilization closed loop system are given.**

I. Introduction

The quality factor (Q-factor) of resonators and the frequency stability of frequency sources are closely related. Thus, the time and frequency community is always eager for new resonators with higher Q values of any physical nature, i.e. electromagnetic, acoustic, mechanical, etc. Bulk acoustic wave (BAW) quartz resonators at room temperatures have rather high $Q \cdot f$ product of about $15 \cdot 10^{13}$ for the frequency band of 1-100 MHz. The properties of these devices at room temperatures are widely investigated and their limitations are known [1]–[6]. Indeed, the Q-factor is not the only parameter that counts for the frequency stability or even for resonator applicability in frequency sources. Others may be frequency-temperature characteristics, nonlinear phenomena, vibration sensitivity, required environment, etc. Contrary to that, though it is well-known that quartz resonators have much higher Q-factor at cryogenic temperatures, their properties and limitations at these temperatures have not yet been deeply investigated. This work is dedicated to this problem. First, the working conditions and measurement methods for BAW resonators are discussed. Second, three vibration modes, A, B and C are considered at liquid helium temperatures for quartz SC-cut [7] BVA (Boîtier à Vieillissement Amélioré) [8] resonators optimized for working at their 3rd or 5th overtones at 5 or 10 MHz at usual temperatures. An important point here is the temperature sensitivity of this devices. Also, this section concerns amplitude-frequency and self-heating effects and associated limitations. In addition, some results for two higher overtones are given. The next section gives the results of investigation on resonators of a new synthetic material known as Lanthanum Gallium Tantalate (LGT). Finally, the frequency stability results of one possible reference system with a cryogenic quartz resonator are considered.

II. Experimental Set-up

Since the first investigations on cryogenic crystal resonators, the cryocooling technology has made a considerable progress. Thus, for example, cryostats can be substituted with cryogenerators. This substitution simplifies the cryogenic system operation and does not superposes any limitations on experiment time duration. But cryogenerators themselves introduce additional environmental disturbances, such as temperature fluctuations and vibrations mainly due to the helium pulsation at the frequency of 1.7 Hz.

A. Cryogenic System

For all the presented measurements a two-stage pulse-tube cryocooler is used (F-70H from Sumitomo Heavy Industries). The cryocooler is equipped with two shields: a vacuum chamber and an anti-radiation shield to prevent the heat exchange by means of air conduction and radiation respectively. The vacuum level inside the chamber is about 10^{-7} mBar. Both primary and secondary pumps are cut off from the chamber during measurements. Nominally, the cryocooler can absorb up to 1 W at the second stage at the temperature of 4 K. The temperature of the second stage can go down to almost 3 K if no additional thermal losses are present. The thermal losses are mainly introduced with the connecting cables needed for measurement purposes and environmental control. The resonators are inserted inside a copper block attached to the second pulse-tube stage [6].

B. Environmental Control

As it is said above, two main environmental disturbances are temperature fluctuations and vibrations. The temperature fluctuations of the cryocooler second stage due to helium pulses are about 0.3 K. The power spectral density of temperature fluctuations of the second stage in the steady state regime consists of f^{-2} region for frequencies less than about 10^{-2} Hz and f^0 region for higher frequencies. In addition, a clear spurious frequency of 1.7 Hz and its harmonics are present due to the temperature pulsation. To improve the thermal conditions passive and active instability suppression

978-1-61284-110-6/11/$26.00 ©2011 IEEE

methods are used. First, a thermal filter is installed between the second stage and a device under test (DUT). The filter reduces the temperature pulsation down to 15 mK, but increases the absolute temperature difference between these parts. Second, the active closed loop temperature regulation is implemented with a 332 Temperature Controller from Lake Shore, a CERNOX sensor and 20 Ohms heating resistor. The sensor and the actuator are installed in a copper block under the filter. The control system eliminates the f^{-2} region in the temperature fluctuation spectrum and reduces pulses down to 5 mK.

Another type of environmental disturbances is vibration. The permanent pulsation of the helium inside the pulse-tube causes DUT vibrations with a nominal amplitude of $A = 10\mu$m and frequency $f = 1.7$ Hz. The influence of the vibration on resonator parameters and noise can be reduced simply by choosing a proper angle of resonator orientation relatively to the main (vertical) axis of the vibration. No other vibration compensation system is installed for the presented measurements.

C. Measurement Techniques

The resonator characteristics are measured with a 10Hz-500MHz network analyzer HP 4195A equipped with its impedance test adapter. This method is preferable to traditional π-network method for this kind of measurements because the resonator parameters, in particular its equivalent motional resistance, change significantly with temperature. This fact results in an impedance mismatch in the π-network. The measurement capability provides a frequency resolution of 1 mHz, a phase resolution of 0.01 degree and a magnitude resolution of 0.01 dB. The minimum power of the signal source is -50 dBm. A distinctive feature of the network analyzer method is the need for compensation of long connecting cables. Indeed, the resonators are connected to the analyzer with 1 m coaxial cables passing a temperature range from 4 K to the ambient temperature. To compensate cable effects, three calibration references - the open circuit, the short cut and a 50 Ohms resistor - are put close to DUTs at the end of identical cables. Measurements are made with -40 dBm source power for 3rd and 5th overtones and -50 dBm for higher overtones.

The network analyzer is used to trace a so-called GB-plot, i.e. real and imaginary parts of the device admittance $Y(j\omega) = G(\omega) + jB(\omega)$ versus frequency $f = 2\pi\omega$ near a resonance of interest. These data are acquired by means of the GPIB connection and Labview software. After that the parameters of the traditional series $R - L - C$ lumped resonator model are optimized to fit the measured data.

III. SC-cut Quartz Resonators at Cryogenic Temperatures

Quartz BVA resonators are the subject of investigation of the present section, because it has been already shown that electrodeless resonators exhibit higher quality factors than electrode-deposited resonators [5]. More precisely the plano-convex SC-cut resonators optimized at room temperatures are chosen here as the most modern devices (active part diameter: 11 mm, thickness: 0.54 mm, curvature radius: 300 mm).

A. Resonator Losses at Cryogenic Temperatures

The main property of the devices of interest is the total losses that are inversely proportional to the device quality factor Q. The total losses (actually measured results) are a sum of all losses presented in the device, i.e. the material losses, mounting losses, electrical losses, etc. Concerning material part, this type of losses are represented in perfect material with three physical mechanisms [9]–[13]: acoustic wave-phonon dissipation (usually dominant intrinsic loss mechanism in insulating resonators), thermoelastic dissipation (pronounced in plates or rods when the wavelength of flexural vibrations is larger than the thickness of the rod or the plate), phonon-electron dissipation (usually negligible in insulators). Since the first type of the listed material losses is dominant in the devices of interest, it is considered further. The losses due to interaction of the acoustic wave and thermal phonons can be described with two distinct approaches. The first one, introduced by Akheiser [12], considers the interaction of a macroscopic strain wave in an insulator crystal with thermal phonons. Dependency of the phonon frequency on the strain leads to transport of the phonons between macroscopic regions of a crystal restoring the thermal equilibrium. This process is accompanied by acoustic wave energy loss. This approach is valid when the phonon life time is much smaller than a period of the acoustic wave, i.e. $\tau\omega \ll 1$, where τ is a thermal phonon life time and ω is an acoustic wave angular frequency. According to Akheiser approach the material $Q \cdot f$ product at high temperature is found as follows:

$$f \cdot Q = \frac{\rho V_a^2 \left(1 + (\omega\tau)^2\right)}{C_v T \gamma^2 \tau}, \tag{1}$$

where $f = 2\pi\omega$, V_a is the wave velocity, h the Planck constant, γ the Grüneisen parameter, C_v the volumetric heat capacity, T the absolute temperature, ρ the density. The second approach, proposed by Landau and Rumer [13], considers the acoustic wave as a parallel beam of interacting acoustic phonons. The interaction process involves acoustic quanta and individual thermal phonons. It is shown that the acoustic phonon attenuation is a result of three phonon interaction and is proportional to the angular frequency ω in the most studied case (also assuming that $\omega\tau \gg 1$ which is relevant at low temperature) [10]. So, the product of the quality factor and the resonance frequency is given by

$$f \cdot Q = \frac{15\rho V_a^5 h^3}{\pi^5 \gamma^2 \tau K^4 T^4}\omega, \tag{2}$$

where K is the Boltzmann constant. According to this approach the material quality factor does not depend on the angular frequency ω.

It is clear that if the acoustic wave-thermal phonon attenuation is dominant for some range of temperatures, the dependence of the losses on temperature can show which regime is valid for the considered material in given conditions. To

do so, for the first experiments, SC-cut BVA quartz resonators optimized for working on their C-mode (about 5 MHz at room temperature) are characterized between 3.8 and 20 K. The results for 5th overtones of three different modes are shown in Fig. 1.

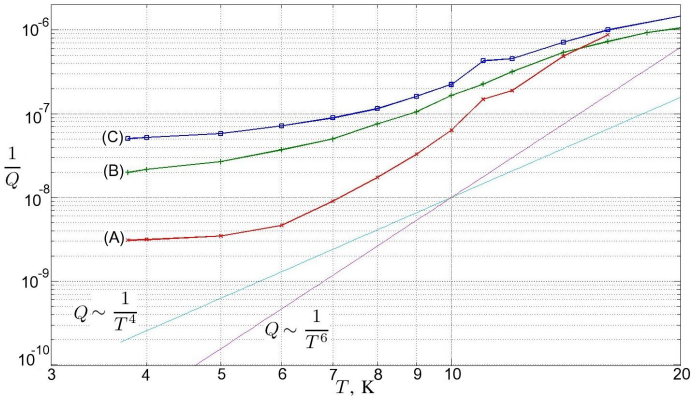

Fig. 1. Measured device losses for 5th overtones of different modes: A-mode (quasi-longitudinal), B-mode (fast quasi-shear), C-mode (slow quasi-shear).

The dependence of the losses on temperature (Fig. 1) clearly shows three regions: a plateau for temperatures less than 6 K (device losses are dominant, such as acoustic diffraction at the resonator surface or damping at the edge of the resonant disk), a linear region in the log-log scale (attributed to acoustic wave - phonon losses) and the second plateau for temperatures about 20 K (region of the maximum absorption [4]). The medium region clearly shows the dependency of the type $Q^{-1} = aT^n + constant$, where n is close to 4 for quasi-shear modes and to 6 for a quasi-longitudinal mode. Though for the latter mode, the dependence does not strictly confirms the slope predicted by the Landau-Rumer theory, the corresponding losses regime is actually dominant in quartz material at the liquid helium temperature. The increase of the power n has been already observed [10], [11].

The highest measured Q-values among 5th overtones of three modes are $325 \cdot 10^6$ for the A-mode, $50.5 \cdot 10^6$ for the B-mode, $1.99 \cdot 10^6$ for the C-mode. This sequency corresponds to the list of modes sorted out from the best trapped mode to the less trapped one according to the Stevens and Tiersten model [14]. Among all modes of 3rd and 5th overtones the best result is achieved for the 5th overtone of the A mode with $Q \cdot f$ product of about $5.1 \cdot 10^{15}$ which is the highest result in comparison with previous investigations [6]. But already starting at this stage, the problems of practical utilization arise. Since at cryogenic temperatures the resonators have very low values of equivalent motional resistance (e.g. about 3 Ohm for the 5A mode), minimization of the active load is required in order to preserve the high quality factor. This considerably complicates the choice of signal sources and amplifiers.

B. Temperature Sensitivity

Another important characteristic of a resonator is its temperature sensitivity. Indeed, to minimize the influence of the environment on the frequency source, the sensitivity of the resonance element has to be minimized. Fig. 2 shows the fractional frequency temperature sensitivity for the three modes considered in the previous subsection.

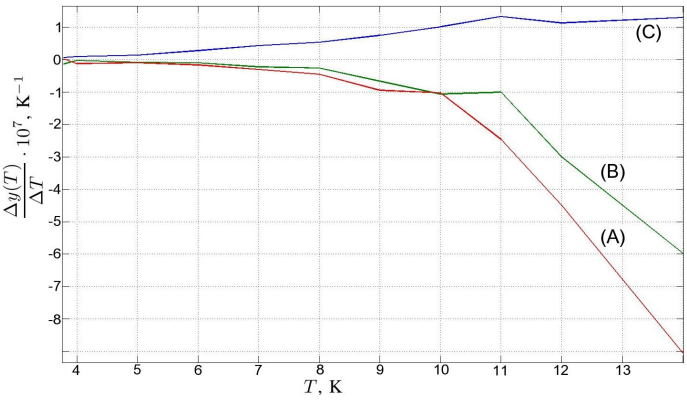

Fig. 2. Fractional frequency temperature sensitivity: A, B and C-modes.

As it is clearly seen from Fig. 2 the investigated modes does not have any turn-over point. The absence of a turn-over point poses serious problems in terms of crystal temperature stabilization. In general, the smaller sensitivity corresponds to lower temperatures for these devices. At 4 K the sensitivities are $2 \cdot 10^{-9}$ K^{-1} for the A-mode, $3 \cdot 10^{-9}$ K^{-1} for the B-mode and $1 \cdot 10^{-8}$ K^{-1} for the C-mode. These results suggest that to obtain a desired fractional frequency stability of 10^{-13}, in best case, the temperature has to be controlled within 0.5 mK.

C. Amplitude-Frequency Effect

BAW resonators are nonlinear devices in nature. Resonator properties considerably depend on the power level of the excitation signal. This dependence becomes even more pronounced with the increase of the quality factors, since the resonance frequency shift is proportional to the product of the dissipated power and Q. To characterize this effect in cryogenic temperatures, the impedance of the resonator under test is measured with different levels of an excitation signal for the 5th overtone of the A-mode (that with the highest Q). The results are shown in Fig. 3.

Fig. 3 suggests that already for the dissipation power of $P = 0.22\mu$W (Curve (2)) the impedance curve distortion exists. Furthermore, for $P = 1.6\mu$W the resonator self-heating effect becomes apparent. Also, it can be seen that for an increasing power P, the equivalent motional resistance also increases. These effects can even lead to temperature-amplitude oscillations. These oscillations are characterized by two states of low and high dissipation powers corresponding also to higher and lower values of motional resistance. In addition, the higher driving signal levels degrades resonator noise characteristics [15].

The strong amplitude-frequency and self-heating effects arise another problem concerning effective utilization of cryogenic quartz crystal resonators in actual applications. Indeed, in order to avoid this effect the driving signal has to be kept

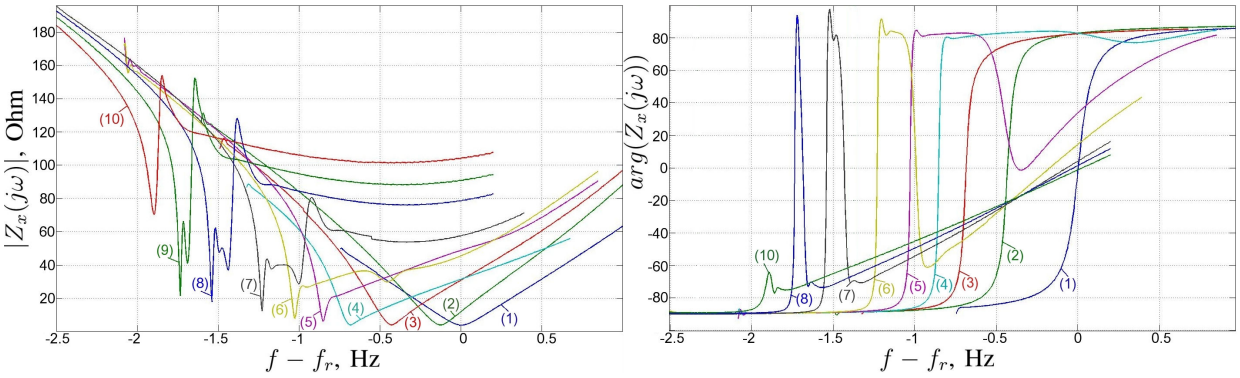

Fig. 3. Impedance of the resonator near the A-mode on 5th overtone for different dissipation powers: (1) $P = 0.09\mu$W, $I = 0.154$mA (2) $P = 0.22\mu$W, $I = 0.237$mA, (3) $P = 0.42\mu$W, $I = 0.324$mA (4) $P = 0.64\mu$W, $I = 0.403$mA, (5) $P = 1.6\mu$W, $I = 0.479$mA (6) $P = 2.26\mu$W, $I = 0.538$mA, (7) $P = 4.87\mu$W, $I = 0.624$mA (8) $P = 9.20\mu$W, $I = 0.719$mA, (9) $P = 12.35\mu$W, $I = 0.757$mA (10) $P = 17.20\mu$W, $I = 0.494$mA.

very low, but this fact degrades the system signal-to-noise ratio as well as it requires additional amplification stages. This problem is even worse lower values of the resonator equivalent motional resistance.

D. Higher Overtones

In order to deeply investigate the abilities of devices under tests, some higher resonator harmonics have been characterized at cryogenic temperatures. Thus, Fig. 4 demonstrates the presence of different anharmonics of the 11th overtone of the A-mode. The corresponding indexes for identifying the anharmonics are marked on the figure. The best anharmonic mode has a quality factor of $417 \cdot 10^6$ at the frequency of 68823167 Hz with an equivalent resistance of 19 Ohms. The estimated $Q \cdot f$ product for this resonance equals to $2.87 \cdot 10^{16}$ Hz. Thus, the DUT working at this resonance at cryogenic temperatures has the highest reported quality factor ever measured on BAW resonators.

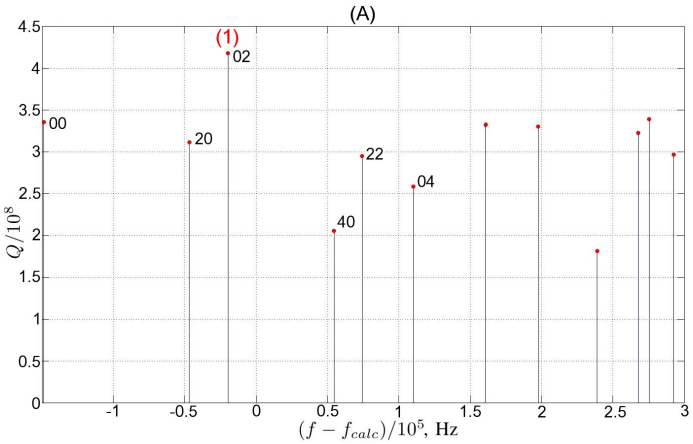

Fig. 4. Different anharmonics of the 11th overtone of the the A mode ($f_{calc} = 68.842620$ MHz).

In the same way the 13th overtone of the A-mode is characterized. Here only three anharmonics are found. The best of them has a Q value of $377 \cdot 10^6$ at 81392723 Hz with an equivalent resistance of 30 Ohms. Thus, the highest $Q \cdot f$ measured on BAW resonators can reach $3.07 \cdot 10^{16}$Hz

So, these modes could be perspective for a practical utilization. But the issue of the selection or rejection of the undesired modes should be solved first in autonomous systems such as oscillators. Also, higher Q values result in a stronger amplitude-frequency effect [16].

IV. LGT Resonators at Cryogenic Temperatures

The LGX material family is promising for designing BAW resonators with high quality factors. Among this materials the Lanthanum Gallium Tantalate (LGT) and Lanthanum Gallium Silicate (LGS) are the most commonly known. Nevertheless, their properties have not been yet investigated for temperatures lower than 80 K. In this section, investigation results on BVA-type plano-convex Y-cut LGT resonators (active part diameter: 10.2 mm, thickness: 0.65 mm, curvature radius: 100 mm) are presented. The attempts to characterize their LGS counterparts have been abandoned since they show a decrease of quality going from room to cryogenic temperatures.

A. LGT Resonator Losses

The characteristics of two LGT resonators of similar origin have been measured in the wide temperature range $(4-80$ K). The results for their quality factors are shown in Fig. 5. The maximum Q-factor is just about $7.2 \cdot 10^6$ that is only 5 times higher than its value at room temperature. Unlike in the case of quartz resonators, device losses dependence on temperature seem to be rather uniform. The only physical phenomenon clearly seen is the peak of losses at about 40 K. It can be attributed to relaxation processes due to the presence of impurities. In addition, a very important difference between two resonators is observed. These results suggest that the LGT resonator technology is far from being optimized in terms of different types of losses: device losses cover material losses. On the other hand, further technology development might lead to considerable increase of their quality factors in cryogenic conditions.

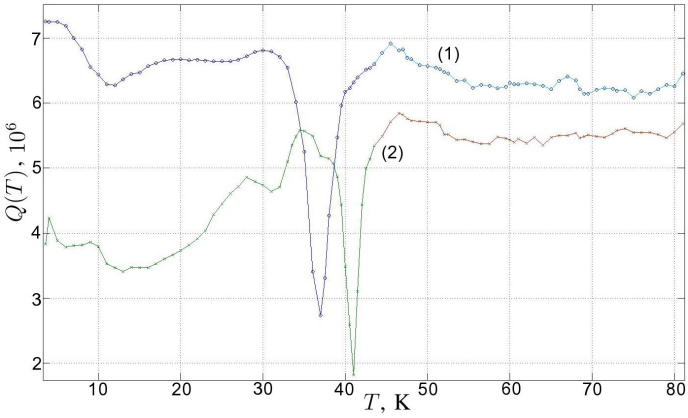

Fig. 5. LGT resonator quality factor Q as a function of temperature T (two resonators).

B. LGT Resonator Temperature Sensitivity

The dependence of the fractional stability on the temperature is also examined for the LGT resonators (see Fig. 6). Both resonators have a turn-over point between 6 and 7 K which is advantageous for creating a high quality temperature stabilization system.

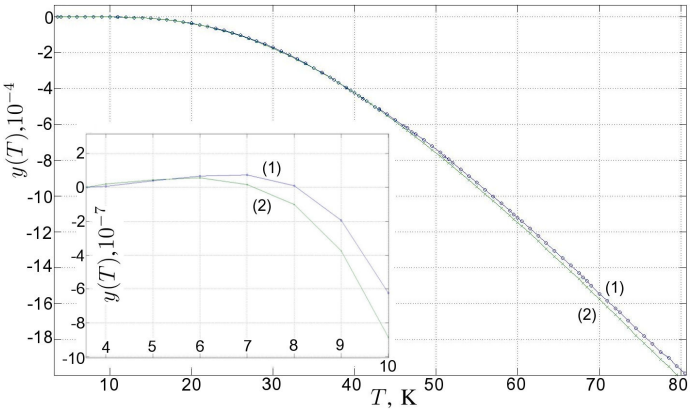

Fig. 6. Fractional frequency y versus temperature T for two LGT resonators.

V. Frequency Stabilization System Based on Cryogenic Quartz Resonator

This section shows the preliminary results on a system based on a quartz resonator working at liquid helium temperatures. For this purpose a frequency stabilization system based on an external high quality resonator is implemented [17]. The general scheme of this system is shown in Fig. 7. The system consists of a voltage-controlled oscillator used as a reference for a frequency synthesizer whose output signal frequency corresponds to the resonant frequency of the BAW device. The resonator is put into a so-called π-network implemented at cryogenic conditions and connected with the long cables with the other components. The signal filtrated by the resonator is compared with the original one (also passed through the cryogenerator to compensate the parasitic effects of cables) with a double balanced mixer. The resulting signal is filtrated and used to correct the frequency variation of the VCO. In fact, only the resonator π-network and the through connection for the original signal channel are placed inside the cryogenerator.

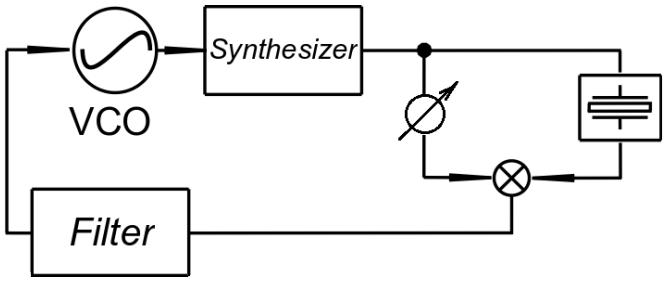

Fig. 7. External frequency discriminator system.

The system is designed for working on the resonator 5th overtone of the A-mode preserving a loaded Q of only $16{\cdot}10^6$. The frequency stability results in terms of Allan deviation are shown in Fig. 8. This figure compares the results measured for the stand-alone voltage-controlled oscillator and the closed loop system after different periods of continuous cryogenic system operation. The stability improvement is clearly seen for the long averaging times τ, though for short τ the stability is degraded due to internal loop noise sources. Comparing two cases of closed loop system, the 12-hours case (measurements are made within first 12 hours of cryogenerator permanent operation) exhibits a τ^{+1} slope of the Allan deviation that corresponds to the linear frequency drift. The 60-hours case (measurements after at least 60 hours of operation) uncover a $\tau^{+1/2}$ behavior that is a result of the VCO f^{-4} or cryogenic resonator f^{-2} phase noises. Both types of noise can be attributed to resonance frequency sensitivity to the temperature random-walk noise [18]. These results suggests the presence of very long time constants in the system (probably due to thermal effects).

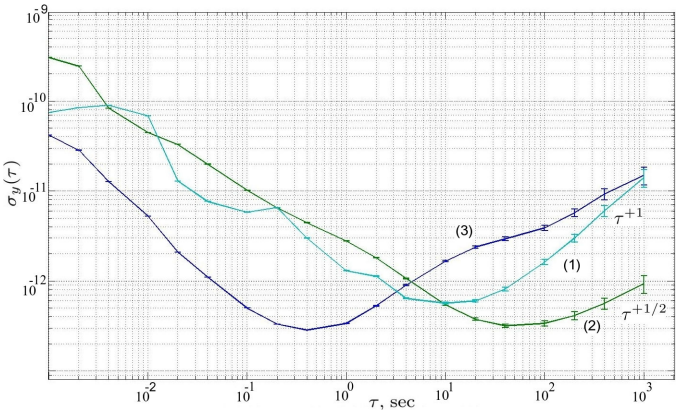

Fig. 8. Allan deviation of the closed-loop frequency stabilization system measured at first 12 hours of cryogenerator operation (1), measured after at least 60 hours of cryogenerator permanent operation (2) and compared with a stand-alone oscillator (3).

Though experimental conditions are not so ideal, tests with a passive reference as well as an oscillator based on the

presented devices are presently in progress. The aim of these tests is to achieve the frequency stability corresponding to the measured values of the quality factor.

VI. Conclusion

Though quartz resonators can achieve extraordinary values of quality factors at cryogenic conditions, deeper investigations show the presence of severe problems concerning practical utilization of these devices. The difficulties come from the small values of equivalent motional resistances, the strong amplitude-frequency effect, the self-heating, the absence of a temperature turn-over point. Some of these disadvantages could be overcome for higher overtones, such as 11th or 13th, exhibiting even higher Q values. The LGT resonators are still perspective candidates for cryogenic operation, since the device losses overshadow material losses. The preliminary investigations on the passive frequency stabilization system based on cryogenic BAW resonators show rather moderate results due to a non-optimized environment, internal noise sources and a reduced quality factor.

Nonlinearities for Parametric Pumping of Quartz UHF Oscillators

R.L. Kubena[1], Y-K Yong[2], D.J. Kirby[1] and R.J. Joyce[1]

***Abstract*— The feasibility of a parametric amplification method for improving the *Q* of UHF quartz oscillators is considered. A fundamental thickness shear resonator operating at about 500 MHz was studied for estimating the magnitude of fractional change in stiffness, $\Delta k/k$ that could be obtained at resonance and off-resonance. The $\Delta k/k$ is employed in a parametric pumping of the thickness shear mode of vibration. A relationship between the $\Delta k/k$ at resonance and $\Delta k/k$ at off-resonance was derived. For a 532 MHz fundamental thickness shear resonator, a $\Delta k/k$ = $3.8\text{x}10^{-4}$ /V at resonance, and a $\Delta k/k$ = $1.6\text{x}10^{-7}$ /V at off-resonance was found. The off-resonance data compares well with measured data of $\Delta k/k$ = $1.7\text{x}10^{-7}$ /V. Our off-resonance study of $\Delta k/k$ established that it is independent of the sign of electric potential drive that is $\Delta k/k$ is a rectified excitation and therefore appears at twice the excitation frequency.**

The parametric amplification phenomenon is governed by the Mathieu equation. MATLAB Simulink models of the Mathieu equation were developed to establish the baseline criteria for parametric amplification to improve the resonator *Q*. The resonator model was excited at a frequency ω_A over a range that included the natural frequency ω_0 and the third overtone ω_3. The parametric drive frequency ω_P was set equal to $2\omega_A/n$ (n=1, 2, 3, ….). The model results showed that for parametric drive frequencies of $\omega_P = \omega_A$ (for fundamental mode operation), and $\omega_P = \omega_A/3$ (for third overtone operation), the $\Delta k/k$ needed for parametric amplification is in the range of 0.001 to 0.003 for a resonator *Q* of 9,000 to 15,000. It was observed that there was shift of the resonance frequency with the parametric amplification resulting from the change in dc stiffness $\Delta k/k$ of the thickness shear mode.

I. INTRODUCTION

It is well known that flicker phase modulation (PM) noise in the sustaining circuit of oscillators causes flicker frequency modulation (FM) noise to the oscillator output frequency given by $L_{osc}(f_f) = L_{ckt}(1\ Hz)f_f^2/(4f_f^3Q_L^2)$ [1]. Thus, increasing the loaded Q_L can help in reducing the phase noise. Previous reports have shown that parametric amplification can be used to increase the *Q* of silicon nano-resonators [2-4]. However, to date very few studies have been made for shear-mode quartz resonators. In this paper, we investigate whether parametric amplification is feasible for improving the Q of UHF quartz resonators.

Fundamental and third overtone thickness shear-mode resonators are investigated to establish the criteria needed for parametric amplification. Specifically the fractional change in stiffness $\Delta k/k$ in the Mathieu equation that governs parametric amplification and the resonator Q are considered. MATLAB Simulink models for the Mathieu equation were developed to study the relationships between the parametric frequencies, $\Delta k/k$, and the resonator *Q*. A study of the $\Delta k/k$ off-resonance was needed to establish the magnitude of the change in stiffness for given applied voltage levels.

II. MECHANICAL NONLINEARITIES IN QUARTZ

Quartz is known to have small mechanical nonlinearities in its elastic stiffness. These nonlinearities in quartz resonators are exhibited in well documented phenomena such as their frequency-temperature [5, 6], acceleration sensitivity [7, 8] and drive level dependency [9, 10]. The nonlinear mechanical effects are governed by the piezoelectric equations with finite strains and nonlinear elastic constants as given below in Equations (1) – (3):

A. Strain-displacement, and electric field-potential relations

$$S_{ij} = \frac{1}{2}(u_{j,i} + u_{i,j} + u_{k,i}u_{k,j} + u_{k,j}u_{k,i})$$
$$E_i = -\phi_{,i} \tag{1}$$

Here S_{ij} is the mechanical finite strain for the relatively large mechanical displacements u_i. E_i and φ are respectively the electric field and electric potential.

B. Constitutive relations

$$T_{ij} = (C_{ijkl} + C_{ijklmn}s_{mn} + C_{ijklmnop}s_{mn}s_{op})s_{kl} + \eta_{ijkl}\dot{s}_{kl} - e_{kij}E_k$$
$$D_i = e_{ijk}s_{jk} + \varepsilon_{ik}E_k \tag{2}$$

where T_{ij}, C_{ijkl}, C_{ijklmn}, $C_{ijklmnop}$, η_{ijkl}, e_{kij}, D_i, ε_{ik} are respectively the mechanical stress, linear elastic constants, third order nonlinear elastic constants, fourth order nonlinear

elastic constants, viscosity constants, piezoelectric stress constants, electric displacements, and dielectric permittivity. The values of the material constants of quartz are well known and could be found in the literature, except for the fourth order nonlinear elastic constants. The fourth order elastic constants are needed for modeling the Duffing effect at very high drive voltages. Since most of the fourth order elastic constants are not well known, we neglect the fourth order elastic constants in our present models.

C. *Equations of motion and electrostatics*

$$\begin{aligned} (T_{ij} + T_{jk}u_{i,k})_{,j} + \rho b_i &= \rho \ddot{u}_i \\ D_{i,i} &= 0 \end{aligned} \tag{3}$$

The equations of motion and electrostatics are for any piezoelectric volume V where for boundary conditions on the surface S enclosing the piezoelectric volume we specify surface traction $P_i = n_j(T_{ij} + T_{jk}u_{i,k})$ or mechanical displacements u_i, and electric displacements D_i or electric potential φ.

III. Nonlinear Piezoelectric Model of an AT-cut Quartz Plate

The governing equations (1) - (3) along with the necessary material constants for the AT-cut quartz were implemented in a COMSOL finite element tool. Figure 1 shows a model of the 532 MHz fundamental thickness shear AT-cut quartz resonator. The mode shape of the energy trapped fundamental thickness shear mode is shown in Figure 2.

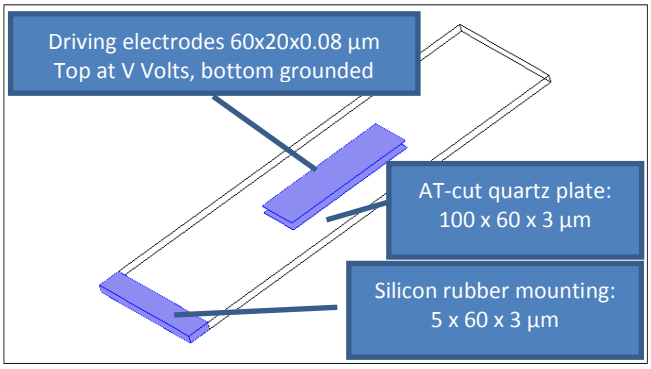

Figure 1. Model of a 532 MHZ AT-cut quartz plate resonator with dimensions for electrodes and mounts.

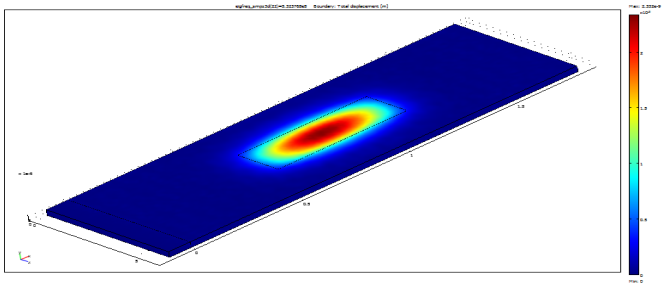

Figure 2. Mode shape of the energy trapped fundamental thickness shear mode in a 532 MHz AT-cut quartz plate resonator.

A. *Drive level dependency of the thickness shear mode resonator*

The effects of nonlinear elastic stiffness are observed in the phenomenon of drive level dependency, that is, the resonant frequency changes with the drive level of electric potential at the top electrode of quartz plate in Figure (2). Figure 3 shows the frequency response of the AT-cut plate resonator at two drive levels: 1 mV and 100 mV. A change in resonant frequency of 18.8 ppm at 100 mV was observed in the data. The resonant frequency is given by:

$$f = \frac{1}{2\pi}\sqrt{\frac{k}{m}} \tag{4}$$

where k is the modal stiffness, and m is the modal mass. Here a small frequency change with drive level electric potential is due to a small change in the modal stiffness Δk. Hence a fractional change in frequency can be related to a fractional change in modal stiffness, and using a binomial expansion:

$$\frac{\Delta f}{f} \cong \frac{1}{2}\frac{\Delta k}{k} \tag{5}$$

Therefore the fractional change in modal stiffness $\Delta k/$k is 37.6 ppm at 100 mV, or with normalization to 1 V,

$$\frac{\Delta k}{k} = 3.76x10^{-4}/\mathrm{V} \tag{6}$$

for the 532-MHz fundamental thickness shear mode of vibration of the AT-cut quart plate resonator represented in Figures (1) and (2).

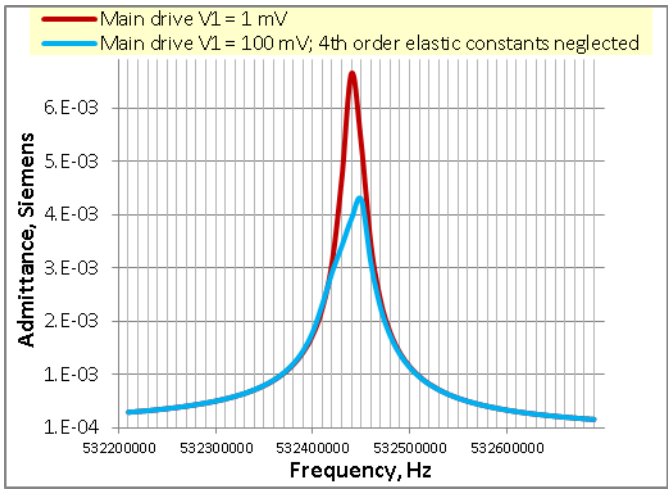

Figure 3. Frequency deviation versus AC electric potential for a 532 MHz AT-cut quart plate resonator.

B. Nonlinear effect of static electric potential on the shear strain in the AT-cut quartz plate resonator

The parametric amplification of a vibration mode in a mechanical resonator requires that the modal stiffness k of the vibration mode can be varied by a pumping excitation; that is k is nonlinear of the form:

$$k(1+\frac{\Delta k}{k}\sin(\omega_P t)) \tag{7}$$

where ω_P is the frequency of the parametric pumping excitation and t is time. Here $\Delta k/k$ is the fractional change in modal stiffness due to the parametric excitation.

For the thickness shear mode of Figure (2), and a 1 V AC applied at the plate resonance frequency, Eqn. (6) gives $\Delta k/k = 3.76\text{x}10^{-4}$. A more general description for parametric excitation may not involve pumping at a mechanical resonance; we therefore first investigated the $\Delta k/k$ at frequencies not near the resonance frequency, that is, at "off-resonance" frequencies, or at DC electric potentials. In this case, we also investigated whether $\Delta k/k$ is dependent on the sign of the drive level electric potential.

The thickness shear mode of vibration in the AT-cut quartz plate is governed predominantly by the shear strain S_{xy} (or S_{12}); therefore a study of the effects of DC electric potential at the top electrode (Figure 1) on the shear strain S_{xy} is useful. Figure 4 shows the COMSOL finite element results of positive and negative electric potential, respectively, on the shear strain S_{xy} at the midpoint of the quartz plate. Two second order regression curve fittings were performed on the COMSOL data: one for the positive electric potential, and the other for the negative electric potential. Two regression equations are shown on the graph, one for positive electric potential and the other for negative electric potential. We note that while the slope of both regression equations is the same, the coefficient of the nonlinear term changes sign with the electric potential. This change in sign indicates that the $\Delta k/k$ for the shear strain S_{xy} is *not* dependent on the sign of the drive level electric potential and that it is a rectified function. The $\Delta k/k$ modulation then appears at twice the excitation frequency.

The regression equations can be written in the form:

$$V = 1.76x10^6 S_{xy}(1 \pm 0.126 S_{xy}) \tag{8}$$

Since the shear strain S_{xy} in eqn. (8) is approximately $5.7\text{x}10^{-7}$ /V, we calculate that

$$\frac{\Delta k}{k} = 0.126 S_{xy} = 7.16x10^{-8}/V \tag{9}$$

C. Quality factor Q of a mode of vibration, dynamic Δk/k versus static Δk/k

If a thickness shear resonator is represented by a single degree of freedom in shear strain S_{xy}, then the ratio of the dynamic shear strain at resonance at drive V to its static shear strain at DC V is equal to its quality factor Q, that is:

$$\frac{S_{xy}\big|_{dynamic}}{S_{xy}\big|_{static}} = Q \tag{10}$$

where $S_{xy}\big|_{dynamic}$ is the peak shear strain at resonance for a given electric potential V_{AC} drive, and $S_{xy}\big|_{static}$ is the static shear strain at the same electric potential, V_{DC}.

Since Eqn. (9) shows that the $\Delta k/k$ is linearly dependent on S_{xy} we could use Eqn. (10) to relate the $\Delta k/k$ of Eqn. (6) that was obtained at peak resonance to a $\Delta k/k$ at "off-resonance". For a given electric potential, the $\Delta k/k$ at peak resonance is equal to Q times the $\Delta k/k$ "off-resonance":

$$\frac{\Delta k}{k}\bigg|_{dynamic} = Q\frac{\Delta k}{k}\bigg|_{static} \tag{11}$$

The Q for the fundamental thickness shear mode in Figure 3 was 24000 which upon substitution into Eqn. (11) we can calculate the equivalent static $\Delta k/k$ from the dynamic $\Delta k/k$ of Eqn. (6):

$$\frac{\Delta k}{k}\bigg|_{static} = 1.57x10^{-7}\ /\text{V} \tag{12}$$

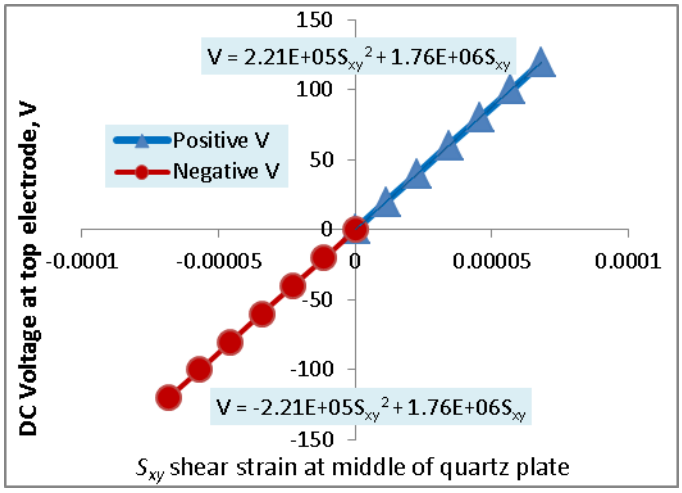

Figure 4. Shear strain s_{xy} at the midpoint of the AT-cut plate versus the static electri potential.

The static $\Delta k/k$ in Eqn. (12) is about two times larger than the static $\Delta k/k$ in Eqn. (9). This agreement is reasonable because the static $\Delta k/k$ of Eqn.(9) is for the shear strain S_{xy} at one point in the plate while the static $\Delta k/k$ of Eqn.(12) is for the thickness shear mode that is predominantly governed by the shear strain S_{xy} distributed across the thickness of the plate.

Equation (11) is useful for estimating the $\Delta k/k$ for parametric excitations at "off-resonance" frequencies. In designing experiments for parametric amplification of the thickness shear mode, the equation is useful for determining the feasibility of parametric pumping at "off-resonance" frequencies.

IV. Mathieu Equation, and Parametric Amplification of Mechanical Resonators

We discuss Mathieu equation in terms of a single degree of freedom resonator in Equation (13). We could modify the spring stiffness k to a nonlinear spring stiffness $k[1+(\Delta k/k)\sin(\omega_P t)]$ so that the governing equation for the resonator is

$$\frac{F}{m}\sin(\omega_A t) = \ddot{u} + \frac{\omega_0}{Q}\dot{u} + \omega_0^2(1+\frac{\Delta k}{k}\sin(\omega_P t))u \qquad (13)$$

where F is the force on the mass m, u is the displacement, and Q is the quality factor. Here ω_A is the activation frequency, while ω_P is the parametric frequency. Equation (13) is the Mathieu equation that yields parametric amplification for parametric frequencies [11]

$$\omega_P = 2\omega_0 / n \text{ for } n = 1,2,3,.... \qquad (14)$$

A. *MATLAB Simulink model of the Mathieu equation*

A MATLAB Simulink model for the Mathieu equation was developed to study the effects of parametric amplification on the Q of a resonator. Figure 5 shows a MATLAB Simulink model of the Mathieu equation. Figure 6 shows sample input acceleration to the model (top graph), the "rectified" parametric excitation (middle graph) using a ω_0 drive (n = 1), and the sample output displacement Z (bottom graph).

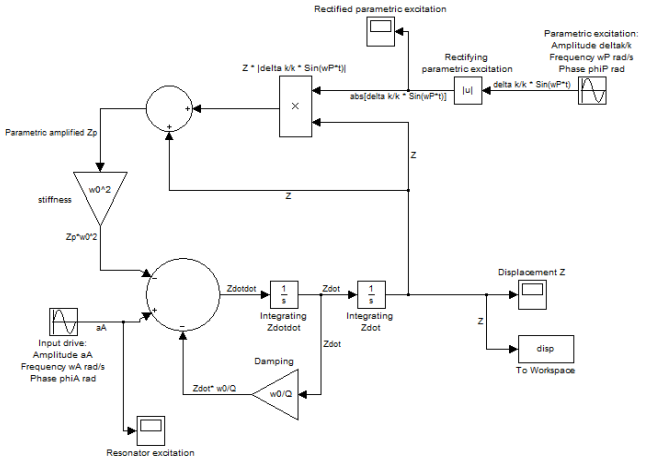

Figure 5. MATLAB Simulink model of the Mathieu equation.

B. *Effects of parametric amplification on the Q of a resonator*

We study the effects of parametric amplification on the Q of a resonator using various values of $\Delta k/k$ and two modes of pumping: (a) pumping the fundamental using a ω_0 drive (n = 1), and (b) pumping the third overtone using a ω_0 drive (n = 3).

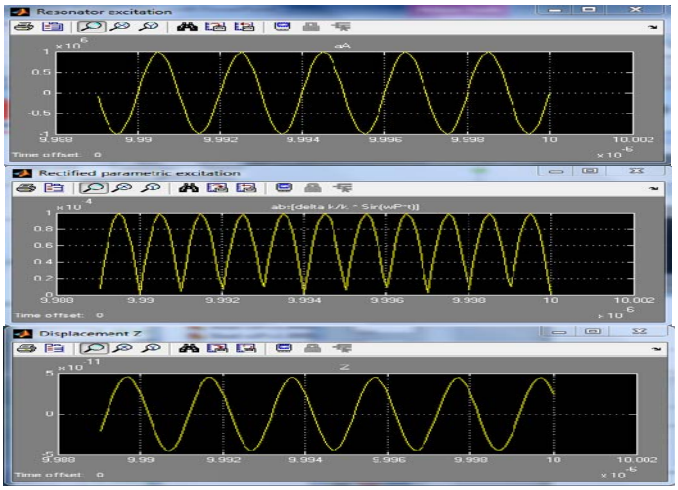

Figure 6. Sample input acceleration (top), parametric excitation (middle), and output displacement (bottom) for the MATLAB Simulink model of the Mathieu equation. ω_0 drive (n = 1).

Figure 7 shows the frequency response of the resonator with a natural frequency ω_0 equal to 500 MHz and an initial Q equal to 15000. In this case, the parametric pumping frequency ω_P is set equal to the activation frequency ω_A. This is equivalent to the pumping of the fundamental thickness shear mode using a ω_0 drive (n = 1). We observe that the starting Q = 15,000 of the resonator could be increased to Q = 70,000 for a $\Delta k/k$ = 0.001.

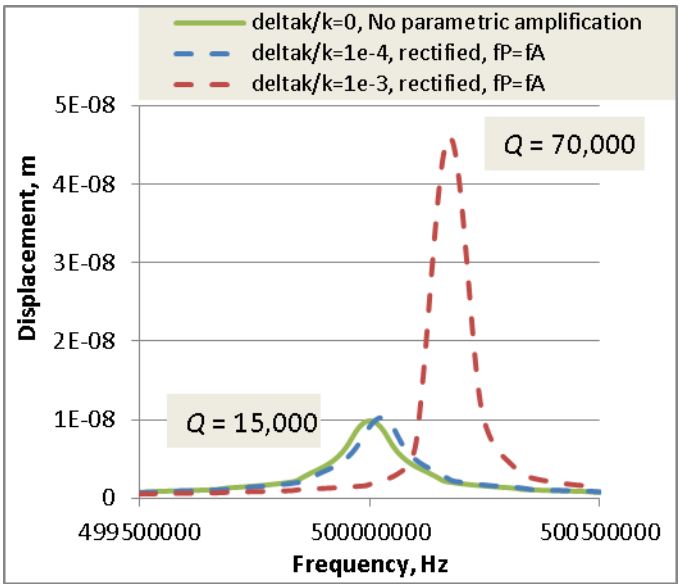

Figure 7. Simulink model result of Mathieu equation with parametric amplification, $\omega_P = \omega_A$ and n = 1.

For our thickness shear resonator when n = 1, there will be parametric self pumping since the excitation force F will yield a $\Delta k/k$ that is "rectified" so that the parametric frequency ω_P is effectively $2\omega_0$. However such parametric self-pumping is

likely limited by the "Duffing" effect if higher order nonlinear terms are included in the modeled dynamics.

Figure 8 shows the frequency response of the resonator with a natural frequency ω_0 equal to 1500 MHz and a Q equal to 9000. Here the parametric pumping frequency ω_P is set equal to one third of the activation frequency ω_A. This is equivalent to the pumping of the third overtone thickness shear mode (~1500 MHz) using a fundamental thickness shear mode (500 MHz) ω_0 drive (n = 3). This will require a resonator design with the third overtone frequency $\omega_3 \sim 3\omega_0$.

We observe that the resonator Q could be increased from 9,000 to Q = 13,000 for a $\Delta k/k$ = 0.003. It was observed that in both Figs. 7 and 8, there was considerable shifting of the resonance frequency; however this frequency shift could be due to the rectified nature of the fractional change in stiffness $\Delta k/k$ of the mode of vibration.

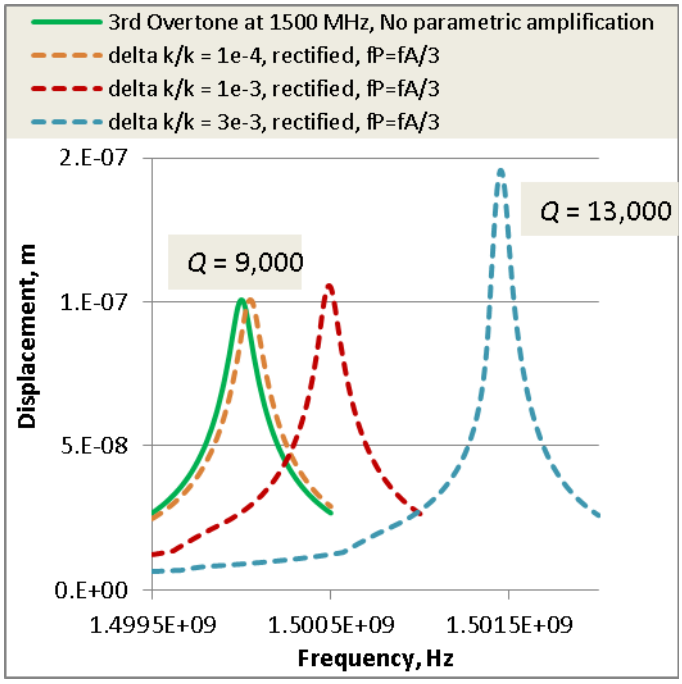

Figure 8. Simulink model result of Mathieu equation with parametric amplification, $\omega_P = \omega_A/3$, n = 3

V. Experimental Results for Nonlinear Shiftness Modulations of Quartz Thickness Shear Resonators.

AT-cut quartz shear mode resonators operating at 507-MHz were used to estimate the magnitude of the fractional change in stiffness, Δk/k, obtained under non-linear drive conditions and also to investigate parametric amplification effects.

A typical admittance measurement involves a single swept frequency source while monitoring the device current and voltage. The magnitude of the admittance Y of the device is then $|Y| = |I/V|$. This measurement can readily be performed with a single source Agilent admittance meter. However, measurement of the admittance of a resonator driven simultaneously with two different frequencies presents a challenge in that the typical admittance meter can no longer provide the dual excitation frequencies. Therefore, an experimental set-up was designed and built specifically to accommodate the dual frequency inputs and provide admittance information of the device-under-test.

A schematic of the experimental set-up for the non-linear drive studies is presented in Figure 9. In this case, the quartz resonator is excited by an input derived from a Holzworth HS300 2A 2-channel synthesizer. The Holzworth synthesizer contains a single OCXO crystal oscillator and provides two drive signals of differing frequency, amplitude and phase. These two drives are phase coherent in that they are driven by the same internal reference which eliminates any drift between them. These signals are swept in frequency and summed in a power combiner to serve as the excitation for the resonator. An Agilent DSO9404A digital storage oscilloscope with differential active probes monitors the voltage and current associated with the resonator and the device admittance Y is computed through post processing. The voltage across the resonator is measured with the first active probe and the current is derived by monitoring the voltage across a 10Ω sense resistor using the second active probe.

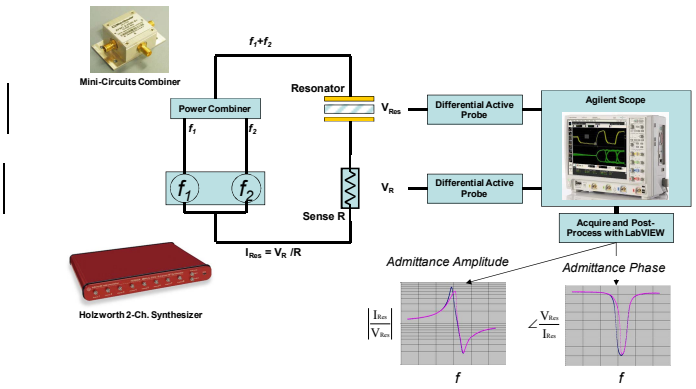

Figure 9. Schematic of the experimental set-up for parametric amplification studies.

A photograph of the experimental set-up (Figure 10) shows the power combiner, the quartz resonator and sense resistor mounted and interrogated by the two differential active probes, along with two directional couplers which are included to provide isolated monitoring of the Holzworth synthesizer outputs. The system permits both on- and off-resonance studies of the non-linear effects in the quartz resonator. We are also able to investigate various configurations of excitation and parametric pump frequencies including the n=1 and n=3 conditions. Additionally, replacing the Holzworth synthesizer with a dc bias voltage source allows static $\Delta k/k$ value estimates.

This new configuration was tested by exciting the resonator around the fundamental mode with a low drive voltage. Figure 11 shows the measured admittance response of an AT-cut UHF 507 MHz quartz resonator with Q ~ 21K. This validates the experimental procedure and illustrates the basic device natural frequency (ω_0) response without non-linear effects.

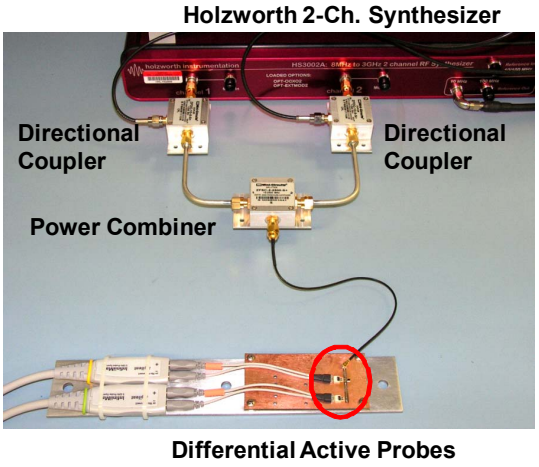

Figure 10. Photograph of the 507 MHz quartz resonator driven with a Holzworth HS300 2A 2-channel synthesizer and interrogated using differential active probes.

In order to estimate the value of $\Delta k/k$ obtained through off-resonance pumping, a varying polarity dc bias voltage was applied to the device. Recalling that $\Delta k/k = 2\Delta f/f$, we can estimate the $\Delta k/k$ achieved through measurement of the frequency shift Δf for ± dc voltages applied to the device. From the result in Figure 12, we observe a small slope of approximately a 0.0824 ppm /V corresponding to a change in the $\Delta k/k$=1.65x10^{-7} /V. This measured value agrees well with the theoretically calculated value of $\Delta k/k$=1.57x10^{-7} /V. From this result we conclude that off-resonance parametric pumping will require voltages which far exceed realistic values that can be easily implemented. However, on-resonance pumping, in which we utilize the high Q of the device, can provide significantly larger $\Delta k/k$ values and hence a more practical parametric pumping condition.

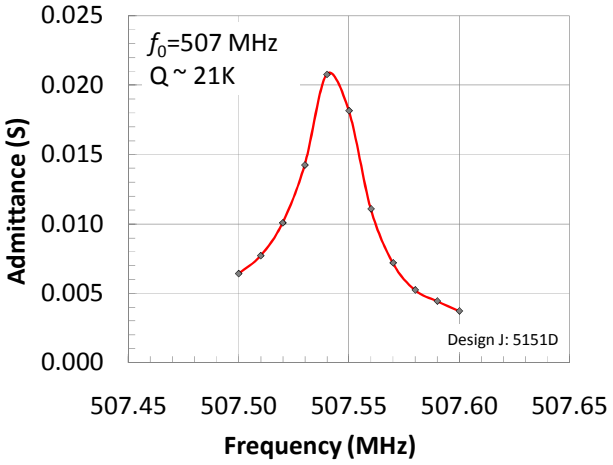

Figure 11. Admittance response of an AT-cut UHF 507 MHz quartz resonator at the fundamental thickness shear resonance.

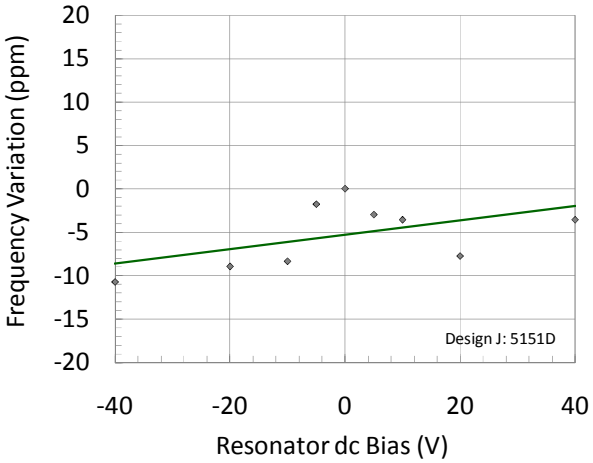

Figure 12. Resonator ω_0 frequency variation versus applied dc bias voltage for a AT-cut UHF 507 MHz device. A small positive slope is observed indicating prohibitively high voltage requirements for off-resonance parametric pumping.

Recalling that $\omega_P = 2\omega_0/n$, where ω_0= natural resonance frequency of the resonator, and ω_P = pump frequency, which in this case is the frequency at which the $\Delta k/k$ occurs. Therefore for n=1,2 &3 the corresponding $\Delta k/k$ occurs at $2\omega_0$, ω_0, & $2\omega_0/3$ respectively, and the parametric excitation frequency falls at ω_0, $\omega_0/2$, & $\omega_0/3$ for rectified $\Delta k/k$. Pumping at $\omega_0/2$ is an off-resonance condition which will be inefficient. Thus, we have two scenarios which satisfy the on-resonance pumping condition. Consider a pump at ω_0, for which one can use the rectified $\Delta k/k$ at $2\omega_0$ to either pump the fundamental mode at ω_0 (n=1) or the 3rd overtone at ω_3 (n=3). Note that in order to implement the latter case of n=3, the 3rd harmonic of the device should be well matched (within the linewidth) of the 3rd overtone mode.

VI. Summary

In summary, new simulation tools have being developed for a complete COMSOL model of the quartz non-linearities including computation of $\Delta k/k$ for resonance and off-resonance conditions using the second and third order elastic constants. New experimental techniques have been developed to directly measure the amplified response and $\Delta k/k$ values at UHF frequencies with multiple inputs applied to a resonator simultaneously. We have determined that the $\Delta k/k$ change is a rectified function of the excitation voltage and its measured magnitude agrees closely with our predictions.

Parametric amplification in quartz shear-mode resonators may be possible with reasonable voltages if the strain due to a resonant response is utilized. The off-resonant pumping condition appears to be impractical using reasonable voltages. Future work will investigate using the fundamental mode to parametrically pump the third overtone for improved phase noise.

Abstract— **High quality resonators for spatial and military applications are only made by unitary way and high speed directional etching of piezoelectric material is yet insufficiently developed to produce high aspect ratio microstructures.**
So, in this paper, we report on the theoretical definition and on the realization of BAW resonators, working at 20 and 40 MHz. Part of mechanical process is made by deep Reactive Ion Etching of AT- and SC-cut quartz crystal wafers. To avoid edge effects such as mechanical stresses induced by mounting structure or leakage of the vibration mode, we have to realize a good energy trapping of the selected resonant frequency. Several trapping methods can be used depending on the frequency, thereby changing the resonator design, such as mass loading by electrodes themselves, mesa forms (i.e. 1 to 3 µm circular or elliptical steps), or radius of curvature on one face of the resonator at least. Here, for question of manufacturing, we choose to trap the energy by a mesa form.
Fabrication of complete mesa architecture with bridges aperture (like in a bva structure) requires combining high depth (about 140 µm for a 40 MHz 3rd overtone resonator), high aspect ratios, good uniformity over the entire wafer (for about 40 resonators), vertical wall profiles and reasonable etching selectivity.
After describing different RIE processes, we analyze the quality of the realization through the surface roughness, the geometry, the homogeneity of the mesa-step, the wall profile.

I. INTRODUCTION

Within the framework of a french project aimed achieving quartz resonators for Time and Frequency applications, and entitled "*Crystal resonators modeling and innovative process for miniaturization*", we investigate several manufacturing processes compatible with 3 or 4" wafers. Indeed, innovative technological processes, such as micromachining, multi-layers assembly or wafer bonding can be successfully applied to quartz, in order to minimize packaged resonators while optimizing their performances. Our challenge is summarized in the following sentence:

"Smaller, cheaper and better performances"

Unfortunately, current manufacturing technology for BAW quartz resonators does not allow reducing the size and the cost. We therefore have to study collective processes, which are well-known in the Silicon industry.

II. PRESENTATION OF OUR PROCEDURE

In this paper, we present the manufacturing process of small resonators designed to vibrate at 20 MHz on their 3rd overtone (corresponding to a thickness of about 280 µm, which is a standard value for the purchased quartz wafers). Among different collective etching techniques (chemical etching, UltraSonic Machining or grinding and polishing…), we study the realization of resonators using the DRIE technique which is described in [1]. This technique has already proved that it is conceivable to realize mesa on the active part of the resonator and the apertures defining the links (or bridges) between active and dormant parts. Indeed, previously, we have fabricated few resonators in a 140 µm thick quartz wafer of 1.5 x 1.5 square inches using DRIE. The apertures were completely opened at least in the resonator made in the center as shown in the Fig. 1. We see here that the etching depth is not exactly the same in the entire surface of the wafer, but it is very difficult to measure it due to the strains (and fractures) induced by the thermal expansion created during the etching.

Fig. 1: DRIE of a small quartz wafer (1.5 x 1.5'' square)

So hereafter, we describe two different procedures in order to manufacture resonators with a "double step" on one face as shown in Fig. 2. This succession of steps on the surface is necessary if we want to discretize correctly the radius of curvature realized on resonators working at a few MHz in the way to correctly trap the energy of vibration. Therefore, we will first realize 2 steps with a size of few tens of µm each. After the machining of the apertures, we plan to implement the full procedure for manufacturing 37 resonators on a 3" AT-cut quartz wafer.

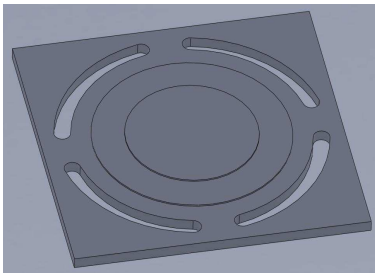

Fig. 2: design of the desired resonator

III. FIRST DRIE QUARTZ ETCHING PROCESS

In this first test procedure, we realize a succession of wet etchings in order to structure layers of Nickel. The total thickness has first been deposited to allow the total etching of about 140 µm. To etch 150 µm of quartz, we have to coat 8 µm of Nickel using the "electrolytic" method (selectivity 1:20). These two preliminary etching operations are separated by a coating of photoresist, exposed to light through a mask defining our pattern. Another etch of about 2 µm of Ni by *Ferric Chloride* is performed. The last etching operation is made to remove the last 4 µm of Ni at the level of the apertures.

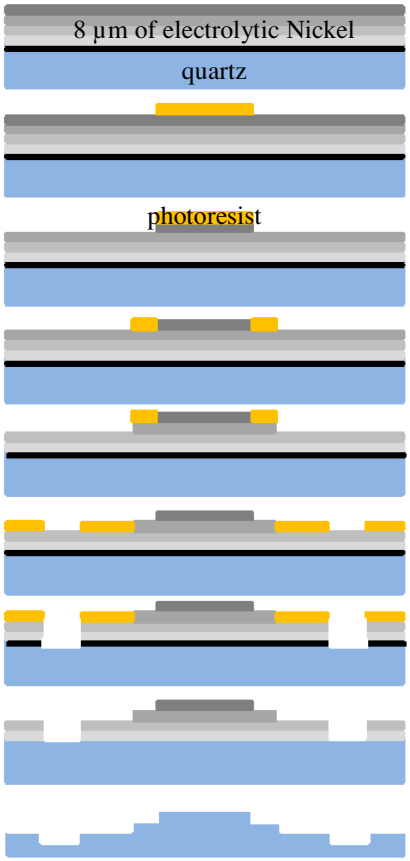

Fig. 3: procedure to structure layers of Nickel

Unfortunately, the chemical etching process of the Ni by Ferric Chloride is very inhomogeneous. Up to now, it is impossible to calibrate the thickness to be removed. Furthermore, the thickness of Ni on the quartz wafer is too thick and cracks appear systematically during the ionic etching which generates very high stresses.

IV. SECOND PROCEDURE

We have then tested a second procedure, which is more "classical" and consists in 3 successive phases with 3 different masks (Fig. 4): the first one realizes the apertures (first mask on the left) with the coating of 4 µm of electrolytic Ni allowing the dry etching of 80 µm of quartz.

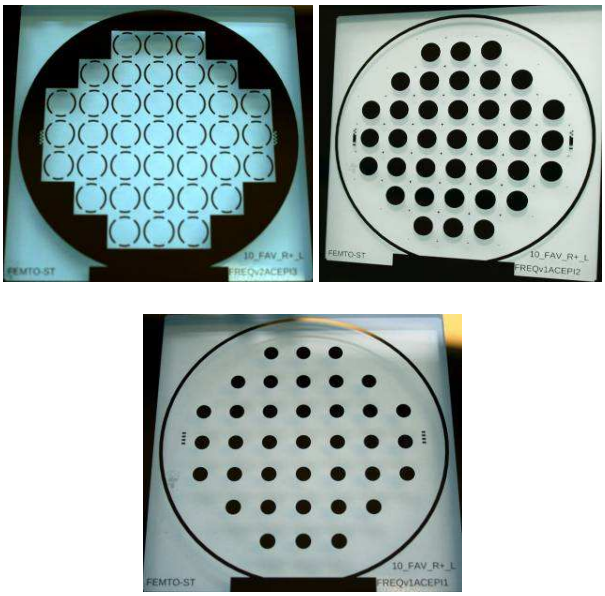

Fig. 4: Three successive masks for our second procedure

Then, coating of a new layer (about 2µm) corresponding to the pattern defining the biggest mesa and dry etching for a 40 µm step is performed. Finally, the third coating defines the small mesa with also 2 µm of Ni. Unfortunately, here also, the mechanical stresses induced by the layer of electrolytic Ni submitted to high temperatures during the DRIE process deform the quartz wafer up to cracks (see Fig. 5). Several tests have been realized in changing the temperature in the back of the substrate, but the problem remains the same: the wafers still break down.

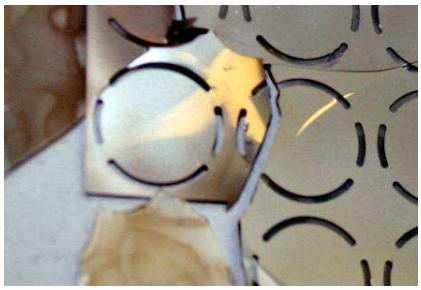

Fig. 5: photography of an example of crack after DRIE

Nevertheless, we have observed MESAs on the AT-cut quartz wafer and we have measured the height of some steps.

Classically, on our STS machine, the etching process is faster on the edges than on the center. Here, we have etched 27 µm in the edges and only 17 µm in the middle.

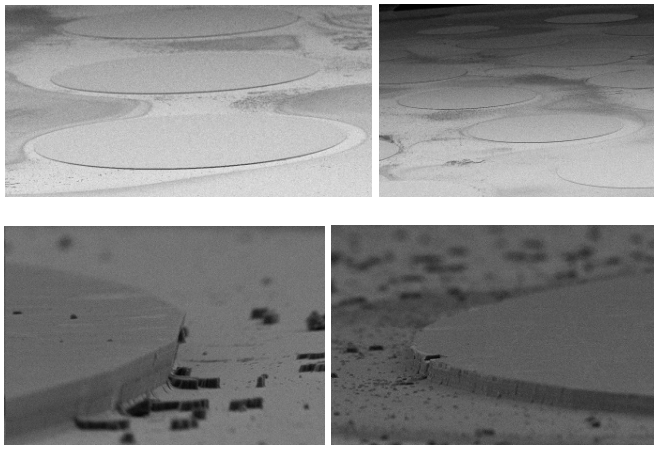

Fig. 6: MESAs observed by BEM… and details of the steps

V. THIRD PROCEDURE

The last procedure described here aims to prove that it is possible to chain 2 realizations of mesa one after another; the apertures (defining the bridges) may be made, at the end, using Ultrasonic Machining [2].

Considering the small heights of the steps to realize (see Fig. 7 below), we have finally chained here 2 Reactive Ion Etching processes, allowing etching 2 to 2.5 µm thick on quartz. Indeed, our wafer is 280 µm thick, processed to realize resonators working at about 20 MHz on their 3rd overtones. So, a 1000 mm radius of curvature seems satisfactory to trap correctly the vibrating energy and the 2 corresponding steps have to be of about 2 to 2.5 µm height.

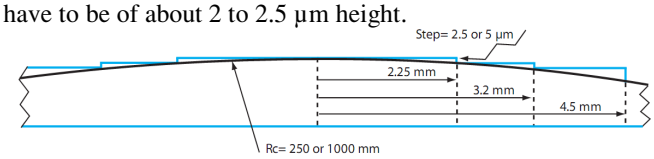

Fig. 7: example of discretization of a given radius of curvature

If the photoresist has been deposited by spin coating for the first step, we have coated it by spray coating for the second one, the relief of the first deposit being too high. We see in Fig. 8 that the quality of the pattern is the same than previously.

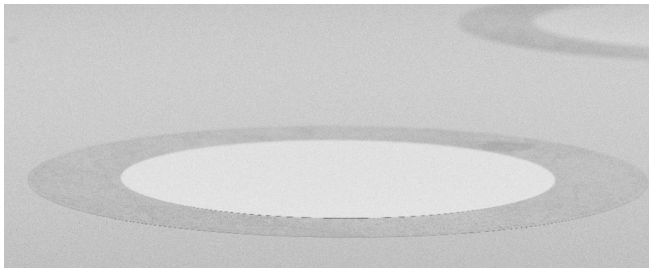

Fig. 8: The 2 MESAs with 4.5 and 6.4 mm of diameters

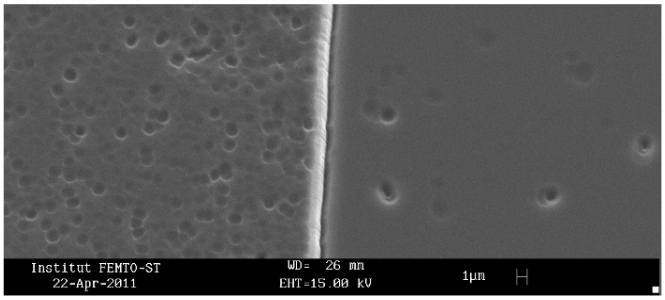
But, if the surface roughness does not depend on the number of the manufacturing process, the quality of the edge of the pattern is highly dependent on how the photoresist is deposited. Indeed, a thickness of the resin deposited by spin coating is uniform only if the surface of the wafer is uniform, a pattern higher than 2 µm creating a kind of bulge in the thickness of the coating. And consequently, the edge of the pattern will have the quality of the deposition, this defined by the spray coating being linked to the microbubble size of the spray. The 2 Fig. 9 below illustrate this difference.



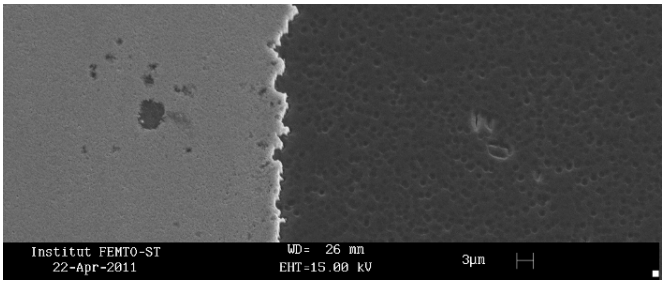


Fig. 9a and 9b: definition of the edges of the first and second MESA, linked to the quality of the deposition to the Nickel (spin coating for the first one and spray coating after).

And so, the height of the step is not uniform as shown in the Fig. 10 where we indicate 2 different values of steps: 2 and 3 µm which are the minimum and the maximum of the step heights.

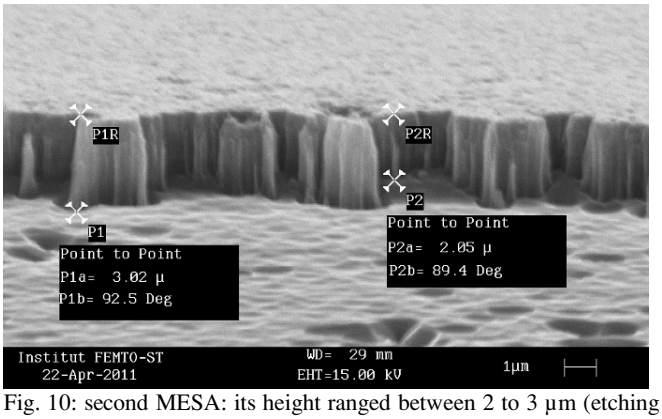

Fig. 10: second MESA: its height ranged between 2 to 3 µm (etching time: 70 min)

We note, at least, the second pattern has been obtained with the following conditions of Reactive Ion Etching:

- deposition of 320 nm of Ni/Cr
- spray coating of S1813 photoresist (4.2 µm)
- photolithography with the given mask,
- annealing at 120°C during 1 min,
- Cr etch / Ni etch and finally
- 7 steps of 10 min with SF_6 gas at 2mT and 220 W.

This work will be followed by the deposition of the metallization allowed to excite the chosen mode of vibration, which is the C-mode 3rd overtone, working at about 20 MHz for a 280 µm thick wafer (in fact 17.68 MHz, the required value of thickness being not reached). Then, we will open the apertures by UltraSonic Machining (USM) before bonding the covers on each side.

VI. FEM SIMULATION OF THE RESONATORS

Previously to this technical work, we have initiated efforts in the calculation of the best design to well trap the vibration energy of the C-mode, 3rd overtone. For that, we use the Finite Element Method allowing calculating resonant frequency and Q-factor for a single-step-mesa resonator and a stepped bi-mesa structure. Below, we compare these calculated values with the output frequency characteristics of a beveled "standard" quartz crystal resonator working at about 20 MHz. Finally, this tool should help us to simulate the complete behavior of any resonator, including the mounting structure and its influence on the resonant frequency.

Few works have been done in this area [3-4], completed by the realization of QCM resonators (Quartz Crystal Microbalance) for which the goal is not to reach very high Q-factors, dedicated to frequency and time applications [5], but only to measure mass loading effect.

So, to evaluate our simulation, we have modeled a resonator with an external diameter of 9 mm, a diameter of 3 mm for the electrodes (constituted by 200 nm of gold) and 6 layers in the thickness of quadratic elements (see Fig. 11).

At least, to calculate the acoustic loss of the desired resonant frequency, we have introduced the tensor of the viscosity constant measured by Lamb and Richter [6]. And so, the displacement along the X-axis for different designs is as indicated in the following figures (Fig. 12a to Fig. 12d).

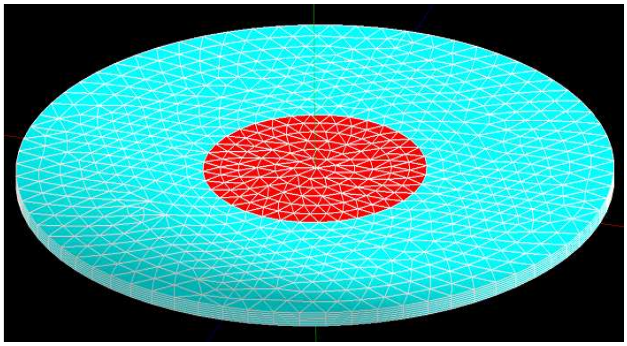

Fig. 11: finite elements model of the resonator and its electrode

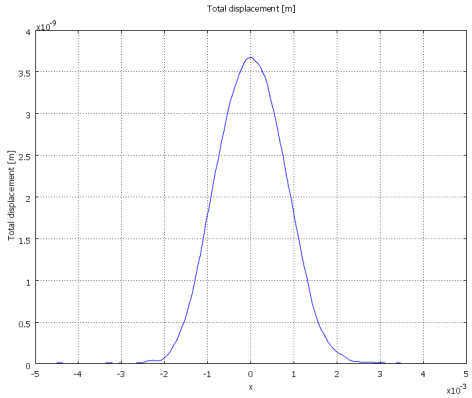

Fig. 12a: displacement along X-axis for a plano-convex resonator

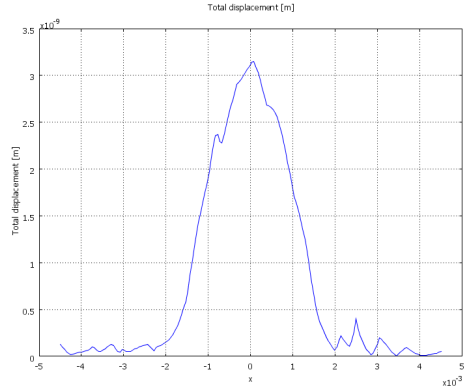

Fig. 12b: displacement along X-axis for a plano-plano resonator

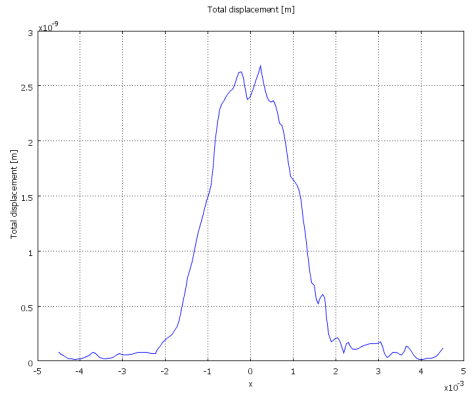

Fig. 12c: displacement along X-axis for a "1 MESA" resonator

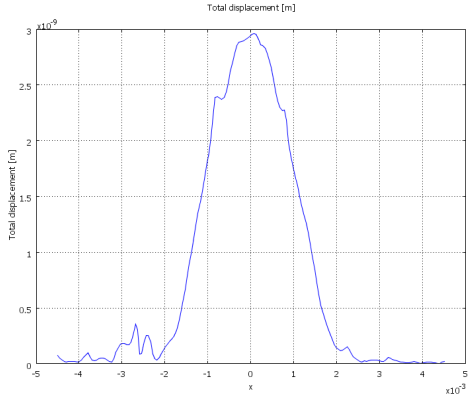

Fig. 12d: displacement along X-axis for a "2 MESAs" resonator

The Q-factor of the C-mode 3rd overtone has been calculated for each design. They are indicated in the following table:

design	Q-factor
Flat resonator	771,000
with Rc = 1000 mm	766,000
with 1 MESA	767,500
with 2 MESA	767,200

Table 1: Q-factor calculated by Finite Element Modeling

We observe that the design has a very little influence on Q values. It is not surprising because the working frequency of 20 MHz corresponds to the point for which a curvature or the mass loading have almost the same influence on the energy trapping.

VII. CONCLUSION

Our test vehicle is not achieved and we have to develop:

Metallization, wafer bonding, dicing,
Chemical etching,
ultrasonic machining of the covers,
…

and to realize 3 and 4'' SC-cut quartz wafers.

Nevertheless, we have demonstrated several points:

- ✓ DRIE shall be an efficient tool to realize deep patterns if we anneal the thermal stresses induced by the electrolytic Ni layer (by deposition of new Ni layer on the other side of the wafer, for example). So, we hope to etch more than 80 µm deep currently,
- ✓ we are able to chain 2 or more RIE processes on the same wafer,
- ✓ …

and we own an efficient tool to calculate the motional parameters of a given resonant frequency of a resonator with particular design.

ACKNOWLEDGMENT

We thank Aurelie Lecestre and Artur Zarzycki who have performed the different etching processes.

Abstract—**Quartz crystal devices have been playing important roles as enablers in modern electronics, and China also has a strong industry for circuit applications in the beginning and as a leading global supplier and end-user lately. The transformation of the quartz crystal industry in the US and Europe has led to the globalization and reorganization of the production of quartz crystal devices in China with significant impact in the market and technology. It has also been known that as a producer of quartz crystal products, leading companies in China have been collaborating with partners outside China for technology and marketing to promote trade and production. In the meantime, many manufacturing hubs for leading OEM companies of consumer electronics industry, with telecommunication and appliances in particular, have been using many quartz crystal products from Japan and Korea. It is possible that large producers in Japan and Korea will continue their production through technology leadership, but the market share can be significantly weakened by Chinese manufacturers. As an initiative to foster the technology development and innovation, Chinese companies have been encouraged and assisted through various partnerships such as joint ventures with foreign companies, research and development collaboration with universities, and governmental subsidy for innovative and quality products, to upgrade technology and serve the high-end application in China.**

I. INTRODUCTION

The quartz crystal industry in China has been making great impact on the global market and industry landscape through supplying vast quantity of lower-end products and force many manufacturers in the United States and other countries to move their production facilities to China and other low-cost nations. This has been noted in the industry for a while and many strategies to counter change have been developed and implemented. For instance, many manufacturing operations of US companies have been relocated to China or even sold to other operators as major indicators of industry-wide changes. On the other hand, the Chinese industry has also been greatly influenced by changes in the US, notably the emergence of newer technology such as the micro-electrical-mechanical systems (MEMS) and film bulk acoustic resonators (FBAR) products which are already invading certain portion of traditional market of acoustic wave resonators in electronic products and new applications. One frequent question we encountered in various occasion is that how the new and emerging technologies in the US will impact the existing investments in the quartz crystal and larger acoustic wave device industry? Then an immediate question followed is that do we need to invest in quartz crystal technology while the emerging products are imminent? The answers to these questions will not only impact the individual company looking for advices but also the industry in China and the global market.

Fig. 1 Major production clusters of quartz crystal products in China (Quartz crystals; Resonators and oscillators)

As an attempt to address these and similar questions and answering more outside of China, we have already had many discussions in China in various occasions with business and industrial leaders. Our general impression is that while the quartz crystal industry in China is growing at a much faster

This industry surveying project is supported by Zhejiang Province through the Key Team of Excellence for Technological Innovation under Grant 2011R09025.

pace than the overall economy because the electronics sector has been the leading force of the recent fast growth and it is specially encouraged by central and local government under many incentives, which often are on competitive basis in coastal regions. In addition, the quartz crystal and acoustic wave device industry is China is still one of the many high-tech sectors and product categories under special promotion in economic plans and policy. Of course, as many of us already know, there are also generous incentives on tax-relief from local governments and export tariff refund for selling products to international market. Such coupled efforts in promotion of quartz crystal industry and other sectors have significant effect on the fast growth, since the production of quartz crystal products have been growing over 10% a year as shown in Table 1. Besides, quartz crystal manufactures outside China, Japan in particular, have been under intensive pressure in terms of the change of market share and fast advances in product quality and manufacturing efficiency. In other words, the gap between Chinese manufacturers and the leaders in Japan has been shrinking and it is always a question of how the advantage can be kept or changed for different competitors.

Table 1 Yearly production of quartz crystals in China

Year	Product (billion pieces)
2002	1.08
2003	1.21
2004	1.39
2005	1.54
2006	1.77
2008	2.25
2009	2.41

For a snapshot of quartz crystal industry in China, here are some basic figures: there are about 500 hundred companies with annual production of 3 billion pieces of quartz crystal products in the Year 2010. The total annual sales are about 1 billion US dollars, about a quarter or less of the international total sales. Not surprisingly, also contrary to our impression, China buys more quartz crystal components than it produces (see Table 2), obviously leading manufacturers of electronic products like computers and mobile phones use more components made outside of China. Most lower-end products are made with everything, production equipments and raw materials included, supplied in China while the high-end products are made with Japanese equipments and even materials. Also there are Japanese engineers, some retired, working in Chinese companies for the production and design.

Table 2 Quartz crystal export and import in China

Year	Export (pieces, billions)	Import (pieces, billions)
2008	0.94	1.43
2009	1.05 (USD 0.8 billion)	1.61 (USD 2 billion)
2010	1.18	1.80

As an indicator of slowing moving up of business ladder, two major producers of quartz crystal products have been listed in stock changes in China so far: Jingyuan Electronic, Tangshan, and East China Electronic Crystal Company (ECEC). It is a measure of maturity of these leading companies in the business world in China. Research and development is inadequate in this industry in China because many companies cannot afford the talents and related costs.

II. Industrial Resources and Advantages

In the international market, the competitive edge of Chinese quartz crystal products is the price, as the majority consumer products made in China. This is the outcome of the abundance of low-cost labors available to industry. Of course, as said before, the preferential policy for electronics components including quartz crystal products also plays an important role in the fast growth in recent years. The availability of land, raw materials, and electricity in certain regions are also major factors of the continuing growth.

If we look into the quartz crystal industry further, we can find more factors which contributed to the fast growth of the sector in China. One major reason is the availability of quartz crystal resonator production equipments from Japan, which enable many companies to make competitive products without invest too much efforts in making and improving production lines as did by major producers in Japan and the US before. Actually, there are also manufacturers in Hong Kong and China to accelerate the growth through even lower costs in obtaining a quality production line. Of course, this also contributes to the fact that many products from Japan are almost same because they do not differentiate from the production equipments and accessories needed for the packaging of resonators and oscillators. With the production line installed, the manufacturing is a straightforward process as we know, and it can churn out products with the standard supplies of all elements and accessories. In other words, the entry barrier of quartz crystal products is relatively low and this also contributes to the fast spread of companies making the same products in China. In fact, companies are clustered after one demonstrated the technology and production process.

We have mentioned that even leading producers of quartz crystal resonators lack technical capabilities in research and development, thus keeping the products and process in a much lower level in the global competition. There are a few focused research institutes in government laboratory systems, such the few in the China Electronics Technology Group Corporation (CETC), and BIRMM, and the research groups and laboratories in leading companies such as the Beijing Chengjing Electronic Technology Company (China 707), which have relatively strong technical team to engage in research activities for the design and fabrication. It is generally expected that these work should contribute to advances of technology of the quartz crystal industry in China, but in fact this did not happen. The main reason, as we can guess, is that most such research oriented organizations are also production companies making devices for specific applications of their parental industry. For instance, BIRMM is an affiliate of the space industry in China and their products are being used primarily in the space programs. As a result, it is regrettable that these research laboratories, with considerable resources in technical talents and equipments, cannot be utilized effectively to lead the industry. Earlier attempts to improve the overall maturity of quartz crystal products in China through research led process did not succeed as the mass production seems not always correlated

with the technology supremacy they have. This reminds us how to use the full potential of research laboratories in the quartz crystal industry in China in the near future is still a challenge to be solved. However, recently increased participation of the annual Symposium on Piezoelectricity, Acoustic Waves, and Device Applications (SPAWDA) by industry is a good sign of embrace to technology and research through interactions with academic institutions.

On the other hand, there are many manufacturing subsidiaries of leading international quartz crystal producers in China today. Their core developments activities are largely kept in the home office like Japan and the US, as we always meet engineers come to China to discuss potential products for Chinese markets. However, more or less, as we have seen in past few years, many engineers and managers from such companies are also migrating to Chinese companies and this will inevitably add momentums to accelerate changes. Many such multinational companies, particularly manufactures from Japan, are concentrated in Yangtze Delta (including Suzhou, Nanjing, and Zhejiang), while a few others particularly Korean companies are in Yantai area and a few others are in Shenzhen area. Some of them are joint ventures with local partner companies in China and this will contribute to the growth of Chinese companies with technology and management advantages. It is clear that the globalization of this industry will also give the advantage, although limited, to the Chinese industry.

It has been clear that the economic growth and accumulation of wealth in China in recent decades add the power to invest in the quartz crystal industry also, as it is viewed as one of the high-tech sector with relatively lower entry barrier. Indeed we have seen new companies of various sizes in almost every process of quartz crystal products through crystal growth, blanks, holders, and equipments. The global financial crisis has some effects on the growth and investments in this traditional technology and the further relocation to China is expected. On the other hand, it is generally sensed that newer technologies in competition with traditional frequency control devices have some impact on the sentiment of investment, because many investors are not sure how and when the alternative technology will phase out the current products. This concern also reflects the lack of research and understanding of the technology trend in this industry and applications. It is generally recognized now that new technologies will replace some products and applications with a much lower pace and it is not the situation that the technology will end abruptly soon. The recent emergence of a few more joint ventures and some expansions of major companies in China may prove that concerns caused by MEMS and FBAR technologies have been smoothed and there are more interests in further investment and improvement of development and production in the quartz crystal industry in China. To speed up the process, again, a short cut is being taken by many companies through increases of investments in buying existing design and technology from international companies. Particularly, many companies in China have expressed interests to buy some small quartz crystal companies to acquire the technology in product development they need badly. Also it is suggested that many companies in the US and Japan may be in the position to sell some of their know-how and technology while their value are at the peak when there are great demands from China. The time window for such buying mood may be limnited and the progress in technology in China could cause depreciation quickly.

III. MAJOR PLAYERS AND GROWTH POTENTIALS

Most Chinese manufactures of quartz crystal products are less well-known even in this global industry, because we do not see engineers and business leaders from China in the IEEE International Frequency Control Symposium and other important occasions. Their appearance in international trade shows is also limited, although we sometimes see Chinese companies in a few events like in Las Vegas and Munich. The reason of their absence in international events is that their products are usually not marketed with their own brand, as most other industries in China. Or, this is the true meaning of "Made in China", while most product today are created outside of China. This is the business strategy of a country and industry while the technical capability is limited and low-cost labor supply is abundant. Such a business practice has its disadvantages, but it will take a long and slow path to change giving the economic and technological reality in China. Then it is easy to understand the choices of Chinese companies and industry, and it also offers the strategy for outsiders to choose the right road to enter the seemingly prosperous and strong economy.

There is a relatively fully fledged quartz crystal industry in China with manufactures for quartz crystal material, quartz blanks and chips, packaging and accessories, and all equipments for the making of resonators. This means the production of quartz crystal devices can be done with all essential materials, accessories, and services in Chinese companies for lower-end products. For high-end products, we know that many elements, especially the holders and high performance materials have to be imported from Japan and the US. The size of market and amount of demands in China is significant and all the major equipment makers and material suppliers have opened offices and branches in China and have been enjoying fast growth of businesses in recent years even with a bright future.

As the industry grows in the technology and market, an industrial association of piezoelectric devices, **Piezoelectric Components Association of China** (PCAC, http://www.chinapcac.org), has been established by the major producers. It is the only official trade association of quartz crystal and acoustic wave device industry in China, and has been enjoying the support nationwide with intensive contacts with global major producers of the industry and joint activities with similar groups. The PCAC has a major mission of promoting the industry and support members through sharing information on government policy and regulation, market, technology, and trade. It is also leading the task to maintain national standards on quartz crystal devices as the IEC TC-49 counterpart. It also holds annual trade shows and meetings of leading producers to review market and technology trends.

Zhejiang East Crystal Electronic Co., Ltd. (ECEC, http://www.ecec.com.cn) is one of the two listed company

with top annual sales (about RMB 300 million / USD 45 million). ECEC has been working with TXC for distribution and improvement. The ECEC has manufacturing equipments and support expertise from Japan. The company is actively seeking growth opportunities with emphasis on engineering and technical leads.

Beijing Chengjing Electronics Technology Company, Ltd. (China 707, http://www.china707crystal.com) is the first quartz crystal resonator manufacturer in China with many years in supporting the nation's needs of technology. After many years and extensive investments by government, Chengjing has also maintained an up-to-date production line for full line of products. It also has invested in research and engineer training with leading academic institutions. Chengjing has also been actively engaged in global marketing of products with its own brand and sales force.

Beijing Institute of Radio Metrology and Measurements (BIRMM, http://www.casic203.com) is a research laboratory of the space engineering company for time standards and metrology in space navigation and communication. To satisfy the precision needs of its space programs, it maintains a division with technical capabilities in the design and manufacrurngof precision quartz crystal products. This is a research laboratory turned production company with many lines of products. BIRMM has a strong presence and interaction with the international frequency control technology community through participation of international conferences and invited visits by many leading experts in Europe and the US. To enable the technology transfer, it is seeking to expand the production capacity and new product development partner outside China. BIRMM also maintains a subsidiary for mass production of quartz crystal products for consumer products.

One fast growing company in the quartz crystal industry is the TXC Corporation, which is the major producer of quartz crystal products and has its major outpost in Ningbo, China as the **TXC (Ningbo) Corporation** (http://www.txccorp.cn). TXC Ningbo is gradually grows its own production and technical capabilities to enable autonomous business in China. TXC (Ningbo) has been helping many quartz crystal companies in China through partnership in quality management, equipment, and engineering capabilities and improvements are clear and significant. TXC (Ningbo) has also been forming close relationships with universities and laboratories for technical capability building and new products.

As a domestic grown company in China with relatively short history, **Timemaker Crystal Technology Company, Ltd.** (http://www.timemaker.com) started as a manufacturer of crystal blanks, but the business has been expanding to resonators through the partnership with Rakon of New Zealand. There are investments in engineering capabilities through collaboration and in-house improvements. The engineering team of Rakon will provide design and support to Timemaker and the joint venture in Chengdu.

Other major producers of quartz crystal products include Jingyuan in Tangshan, close to Beijing, another listed company in the quartz crystal industry with annual sales about RMB 300 million (USD 45 million). Hualianxing (reorganized as part of China Electronics Panda Crystal Technology Corporation, CEC Xtal) is another major producer of quartz crystal resonators in Nanjing. Major clusters of quartz crystal companies are in Beijing, Yantai, Shanghai, and Shenzhen. Production centers of quartz crystal materials are in Lianyongang, Hohhot, and western regions.

For scientific and engineering research related to quartz crystal industry, the internationally renowned research work on crystals are being done at Shanghai Institute of Ceramics, CAS and Institute of Crystal Materials, Shandong University. There are research works on acoustic wave devices in the Institute of Acoustics, CAS and Nanjing University. The Piezoelectric Device Laboratory, Ningbo University, has been focused on the analysis of quartz crystal resonators through analytical and experimental approaches. Electrical circuit analysis and design are done in University of Electronic Science and Technology in Chengdu and Xi'an.

The quartz crystal industry in China also faces challenges in the road ahead. First of all, to supply quartz crystal devices in coming decades with the latest trend of globalization, rising of labor cost, and technology advancement, quartz crystal companies in China have to upgrade the technical capabilities in every aspect: design, process, equipment, and applications. With the increasing of competition, professional engineers with both analytical and experimental skills are needed in product development and production lines. Most companies need to improve the marketing and sales capability in global scale to improve the profitability and product development pace. Investment on technology is essentials and possible through government support and long term planning. The production capability of quartz crystal industry has the weight and size to make a global impact, and industrial relocation and manufacturing concentration in China provide unique opportunity to accelerate the change. Demands of technology and know-hows in China offer opportunities for Western and Japanese companies in the near future. Chinese industry needs to invest on technology through well-trained engineers, management efficiency, and marketing and sales skills. Chinese industry should also invest in the new and alternative technology to satisfy the international market as it emerges as a strong industrial player in the near future.

IV. SUMMARY

There are heavily invested production facilities and adequate material supply for quartz crystal products in China. Production equipment are on par with international standard and production management are also up to the need. The major hurdles are on the engineering capabilities of design and precision manufacturing, but the rising cost of labor, land, and energy should also be kept in mind. Quartz crystal and frequency control products are still encouraged with government incentives on investment and aid, but the true advantage has to be maintained for the future growth and included in new investments. Globalization should also be expanded to include technical talents and intellectual properties for balanced and sustainable growth.

Straightforward estimations of GNSS on-board clocks

***Abstract*— In this paper, we present two techniques to estimate GNSS on-board clocks. These techniques only require a single GNSS receiver and allow to evaluate the stability on a given pass of the time difference between the GNSS on-board clock and the clock that drives the GNSS receiver. These methods have been validated using IGS clock products for GPS on-board clocks. We also show that they can be used to characterize ground clocks provided a better space clock is available.**

I. INTRODUCTION

Global Navigation Satellite Systems embark atomic frequency standards, the characteristics of which have a direct impact on the overall positioning performance. Therefore the general monitoring and the performance assessment of these on-board frequency standards are of utmost importance. For instance, the performance assessment of the GPS on-board clocks is carried out on a regular basis [1,2].

The estimation of GNSS on-board clocks behaviour is generally a complex task requiring a large ground infrastructure (a global network of ground stations) and an intense computation (the ODTS, Orbit Determination and Time Synchronization). This task consists first in collecting the GNSS measurements on a continuous basis. These stations measurements are then merged through an infrastructure and processed together by a dedicated facility. This facility computes the clock of each ground station and the orbits and clocks for each GNSS space vehicle. The clocks are estimated with respect to the GNSS reference time scale.

The aim of this work is to propose two alternative methods that allow to estimate the behaviour of GNSS on-board clocks with respect to a given ground station. This estimation is therefore limited to the pass duration, but on the other hand provides data at the rate of the station measurements, thus allowing to assess the short term stability of the GNSS on-board clock. Obviously this requires that the stability of the ground station clock is better than the stability of the GNSS on-board clock that we want to estimate. These methods are therefore considered as complementary to the usual method, while being much simpler and, for at least the polynomial method, available in nearly real time.

II. DESCRIPTION OF THE METHODS

The two alternative methods developed here use the phase measurements of a given ground station. The first method, called the polynomial method, consists in applying a high-order polynomial fitting to these measurements. The second method, called the residuals method, consists in carrying out a residuals computation on a given pass using precise ephemerides. This residuals method is somewhat similar to the One-Way Carrier Phase developed in [7]. These methods are described hereafter.

A. The Polynomial Method

This straightforward method is based on the use of raw phase measurements (in RINEX format) coming from a GNSS receiver connected to an atomic clock. Basically the GNSS measurements represent the clock difference between the transmitter and the receiver. The idea is to exploit that feature in a very simple way. The raw phase measurements and their iono-free combination for a given satellite pass is merely adjusted by a polynomial of high order (typically 24). Thus we keep the high-frequency part of the measurement which is expected to be representative of the clock difference. We then compute the Allan deviation excluding end segments that are generally noisier.

B. The Residuals Method

For this method, we carry out a residuals computation on a given pass using precise ephemerides. The computation is carried out as follows:

- the transmission dates are computed using the RINEX pseudo-ranges measurements
- these transmission dates are corrected using a rough satellite clock offset estimation
- the satellites' positions are computed by interpolation of the satellite ephemeris at these corrected dates

978-1-61284-110-6/11/$26.00 ©2011 IEEE

- the geometry is computed using the satellites' position and the measurements
- the corresponding phase residuals are estimated together with vertical troposphere delay adjustment

We then compute the stability of the clock time difference between the on-board clock and the receiver clock for each phase observable and for the iono-free phase combination.

III. RESULTS ON GPS ON-BOARD CLOCKS

For GPS on-board clocks, we compare our estimations to the IGS products [4] of the CODE Analysis Center. COD clock products have a sampling rate of 5 seconds. This can be considered as a validation of the two methods. The data used in this section have been obtained with receivers driven by Hydrogen Masers.

A. GPS PRN 3 Caesium Clock

Fig. 1 shows the stability of GPS PRN 3 (SVN 33) on-board clock (Cs II/IIA) obtained with both methods and compared to the COD clock solution in the very same period. The stability obtained with the polynomial method (in blue) is very close to the one obtained with the residuals method (in red).

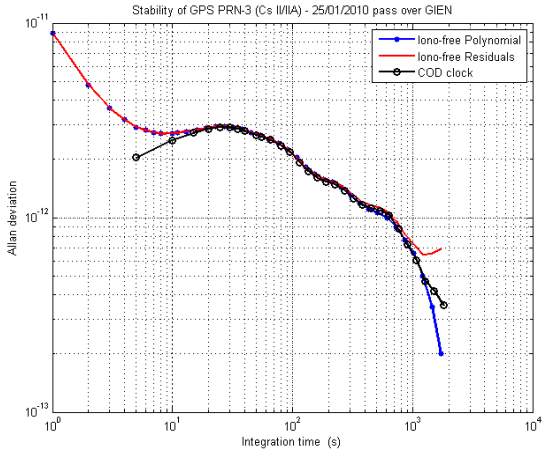

Figure 1. Stability of GPS PRN-3 Cs II/IIA using both methods on the iono-free combination

Both results are consistent with the COD clock solution between 10 seconds and 1000 seconds. It is clear that the stability is limited in the very short term (between 1 and 10 seconds) by the noise of the iono-free phase combination.

Fig. 2 shows the same stabilities computed with the polynomial method only with each phase observable (L1 and L2). Similar results are obtained with the residuals method (the short term stability is the same for a given observable in the 2 methods).

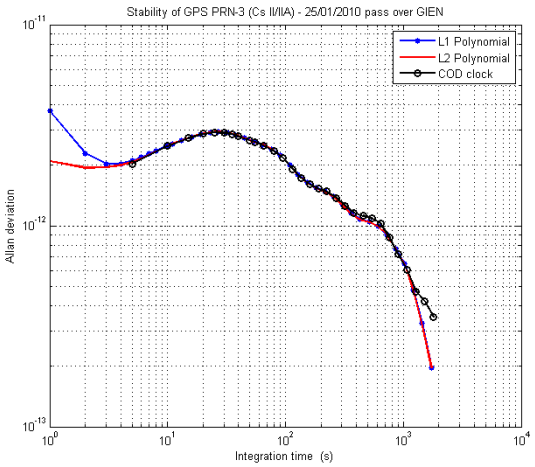

Figure 2. Stability of GPS PRN-3 Caesium II/IIA using the polynomial method on L1 and L2

We notice that the L2 observable is less noisy than L1 in the very short term. We get in this case a better short term noise because the iono-free combination increases the noise. Comparing to the previous figure, we see that the stability obtained with L1 or L2 is consistent with the stability obtained with COD between 5 and 10 seconds. We also observe here a "bump" probably due to the servo of the quartz crystal oscillator on the atomic transition that seems to have a time constant of about 30 seconds for this type of clock. For integration times between 30 and a few hundreds of seconds, we observe the expected white frequency noise.

B. GPS PRN 4 Rubidium II/IIA clock

Fig. 3 is another example with the GPS PRN 4 (SVN 34) which is a Rb of Block II/IIA. The stability obtained with the polynomial method (in blue) and with the residuals method (in red) are in good agreement with the COD clock solution from 5 to up to almost 1000 seconds. We also observe that the polynomial method can sometimes be slightly too optimistic for integration times higher than 1000 seconds.

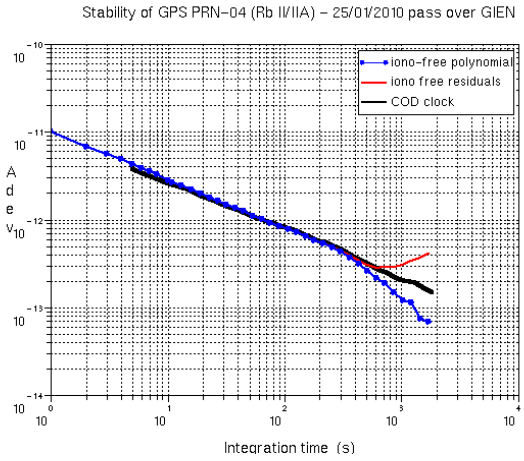

Figure 3. Stability of GPS PRN-4 Rb II/IIA using both methods on the iono-free combination

C. GPS PRN 20 Rubidium IIR

Fig. 4 is another example with the GPS PRN 20 (SVN 51) which is a Rb of Block IIR.

We also notice a very good consistency between 20 and 1000 seconds. Fig. 5 shows the stabilities computed with the polynomial method only with each phase observable (L1 and L2).

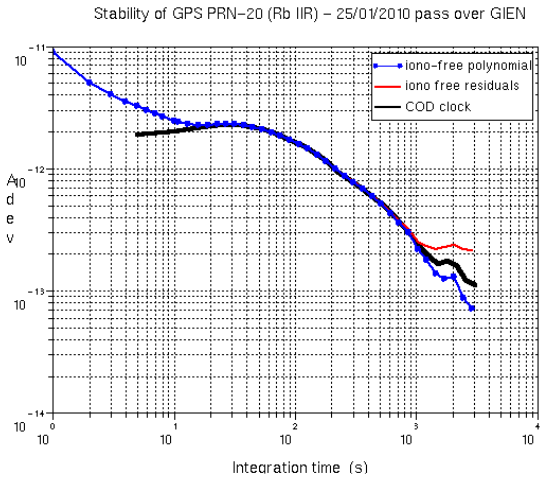

Figure 4. Stability of GPS PRN-20 Rb IIR using both methods on the iono-free combination

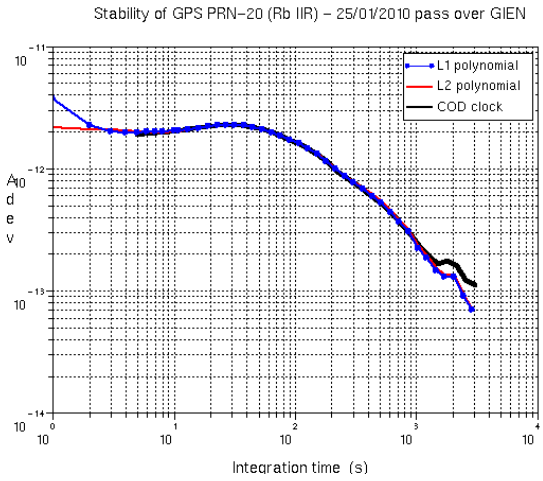

Figure 5. Stability of GPS PRN-20 Rb IIR using the polynomial method on L1 and L2

The same conclusions can be drawn with that type of clock. Similar results have been obtained with the other GPS on-board clocks and also with the measurements of other ground stations. This allows to validate these 2 methods.

D. GPS PRN 25 Rubidium IIF

The GPS PRN 25 (SVN 62) is the first Block IIF satellite, it was launched in May 2010 and embarks two Rubidium and one Caesium clocks. At the time of this experiment, the payload was driven by one of the Rubidium clocks.

Fig. 6 shows the stabilities obtained with both methods using the L1/L2 iono-free combination and compares to the COD clock solution. A white frequency noise of $1.10^{-12}.\tau^{-1/2}$ has also been added.

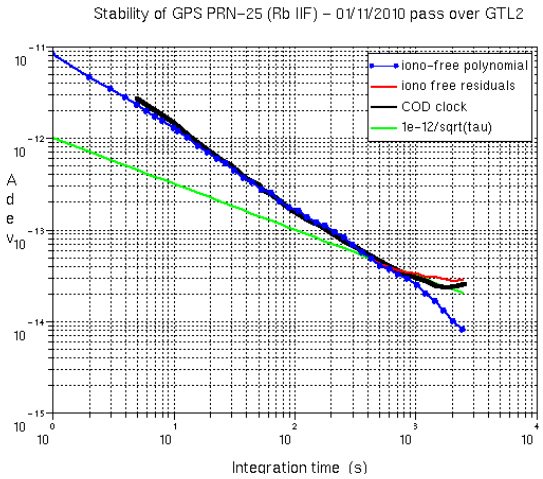

Figure 6. Stability of GPS PRN-25 Rb IIF using both methods on the iono-free combination

The iono-free combination does not allow to fully characterize the short term stability of this clock .Fig. 7 shows the results for the polynomial method on L1 and L2.

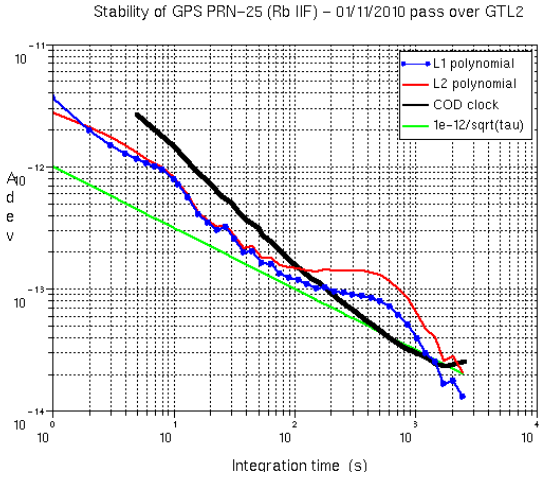

Figure 7. Stability of GPS PRN-25 Rb IIF using the polynomial method on L1 and L2

The estimated stability of this clock is 1 to $2.10^{-12}.\tau^{-1/2}$, this result is consistent with [6]. The sinusoidal perturbations identified in [6] can not be seen with these methods because they have too long a period with respect to the pass duration. However these methods allow to identify sinusoidal perturbations with shorter periods like on Figure 7 where a harmonic at about 20 seconds can be seen.

IV. RESULTS FOR GROUND CLOCKS

We set up another validation experiment in which a GPS receiver (Septentrio PolaRx2) is driven by a high-performance Agilent 5071A-001 Caesium beam clock. In the same time, this clock is measured against an active Hydrogen Maser as reference. We then compare the estimation of the Cs clock by the polynomial method (using GPS PRN 25) to the local measurement.

Fig. 15 shows the stability obtained with the polynomial method on L1 and L2 for a GPS PRN 25 pass and the stability obtained by the local measurement against the H Maser in the very same period.

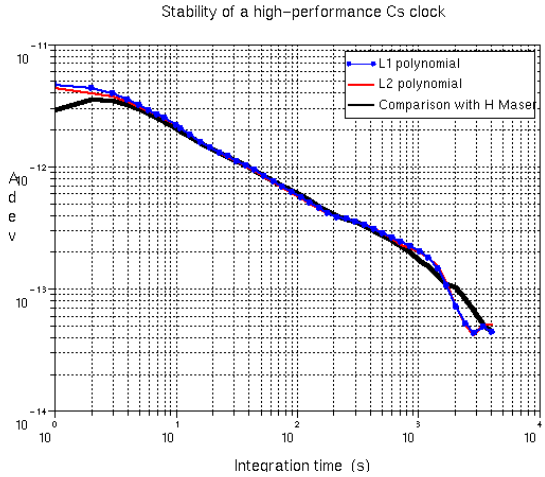

Figure 8. Stability of a ground high-performance commercial Cs beam clock using the polynomial method on L1 and L2

This figure shows an excellent agreement up to at least 1000 seconds between the polynomial results and the local measurements. This highlights the possibility to easily characterize the performance of atomic clocks such as high performance Cs beam clock with these simple techniques, i.e. without the need for a local clock with a better stability. This amounts to having a reference clock in space and therefore it works only with a GNSS on-board clock with better characteristics than the ground clock under test.

CONCLUSION

The methods developed here represent alternative ways to characterize the short term stability of GNSS on-board clocks. These methods have been validated using GPS on-board clocks and COD clock products. The results provided by the 2 methods are completely consistent with one another and with the COD clock solution.

The outstanding advantage of the polynomial method is that all you need is a ground receiver connected to a clock, the performances of which are better than the space clock. This feature is obviously extremely interesting when a global network of stations is not yet available (e.g. in a GNSS early development phase) or not accessible, or when the ODTS (Orbit Determination and Time Synchronization) process is not available. Moreover, the ODTS often provides a clock solution with a rate of 300 seconds that does not allow to estimate the short term behavior of the GNSS on-board clocks. The methods developed here provide an estimation of the on-board clock with the rate of the used RINEX observation files.

The polynomial method is considered to provide accurate estimations of the GNSS on-board clock stability up to at least some hundred seconds and then might be slightly too optimistic for longer integration times. The residuals method, which is somewhat similar to the OWCP (One-Way Carrier Phase) [7], is thought to provide accurate estimations of the GNSS on-board clocks stability up to at least one thousand seconds (provided the troposphere delay effects are taken into account).

Giving access to the high rate behaviour of the GNSS on-board clocks, these methods allow to identify potential sinusoidal patterns that may not be clearly visible with the ODTS clock solution. These methods are considered as simple, fast and efficient ways to characterize the behaviour of GNSS on-board clocks on a given pass. They are however limited because, unlike the global approaches, they do not provide continuous estimations of on-board clocks. This limitation might be overcome if the possibility to connect successive passes is demonstrated.

Moreover, these methods can be used also to characterize ground clocks with respect to better GNSS on-board clocks.

ACKNOWLEDGMENT

The authors wish to thank Francisco Gonzalez for helpful discussions.

***Abstract*— The prediction of very long term time stability is a key issue in various fields, such as time keeping, obviously, but also navigation and spatial applications. This is usually performed by extrapolating the measures obtained by estimators such as the Allan deviation, modified Allan deviation, Hadamard deviation, etc.**

Unlike the variance estimates, the deviation estimates are severely biased and it is of importance to perform this extrapolation from a fit over the variance estimates, and not over the deviation estimates. However, the fit should be performed on the log-log graph of the estimates, which corresponds to a least-squares minimization of the relative difference between the variance estimates and the fitting curve. But also in this case, a bias exists between the average of the log of the estimates and the log of the true value of the estimated variance.

This paper presents the theoretical calculation of this "log-log bias" based on the number of equivalent degrees of freedom of the estimates, shows simulations over a large number of realizations, and provides a reliable method of unbiased logarithmic fit. Extrapolating this fit yields a more confident assessment of the very long term time stability.

I. Introduction

The prediction of very long term time stability is usually performed by fitting and extrapolating an Allan variance (AVAR) curve. Such a curve may be modeled as:

$$\sigma_y^2(\tau) = \sum_{i=0}^{4} C_i \Phi_i(\tau) \quad \text{with} \quad \Phi_i(\tau) = \tau^{i-2}. \tag{1}$$

An extrapolation may be achieved by extending the asymptotes of such a curve beyond the largest τ value (see figure 1).

Thanks to table I, the C_i coefficient are related to the noise levels h_α of the power law noise model:

$$S_y(f) = \sum_{\alpha=-2}^{+2} h_\alpha f^\alpha \tag{2}$$

and to the linear frequency drift D_1:

$$y(t) = D_0 + D_1 t + \eta(t) \tag{3}$$

where $\eta(t)$ represents the pure random component of the frequency deviation $y(t)$.

However such an extrapolation is very sensitive to estimation error. It is then of importance to perform a reliable

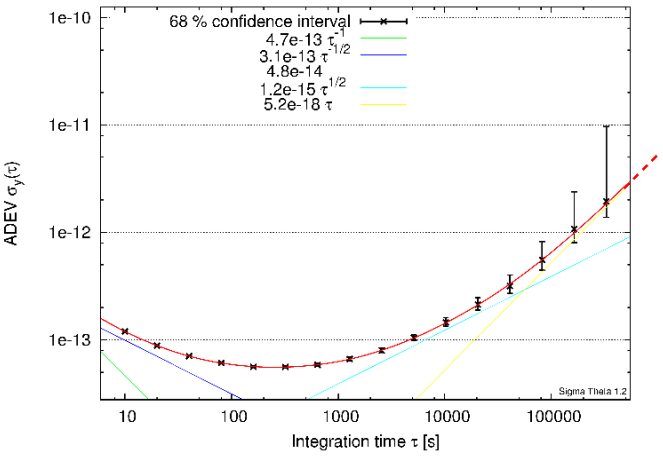

Fig. 1. Extrapolation of a least square fit.

estimation of the C_i coefficients. The weighted relative least squares are an effective method [2]:

- **weighted** in order to take into account the uncertainty Δ_j over each estimate $\hat{\sigma}_y^2(\tau_j)$,
- **relative** in order to be equivalent to a classical least square fit on the log-log plot by minimizing the relative distance between the curve and the estimate $\frac{\text{estimate}-\text{curve}}{\text{estimate}}$,

$$\sum_{j=1}^{N} \left[\frac{1}{\Delta_j} \times \frac{\hat{\sigma}_y^2(\tau_j) - \sum_{i=0}^{4} C_i \Phi_i(\tau_j)}{\hat{\sigma}_y^2(\tau_j)} \right]^2 \text{minimum.} \tag{4}$$

We know that the estimate $\hat{\sigma}_y^2(\tau)$ is an unbiased estimator of $\sigma_y^2(\tau)$, but is $\ln\left(\hat{\sigma}_y^2(\tau)\right)$ an unbiased estimator of $\ln\left(\sigma_y^2(\tau)\right)$?

II. Statistical approach

A. Statistics of the Allan variance and the Allan deviation

The definition of the Allan variance is [3], [4]:

$$\sigma_y^2(\tau) = \frac{1}{2}\left\langle (\bar{y}_2 - \bar{y}_1)^2 \right\rangle. \tag{5}$$

$S_y(f)$	$h_{+2}f^{+2}$	$h_{+1}f^{+1}$	$h_0 f^0$	$h_{-1}f^{-1}$	$h_{-2}f^{-2}$	$y(t) = D_1 t$
$\sigma_y^2(\tau)$	$\frac{3h_{+2}f_h}{4\pi^2\tau^2}$	$\frac{[1.038 + 3\ln(2\pi f_h \tau)]\, h_{+1}}{4\pi^2\tau^2}$	$\frac{h_0}{2\tau}$	$2\ln(2)h_{-1}$	$\frac{2\pi^2 h_{-2}\tau}{3}$	$\frac{D_1^2\tau^2}{2}$

TABLE I

THEORETICAL RESPONSES OF AVAR FOR THE DIFFERENT NOISE TYPES OF THE POWER LAW MODEL AND FOR A LINEAR FREQUENCY DRIFT. FOR THE HIGH FREQUENCY NOISES (f^{+2} FM AND f^{+1} FM), IT IS NECESSARY TO INTRODUCE A HIGH CUT-OFF FREQUENCY f_h [1].

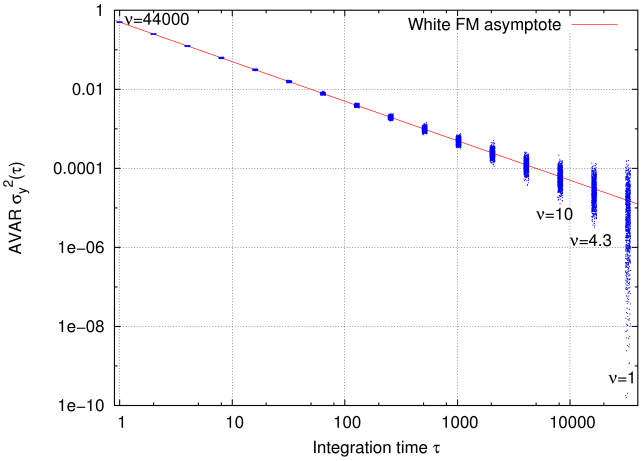

Fig. 2. Dispersion of Allan variance estimates for a pure white frequency noise and their edf ν (65536 samples @ 1 s).

The estimate of the Allan variance may be calculated as:

$$\hat{\sigma}_y^2(\tau) = \frac{1}{2N}\sum_{i=1}^{N}(\bar{y}_2 - \bar{y}_1)^2 . \tag{6}$$

- Since $\bar{y}_2$ and $\bar{y}_1$ are Gaussian centered values,
- then $\bar{y}_2 - \bar{y}_1$ is a Gaussian centered value,
- so $(\bar{y}_2 - \bar{y}_1)^2$ obeys a χ_1^2 distribution,
- therefore $\frac{1}{2N}\sum_{i=1}^{N}(\bar{y}_2 - \bar{y}_1)^2$ is a χ_ν^2 distribution with $\nu = N$ if the $\bar{y}_i$ samples are independent, with $\nu < N$ otherwise.

ν is the number of Equivalent Degrees of Freedom (EDF).

The χ_ν^2 distributions have the following properties:

- $E(\chi_\nu^2) = \nu$
- $\mathrm{Var}(\chi_\nu^2) = 2\nu$ ($\rightarrow \mathrm{Std}(\chi_\nu^2) = \sqrt{2\nu}$).

As shown by figure 2, the number of EDF reflects the AVAR estimates dispersion. A method for assessing the EDF may be found in [5].

B. Model world and measure world

Let us define:

- θ as the model parameter
- ξ as a measure of the parameter

(see figure 3.A).

As an example, we could consider the true value $\sigma_y^2(\tau = 10\text{ s}) = h_0/20$ (where h_0 is the white FM level) as a parameter; $\hat{\sigma}_y^2(\tau)$ is a measure of $\sigma_y^2(\tau = 10\text{ s})$.

1) Model world (direct problem): In the world of the model, the question is *"Knowing the parameter θ_0, how is the measure ξ distributed?"* (see figure 3.B).

However, the parameter θ_0 is precisely the unknown quantity that we want to estimate. Supposing this parameter is known has sense only in theory and simulations.

2) Measure world (inverse problem): In the world of the measures, the question is *"Knowing the measure(s) ξ_0, how to estimate a confidence interval over θ?"* (see figure 3.C).

This is the right question of the metrologist!

C. Study of a χ^2 distribution with $\nu = 1$ degree of freedom

1) Properties: A χ_1^2 distribution has the following properties [6]:

- Probability density function:

$$p(X) = \frac{e^{-X/2}}{\sqrt{2\pi X}} \tag{7}$$

- The pdf is normalized:

$$\int_0^\infty p(X)dX = 1 \tag{8}$$

- Mathematical expectation:

$$\int_0^\infty X \cdot p(X)dX = \nu = 1 \tag{9}$$

- Cumulative distribution function:

$$P(X) = \int_0^X p(y)dy = 1 - \frac{\Gamma_{\mathrm{inc}}(1/2, X/2)}{\sqrt{\pi}} \tag{10}$$

- Inverse cdf:

$$P^{-1}(\alpha) = 2\Gamma_{\mathrm{inc}}^{-1}\left(1/2, \sqrt{\pi}(1-\alpha)\right) \tag{11}$$

This relationship is useful for getting the bounds of a confidence interval.

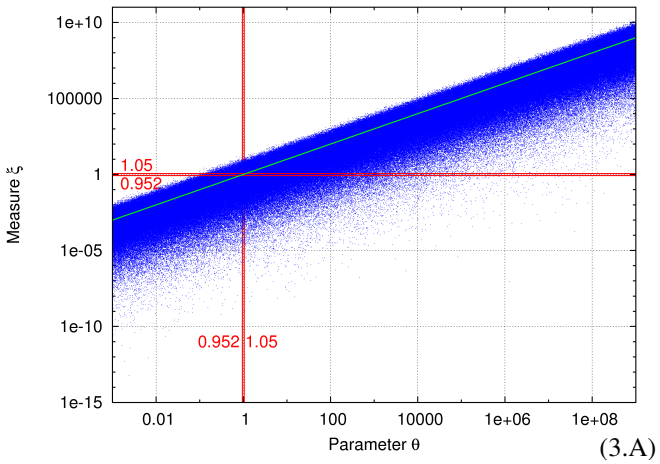
How is the reduced variable X of the relationships (7) to (10) related to the measure ξ and the model parameter θ?

2) Parameter, measure and reduced variable: Let us consider the standard χ_1^2 variable $X = x^2$ where x is a Gaussian centered standard random variable

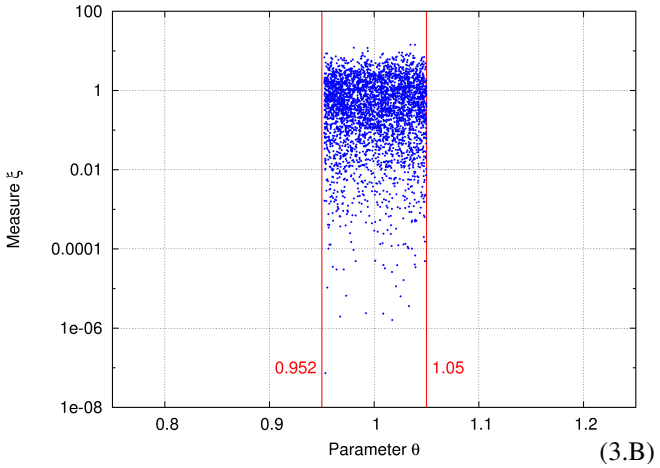
$$E(X) = \nu = 1 \quad \Rightarrow \quad E\left(\frac{X}{\nu}\right) = 1. \tag{12}$$

It is well known that:

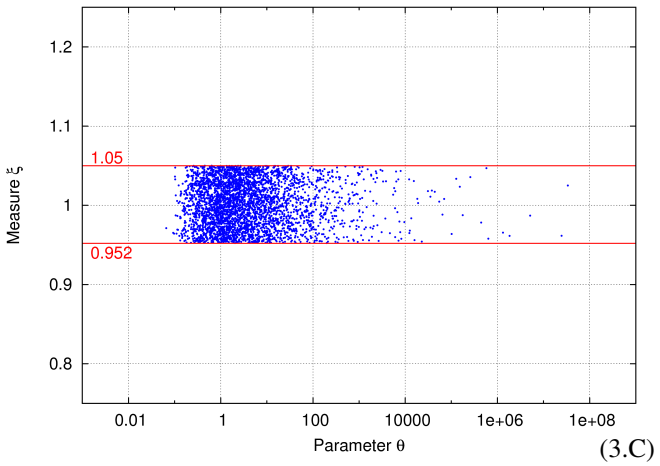
1) $\hat{\sigma}_y^2(\tau) = \xi$ is χ_1^2 distributed
2) ξ is an *unbiased* estimator of the parameter $\sigma_y^2(\tau) = \theta$.



(3.A)



(3.B)



(3.C)

Fig. 3. A: Model parameter and measure for a χ_1^2 distribution (10^6 realizations of $\theta \cdot \chi_1^2$ for $\theta = 10^k$ and $-3 < k < +9$). B: Measure dispersion for a parameter $\theta_0 \approx 1$. C: Model parameter values for a measure $\xi_0 \approx 1$.

Therefore:

$$E\left(\frac{\xi}{\theta}\right) = 1. \tag{13}$$

We can then define the reduced variable X as:

$$X = \nu\frac{\xi}{\theta} = \frac{\xi}{\theta}. \tag{14}$$

The differential dX is then:

$$dX = \frac{\partial X}{\partial \xi}d\xi + \frac{\partial X}{\partial \theta}d\theta. \tag{15}$$

3) Conditional probabilities in the model world (direct problem): The parameter θ is a constant. Let $\theta = \theta_0$, the differential dx is then:

$$dX = \frac{\nu}{\theta_0}d\xi = \frac{1}{\theta_0}d\xi. \tag{16}$$

From (16) and the relationships (7) to (9) it comes:

- Conditional probability density function:

$$p(\xi|\theta_0) = \frac{e^{-\xi/(2\theta_0)}}{\sqrt{2\pi\theta_0\xi}}. \tag{17}$$

- *ξ is unbiased:*

$$E(\xi) = \int_0^\infty \xi \cdot p(\xi|\theta_0)d\xi = \theta_0. \tag{18}$$

- Logarithmic mean:

$$\begin{aligned} e^{E[\ln(\xi)]} &= \exp\left[\int_0^\infty \ln(\xi) \cdot p(\xi|\theta_0)d\xi\right] \\ &= \frac{e^{-C}}{2}\theta_0 \approx 0.2807 \cdot \theta_0 \end{aligned} \tag{19}$$

where C is the Euler constant : $C \approx 0.57722$.

Thus, the mathematical expectation of the log of the measure doesn't converge to the log of the parameter. Therefore, there is a significant bias for log-log representation (and fit): let us call it the *"log-log bias"*.

4) Conditional probabilities in the measure world (inverse problem): The measure ξ is a constant. Let $\xi = \xi_0$, the differential dX is then:

$$dX = -\frac{\xi_0}{\theta^2}d\theta. \tag{20}$$

From (20) and the relationships (7) to (9) it comes:

- Conditional probability density function:

$$p(\theta|\xi_0) = \sqrt{\frac{\xi_0}{2\pi\theta^3}}e^{-\xi_0/(2\theta)}. \tag{21}$$

- There is **no mean value**:

$$E(\theta) = \int_0^\infty \theta \cdot p(\theta|\xi_0)d\theta \tag{22}$$

doesn't converge!

- Logarithmic mean:

$$\begin{aligned} e^{E[\ln(\theta)]} &= \exp\left[\int_0^\infty \ln(\theta) \cdot p(\theta|\xi_0)d\theta\right] \\ &= 2e^C\xi_0 \approx 3.562 \cdot \xi_0 \end{aligned} \tag{23}$$

In the measure world also, the mathematical expectation of the log of the parameter doesn't converge to the log of the measure. However, this bias is exactly the inverse of the log-log bias defined above. This implies that we just have to renormalize the measure by the log-log bias for getting both an **unbiased estimator** in the model world and a **mathematical expectation of the parameter equal to the measure** in the measure world.

D. Generalization to a χ^2_ν distribution

These results can be extended to any χ^2_ν distribution regardless of the number of degrees of freedom ν.

1) Model world:

- Reduced variable
$$X = \nu \frac{\xi}{\theta_0} \tag{24}$$
- Pdf:
$$p(\xi|\theta_0) = \frac{\nu^{\nu/2}\xi^{\nu/2-1}e^{-\frac{\nu\xi}{2\theta_0}}}{2^{\nu/2}\Gamma(\nu/2)\theta_0^{\nu/2}} \tag{25}$$
- Mean:
$$E(\xi) = \theta_0 \tag{26}$$
- Log mean:
$$e^{E[\ln(\xi)]} = \frac{2}{\nu}\exp\left[\psi^{(0)}\left(\frac{\nu}{2}\right)\right]\theta_0 \tag{27}$$
where $\psi^{(0)}(x)$ is the "digamma function" [7].

2) Measure world:

- Reduced variable:
$$X = \nu \frac{\xi_0}{\theta} \tag{28}$$
- Pdf:
$$p(\theta|\xi_0) = \frac{\nu^{\nu/2}\xi_0^{\nu/2}e^{-\frac{\nu\xi_0}{2\theta}}}{2^{\nu/2}\Gamma(\nu/2)\theta^{\nu/2+1}} \tag{29}$$
- Mean ($\nu > 2$):
$$E(\theta) = \frac{\nu}{\nu-2}\xi_0 \tag{30}$$
- Log mean:
$$e^{E[\ln(\theta)]} = \frac{\nu}{2}\exp\left[-\psi^{(0)}\left(\frac{\nu}{2}\right)\right]\xi_0 \tag{31}$$

Table II and figure 4 show the biases and the 95 % confidence interval versus edf.

III. Discussion

A. A "log-unbiased" estimator

We know that $\hat{\sigma}_y^2(\tau)$ is an unbiased estimator of $\sigma_y^2(\tau)$. However $E\left[\ln(\xi)\right] \neq \ln(\theta_0)$ and $e^{E[\ln(\xi)]} \neq \theta_0$. Similarly, $E\left[\ln(\theta)\right] \neq \ln(\xi_0)$ and $e^{E[\ln(\theta)]} \neq \xi_0$.

Let us define a new estimator $\hat{\mathcal{L}}_\theta$ as (with $\nu = 1$):

$$\hat{\mathcal{L}}_\theta = \ln(3.5625 \cdot \xi) = \ln(\xi) + 1.2705. \tag{32}$$

The mathematical expectation of $\hat{\mathcal{L}}_\theta$ is then:

$$< \hat{\mathcal{L}}_\theta >= \ln(\theta_0) \tag{33}$$

$\hat{\mathcal{L}}_\theta$ is then an **unbiased estimator** of $\ln(\theta_0)$.

ν	$E(\theta)/\xi_0$	$e^{E[\ln(\theta)]}/\xi_0$	$B_{2.5\%}$	$B_{97.5\%}$
1	∞	3.56213	0.19905	1018.26086
2	∞	1.78108	0.27108	39.49783
3	3.00000	1.44625	0.32091	13.90209
4	2.00000	1.31043	0.35896	8.25735
5	1.66667	1.23754	0.38964	6.01530
6	1.50000	1.19222	0.41524	4.84911
7	1.40000	1.16137	0.43715	4.14232
8	1.33333	1.13902	0.45624	3.67017
9	1.28571	1.12210	0.47312	3.33285
10	1.25000	1.10885	0.48821	3.07978

TABLE II
BIASES AND 95 % CONFIDENCE INTERVAL BOUNDS VERSUS EDF ν.

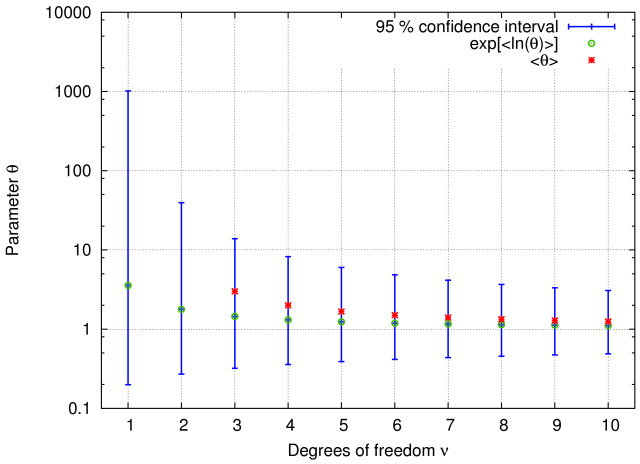


Fig. 4. Biases and 95 % confidence intervals versus edf ν.

On the other hand, for a measure ξ_0 (with $\nu = 1$):

$$E\left[\ln(\theta)\right] = \ln(3.5625 \cdot \xi_0) = \hat{\mathcal{L}}_\theta. \tag{34}$$

The mathematical expectation of $\ln(\theta)$ is equal to $\hat{\mathcal{L}}_\theta$.

Therefore, $e^{\hat{\mathcal{L}}_\theta}$ is a **log-unbiased estimator** of θ. For fitting a log-log plot, it's then better to use this "log-unbiased estimator" rather than $\ln(\xi_0)$.

B. Fitting an Allan variance curve

Figure 5 displays the AVAR estimates (black $\times$) as well as the log-unbiased estimates (green circles) of a simulated oscillator. Fitting the AVAR estimates rather than the log-unbiased estimates leads to a significant underestimation of the long term asymptotes (τ and τ^2 asymptotes) and therefore of the very long term stability of the oscillator.

C. Simulation results

1) Pure random walk FM: We simulated 3,500 sequences of pure random walk FM with a unit noise level:

- Model parameter: $h_{-2} = 1$ arbitrary unit
- Fit over classical estimates: $< \hat{h}_{-2} >= 0.911$ a.u. (-8.9 %)
- Fit over log-unbiased estimates: $< \hat{h}_{-2} >= 0.991$ a.u. (-0.9 %)

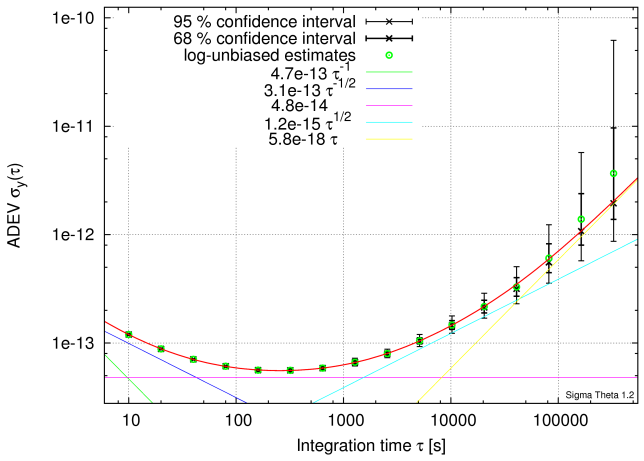

Fig. 5. Example of log-log fit (obtained with *SigmaTheta-1.2*).

The estimation of the random walk noise level is clearly better with the fit over the log-unbiased estimates, but the estimation of h_{-2} over the classical estimates is only slightly underestimated because it is based on all estimates, including those obtained for low tau values that are little biased.

2) White FM + random walk FM: We simulated 10,000 sequences of a combination of white FM and random walk FM in such a way that the random walk FM is the dominating noise over the last decade.

- Model parameter:
  - $h_0 = 1$ a.u.
  - $h_{-2} = 1.5 \cdot 10^{-5}$ a.u.
- Fit over classical estimates:
  - $< \hat{h}_0 >= 0.969$ a.u. (-3.1 %)
  - $< \hat{h}_{-2} >= 1.01 \cdot 10^{-5}$ a.u. (-33 %)
- Fit over log-unbiased estimates:
  - $< \hat{h}_0 >= 0.983$ a.u. (-1.7 %)
  - $< \hat{h}_{-2} >= 1.42 \cdot 10^{-5}$ *a.u. (-5.5 %)*

In this case, the estimation of the random walk FM noise level is drastically improved by the use of the log-unbiased estimates since the random walk asymptote is fitted over the very last tau values which are significantly affected by the log-log bias.

IV. Conclusion

AVAR estimates are not biased and are easily fitted by weighted relative least squares. However, ln(AVAR) estimates are biased, and this "log-log bias" affects the fits performed on log-log plots.

A **log-unbiased estimator** has been defined in such a way that its log is an unbiased estimator of the log of the model parameter. On a log-log AVAR plot, it's then recommended to fit the log-unbiased estimates rather than the classical AVAR estimates.

The *SigmaTheta* software package (including log-unbiased estimator) is available at the following url: `theta.obs-besancon.fr/spip.php?article103`. It is a free software developed under a GNU license for UNIX and windows systems (authors: F. Vernotte, P.Y. Bourgeois, F. Meyer).

A new prediction algorithm for EAL

Gianna Panfilo, Aurelie Harmegnies, Laurent Tisserand

Email: gpanfilo@bipm.org

***Abstract*— In this paper the new algorithm for the prediction of EAL (Echelle Atomique Libre) is presented. The effect of the application of the new model for the prediction term on the EAL frequency drift is quantified and presented together with its effect on TAI and on the atomic clock weights.**

I. Introduction

The EAL (Echelle Atomique Libre) time scale is computed at the BIPM as a weighted average of about 380 free running atomic clocks spread world wide. The weighting algorithm is designed to optimize long-term stability performance. At this stage the time and frequency continuity of the scale is provided by a time correction applied to each clock and calculated with a frequency prediction based on clock past data. In the present version of the algorithm the clock frequency prediction is taken constant over a month interval for all type of clocks. This simple approach does not take into account the frequency drift affecting the atomic clocks. Comparing EAL frequency to TT (Terrestrial Time, a time scale optimized for frequency accuracy) a frequency drift is clear. In a previous work [1] the role of the H-masers frequency drift as a possible source of the EAL frequency drift was studied and quantified. The result shown that the contribution of the H-masers to the drift is not negligible and detected a frequency drift (aging) for the cesium clocks at long term. In this paper we present a new model for the prediction term taking into account the frequency drift affecting the atomic clocks. This model is applied to all kind of atomic clocks. The use of TT as reference and the possibility to consider a longer past period to estimate the frequency drift affecting the atomic clocks are investigated. The effect of the application of the new model for the prediction term on the EAL frequency drift is quantified and presented together with the effect on the atomic clock weights. In section II a brief summary of the calculation of Coordinated Universal Time (UTC) and International Atomic Time (TAI) is presented; the present performance of EAL in term of stability with respect to TT is discussed in section III; in section IV the present and the new prediction algorithms are predented; particular attention is put on the parameter estimation given in section V. A discussion on the choice of TT and EAL as frequency references and on the length of the evaluation period is given respectively in sections VI and VII. The section VIII considers the effect of the new prediction algorithm on TAI and on the clock weights.

II. The calculation of UTC and TAI

The various time laboratories realize a stable local time scale using individual atomic clocks or a clock ensemble. Clock readings are then combined at the BIPM through an algorithm designed to optimize the frequency stability and accuracy and the reliability of the time scale beyond the level of performance that can be realized by any individual clock in the ensemble. An efficient algorithm is necessary for the statistical generation of the world reference time scale. The algorithm ALGOS [2]- [5] is used in the Time Department of the BIPM to generate, monthly, the international reference UTC. The calculation of UTC using ALGOS is carried out in three steps:

- The free atomic time scale EAL is computed as a weighted average of about 380 free-running atomic clocks spread world-wide. A clock weighting procedure has been designed to optimize the long-term frequency stability of the scale.
- The frequency of EAL is steered to maintain agreement with the definition of the SI second, and the resulting time scale is TAI. The steering correction is determined by comparing the EAL frequency with that of primary frequency standards (PFS).
- Leap seconds are inserted to maintain agreement with the time derived from the rotation of the Earth. The resulting time scale is UTC.

Different algorithms can be considered depending on the requirements on the scale; for an international reference such as UTC, the requirement is extreme reliability and long-term frequency stability. UTC therefore relies on the largest possible number of atomic clocks of different types, located in different parts of the world and connected in a network that allows precise time comparisons between remote sites. Each month the differences between the international time scale UTC and the local time scales UTC(k) maintained at the contributing time laboratories are reported at 5-day intervals in the official document called BIPM *Circular T* [6]. The original algorithm ALGOS for defining EAL gives the difference between EAL and each participant clock:

$$x_j(t) = EAL(t) - h_j(t) = \sum_{i=1}^{N} w_i \left[h'_i(t) - x_{i,j}(t)\right] \qquad (1)$$

where N is the number of participating clocks, w_i the relative weight of clock H_i, $h_i(t)$ is the reading of clock H_i at time t, and $h'_i(t)$ is the prediction of the reading of clock H_i that

978-1-61284-110-6/11/$26.00 ©2011 IEEE

serves to guarantee the continuity of the time scale. The data used by ALGOS and reported in (1) take the form of the time differences between readings of clocks, written as:

$$x_{i,j}(t) = h_j(t) - h_i(t) \tag{2}$$

The weight attributed to a clock reflects its long-term stability, since the objective is to obtain a weighted average that is more stable in the long term than any of the contributing elements [7]- [8]. Clock weights are determined from the variance of monthly average frequencies, constrained to a maximum value to avoid a few very stable clocks becoming dominant in the scale.

III. EAL FREQUENCY DRIFT ANALYSIS

TT provides a stable and accurate reference [9]- [10] for characterizing the performance of EAL frequency and for quantifying the frequency drift of the H-masers and the cesium clocks. TT is a time scale optimized for frequency accuracy, evaluated annually by making use of all available primary frequency standard data reported to the BIPM by national laboratories. By comparing the relative frequency of EAL with respect to TT a frequency drift of about -1.3x10^{-17}/day is clear. In a previous work [1] the possible reasons of the EAL frequency drift have been investigated and the role of the unmodelled drift of the H-masers has been quantified. Tests over a 3-year period (2006-2008) have been performed by calculating EAL without H-masers and the results seem to indicate that the H-masers could be responsible for 40% of the drift of EAL. We have used TT(BIPM) as the reference for characterizing the frequency drift of the H-masers and of the cesium clocks. The mean value for the H-masers frequency drift is -4x10^{-16}/day whereas for the cesium clocks it is -1x10^{-17}/day. Even if the frequency drift (or aging) observed for the cesium clocks is smaller than that for the H-masers, the cesiums represent about 80% of the weight of the clocks participating in the calculation of EAL, and consequently their impact on the frequency drift of EAL is more significant than that of the H-masers.

IV. PREDICTION ALGORITHM

In this section we will present the prediction algorithm used at present in ALGOS and the new proposed version. In the generation of a time scale, the prediction of the atomic clock behavior plays an important role, in fact the prediction is useful to avoid or minimize the time and frequency jumps of the time scale when a clock is added or removed from the ensemble or when its weight changes.

A. The prediction algorithm in ALGOS

Considering two successive intervals of TAI calculation $I_{i-1}(t_{i-1}, t_i)$ and $I_i(t_i, t_{i+1})$ we impose several conditions on the prediction term $h'_i(t)$ at time t_i to avoid or minimize time and frequency jumps in the resulting time scale. ALGOS operates in a post-processing mode, treating as a whole measurements taken over a basic period of T=30 or 35 days. For each one-month period, the results are the quantities $x_i(t_i + nT/6)$ (or $x_i(t_i + nT/7)$) with $n = 0, ..., 6$ (or $n = 0, ..., 7$) for each clock H_i. The least squares slope of these quantities is referred to as the frequency $B_{i,I_i}(t_i + T)$ of the clock H_i, relative to EAL, for the one-month interval $I_i = [t_i, t_i + T]$. The correction term $h'_i(t)$ for clock H_i is the sum of two terms:

$$h'_i(t) = a_{i,I_i}(t_i) + B_{ip,I_i}(t - t_i) \tag{3}$$

where $a_i(t_i)$ is the time correction relative to EAL of clock H_i at date t_i:

$$a_{i,I_i}(t_i) = EAL(t_i) - h_i(t_i) = x_i(t_i) \tag{4}$$

$B_{ip,I_i}(t - t_i)$ is the frequency of clock H_i, relative to EAL, predicted for the period $I_i = [t_i, t]$ and $(t - t_i) = nT/6$ (or $nT/7$) with $n = 0, ..., 6$ (or $n = 0, ..., 7$). At present, the predicted frequency $B_{ip,I_i}(t)$ for t included in $I_i = [t_i, t_i + T]$ is kept constant for the whole one-month interval. It is chosen to be the frequency computed for the previous one-month interval $I_{i-1} = [t_i - T, t_i]$, that is to say, the least squares slope of $x_i(t_i - T + nT/6)$ (or $x_i(t_i - T + nT/7)$) with $n = 0, ..., 6$ (or $n = 0, ..., 7$). This is a one-step linear prediction written as $B_{ip,I_i}(t) = B_i(t_i)$ for $t = t_i + nT/6$ (or $t = t_i + nT/7$), $n = 0, ..., 6$ (or $n = 0, ..., 7$). The assumption that clock H_i is most likely to behave over the coming one-month interval as it did on the previous one is linked to the choice of the sample duration T.

B. The new prediction algorithm

To evaluate the effect of the prediction in EAL frequency drift and to better describe the long term behavior of the H-masers and the cesium clocks we present here a new clock frequency prediction algorithm [11]- [12]. Considering two successive intervals of calculation of TAI $I_{i-1}(t_{i-1}, t_i)$ and $I_i(t_i, t_{i+1})$ we impose several conditions on the prediction term h'_i at time t_i to avoid or minimize time and frequency jumps in the resulting time scale. Instead of the linear term used in ALGOS we consider a quadratic behavior:

$$h'_i(t) = a_{i,I_i}(t_i) + B_{ip,I_i}(t - t_i) + \frac{1}{2} C_{ip,I_i}(t)(t - t_i)^2 \tag{5}$$

To the linear relation (3) we add the last term of (5) to describe the frequency drift affecting the H-masers and the long term behavior of cesium clocks. To evaluate the parameters in (5) we assume at time t_i the following conditions on h'_i:

1) no time steps by imposing the continuity of EAL;
2) no frequency steps by imposing the continuity to the first derivative of EAL;
3) no change in frequency drift by imposing the continuity to the second derivative of EAL.

We obtain a system of three equations with three variables and solving this system we obtain that the relation (5) can be expressed by the following relationship:

$$\begin{aligned} \widehat{h}'_i(t) = {} & \widehat{a}_{i,I_i}(t_i) + \widehat{B}_{ip,I_i}(t - t_i) \\ & + \frac{1}{2}\widehat{C}_{ip,I_{i-1}}(t)(t_i - t_{i-1})(t - t_i) + \frac{1}{2}\widehat{C}_{ip,I_i}(t)(t - t_i)^2 \end{aligned} \tag{6}$$

The physical meaning of the terms present in (6) is:

- $\widehat{a}_{i,I_i}$ is the estimation of the time correction relative to EAL of clock H_i at date t_i
- $\widehat{B}_{ip,I_i}$ is the estimation of the frequency of clock H_i, relative to EAL, predicted for the period $[t_i, t]$
- $\widehat{C}_{ip,I_i}$ is the estimation of the frequency drift of the clock H_i, relative to a frequency reference, predicted for the period $[t_i, t]$
- $\widehat{C}_{ip,I_{i-1}}$ is the estimation of the frequency drift of the clock H_i, relative to a frequency reference, predicted for the period $[t_{i-1}, t_i]$.

Two aspects are very important in this relation; the first is that we consider a constant drift during the calculation interval; the second is that with respect to the linear prediction the frequency does not remain constant during the interval. The parameters described above are considered constant during the calculation interval, but to avoid a frequency jump the frequency at the end of an interval and at the beginning of the next one should be the same. The frequency at the end of the interval is expressed by the addition of the second and the third term in the relation (6):

$$\widehat{B}_{ip,I_i}(t-t_i) + \frac{1}{2}\widehat{C}_{ip,I_{i-1}}(t)(t_i - t_{i-1})(t-t_i) \qquad (7)$$

and in particular $\widehat{B}_{ip,I_i}(t-t_i)$ is the estimated frequency at the middle of the interval.

V. The Parameter Estimation

The relationship (6) describing the correction applied to the atomic clocks is composed by three parameters. A very important point of this work is the optimization of the estimation procedure. In particular the estimation of the frequency drift needs particular attention. The estimation of the time correction $a_i(t_i)$, added to avoid time jumps, is given by the last known point of the difference between EAL and each clock and expressed by the following formula:

$$\widehat{a}_{i,I_i}(t_i) = EAL(t_i) - h_i(t_i) = x_i(t_i) \qquad (8)$$

From the theoretical point of view the best estimation of the mean frequency B_{ip,I_i} is the difference between the last and the first point on the interval duration of the clock data respect to EAL as expressed by the following relationship:

$$\widehat{B}_{ip,I_i} = \frac{x_i(t_{i+1}) - x_i(t_i)}{t_{i+1} - t_i} \qquad (9)$$

In order to estimate the frequency drift of atomic clocks under the hypothesis that it remains constant on one month interval the choice of the frequency reference is very important. In the following part of the paper we will discuss about the difference on the use of EAL and TT as frequency reference and we will show the improvement in EAL stability when TT is used. If the phase data $(EAL - h_i)$ have been used to estimate the time and frequency corrections the frequency data y_{TT-h_i} of the clock respect to TT are used to estimate the drift. The calculation of the drift is carried out by three steps:

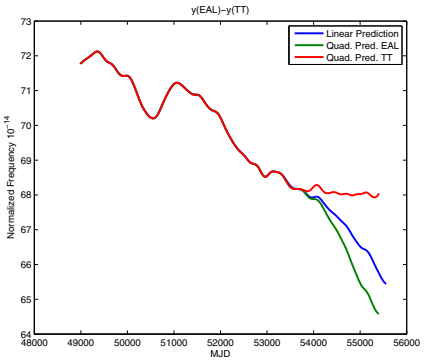

Fig. 1. y(EAL)-y(TT) calculated by applying the linear prediction (blue line), the quadratic prediction with EAL as frequency reference (green line) and the quadratic prediction with TT as frequency reference (red line).

- The frequency data of the clock respect to TT (y_{TT-h}) is filtered with a moving average of 15 days in order to remove the white frequency noise and better estimate the frequency drift. The obtained filtered data are called $\overline{y}_{TT-h_i}$
- The drift for all kind of clocks is estimated by using 4 months of $\overline{y}_{TT-h_i}$
- The relationship used to estimate the frequency drift is:

$$\widehat{C}_{ip,I_i} = \frac{\overline{y}_{TT-h_i,i}(t_{i+1}) - \overline{y}_{TT-h_i,i}(t_i)}{t_{i+1} - t_i} \qquad (10)$$

In the described procedure the biggest impact on the estimation of the drift is given by the choice of the frequency reference and by the choice of the length of the evaluation interval. The next part of this paper will be dedicated to discuss and develop these points.

VI. EAL and TT as Frequency Reference for the Drift Estimation

In this section the use of EAL an TT as frequency reference is discussed. TT-h_i is determinated by the sum of TT-EAL, given by the calculation of TT, and EAL-h_i. To evaluate the EAL performance, the EAL frequency (y(EAL)) is compared to TT frequency (y(TT)) which is a more accurate reference. In Fig. 1 the results of a test performed using 5 years of data from January 2006 to July 2010 are reported. EAL is obtained with the linear prediction (blue line) and quadratic predictions with the drift evaluated considering EAL (green line) and TT (red line) as frequency reference. The new prediction algorithm has been applied by using the described procedure with 6 months of past data to evaluate the frequency drift. The corresponding Allan deviations are reported in Fig.2. It is clear from the stability analysis that the use of EAL as frequency reference for the prediction has a negative impact on EAL performance while when TT is used as frequency reference the stability of EAL is clearly improved and the frequency drift affecting EAL is almost completely removed. To investigate the reasons of this result the comparison between the frequency drifts obtained by using EAL and TT as frequency references has

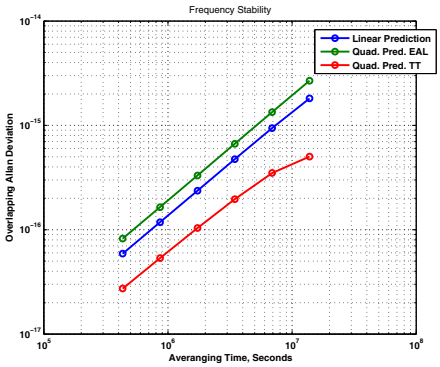

Fig. 2. Stability analysis of y(EAL)-y(TT) corresponding to the data presented in the Fig. 1.

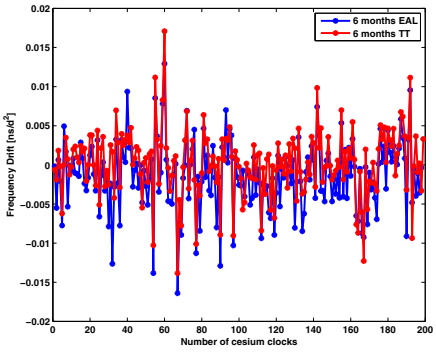

Fig. 3. With the red line the frequency drift calculated by using TT and with the blue line those obtained by using EAL are reported for the cesium clocks.

been made. In the next paragraph a summary of these studies will be presented. Considering the results obtained by using EAL and TT as frequency references it has been decided to choose TT as frequency reference to estimate the frequency drift of the H-Masers and the aging affecting the cesium clocks.

A. *Drift Analysis*

In this paragraph the difference between the drifts evaluated by using EAL and TT as frequency reference is investigated and explained. During the test period (2006- July 2010) the frequency drift has been calculated for all kind of clocks. Considering the mean value of the drift for about 200 cesium clocks (Fig. 3) and 35 H-Masers (Fig. 4) on the calculation period obtained by using EAL (blue line) and TT (red line) a systematic difference is observed. This is due to the fact that the freqency drift of EAL affects the estimation of the clock behaviour so invalidating it as a good reference.

VII. The Length of the Evaluation Period

In this section a study on the optimization of the length of the evaluation interval to estimate the frequency drift is presented. Considering the correlation at short term between TT and EAL it is not possible to use one month of data to

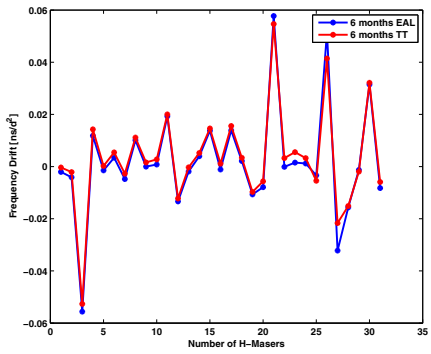

Fig. 4. With the red line the frequency drift calculated by using TT and with the blue line those obtained by using EAL are reported for the H-Masers.

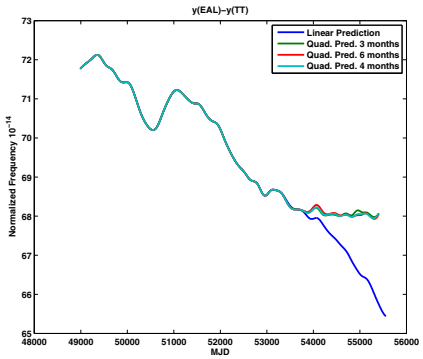

Fig. 5. y(EAL)-y(TT) obtained by using the quadratic algorithm with 3 (green line), 4 (light blue line), and 6 (red line) months of past data to evaluate the drift.

estimate the drift. A test was performed on 5 years of data by using 3, 4 and 6 months of past data to evaluate the drift. The results are compared using the stability of EAL as reference parameter. In Fig. 5 y(EAL)-y(TT) obtained by using the quadratic prediction algorithm with 3 (green line), 4 (light blue line), and 6 (red line) months of past data to evaluate the drift is reported. The zoom of this figure is reported in Fig. 6 in order to show the impact of the use of difference length of past period in the new prediction algorithm to evaluate the frequency drift during the test period.

From the results reported in Fig. 5 we can conclude that the EAL frequency drift is almost completely removed. If we compare the results obtained by using a different number of the months (Fig. 6) to evaluate the frequency drift it seems to have similar performance, in fact not big differences are observed among the results. To better evaluate this effect the stability analysis of EAL respect to TT in term of frequency is reported for the previous data. A substantial improvement of the EAL performance by using the quadratic prediction in term of stability is observed in Fig. 7. The Allan deviation of EAL respect to TT shows an aging or residual drift of about $1\text{x}10^{-18}$/day (1 order of magnitude less than the present case) not easily characterized and a possible random walk. The value

of the frequency stability at 5 days by using a linear prediction is between 5.9x10^{-17} and 4.8x10^{-16} at 40 days. With the new prediction algorithm the obtained values for the stability are 2.5x10^{-17} at 5 days and 1.8x10^{-16} at 40 days. In Fig. 7 with the violet line the stability analysis of the data obtained with the linear prediction algorithm and a linear frequency drift removed is reported. The obtained results are consistent with those obtained by using the quadratic prediction so we can conclude that the linear frequency drift affecting most of the clocks composing the ensemble is removed. A non linear component of the drift could be present but since it cannot be easily estimated it has not been considered for the moment. We can also conclude that the EAL performance does not change by using a different past period. In the following subsection the frequency drifts affecting the cesium clocks and the H-masers will be caracterized to show the difference between them and to make some conclusions about the optimization of the length of the past period to estimate the frequency drift.

A. Drift analysis of the cesium clocks and H-masers

During the test period (5 years) the frequency drift has been calculated in one month interval for cesium clocks and H-masers and time series are obtained. In Figs. 8 and 9 one example of the behavior of the frequency drift obtained by using 6 (red line), 3 (blue line) and 4 (green line) months of past data respectively for one cesium clock and one H-maser is presented. By analyzing the drift evolution of the cesium clocks (see Fig. 8) very stable drifts or drift carachterized by very small instabilities are observed. The situation is very homogeneous for most of the clocks. A very different situation is observed for the H-masers (see Fig.9) in fact the behavior of the drift can be characterized by important instabilities, and also important differences are present between different clocks. In the case of H-masers a long past period (6 months) is not recommended to estimate the frequency drift.

B. The length of the evaluation period

Considering that:

- the stability of EAL calculated with the new prediction algorithm does not change significantly by using 3, 4 or 6 months of past data to evaluate the frequency drift.
- the use of a long past period is not recommended (H-Masers)
- In the weight algorithm the clocks are studied during 4 months before being included in the calculation.

We conclude that the period equal to 4 months is adeguate for the drift prediction.

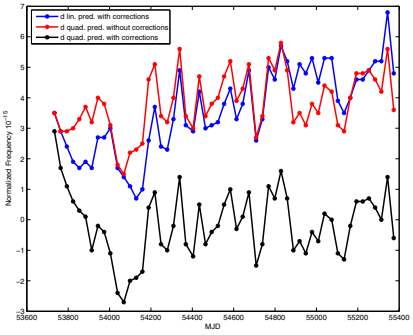

Fig. 10. The value of d as published in Circular T is reported with the blue line. The red line shows the values of d calculated by applying new prediction algorithm without frequency corrections and with the dark line the values of d obtained with corrections equal to -0.6x10^{-15} for the first 7 months.

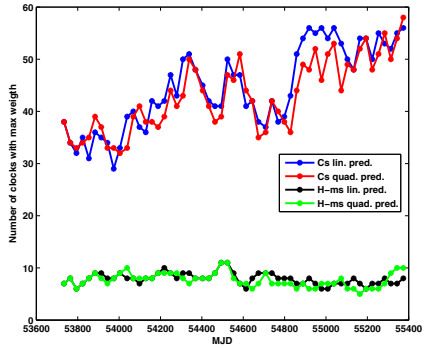

Fig. 11. The number of the clocks (H-masers and Cesium clocks) with maximum weight are reported as obtained by using the linear and the quadratic predictions. The results are reported respectively with the dark and green lines for the H-masers and with the blue and red lines for the Cesium clocks.

VIII. The effect of the new prediction algorithm on TAI and on the weights

In this paragraph we will present an analysis of the effects of the new prediction algorithm on TAI behavior and on the weights.

A. The effect on TAI

TAI is a realization of coordinate time TT. In Section 4 of *Circular T* [6] the fractional deviation d of the scale interval of TAI from that of TT based on all available PFS measurements is reported. In Fig. 10 the values of d as published in *Circular T* are plotted with the blue line. The red line shows the values of d calculated by applying the new prediction algorithm without frequency corrections; the dark line shows the values of d obtained again by using the new prediction algorithm with frequency corrections equal to -0.6x10^{-15} applied only for 7 months of the test period (5 years), after that no corrections are applied. We can conclude that no big differences are observed between TAI and EAL after the application of the new prediction algorithm and only small adjustments of the frequency of EAL are required to obtain TAI.

B. The effect of the weights

The weight algorithm has not been changed during the test period and it seems that the new prediction algorithm has a little effect on the weights. In Fig. 11 the number of the clocks (H-masers and Cesium clocks) with the maximum weight are reported as obtained by using the linear and the quadratic predictions. The results are reported respectively with the dark and green lines for the H-masers and with the blue and red lines for the Cesium clocks.

IX. Conclusion

A new mathematical expression for the prediction has been found including the treatment of the frequency drift. A test for the 5-year period has been done applying quadratic prediction to all atomic clocks and by using 4 months of past data to evaluate frequency drift. Different past periods to evaluate the frequency drift have been tested and the obtained results have been compared. The EAL perfomance has clearly improved and its frequency drift has been almost completely removed. EAL still shows a residual drift which is 1 order of magnitude smaller than before that it is not easily estimated and that is has not been removed. This residual drift can be due to a non-linear signature caracterizing the drift and not included in the model. The effect on TAI of the new prediction algorithm is discussed and now only small adjustments of the frequency of EAL could be necessary to obtain TAI. The new prediction algorithm has little impact on the weights; a revision of the weight algorithm is advisable to increase the role of the H-masers in the time scale ensemble for the future.

Simulation Of Future GPS Clock Scenarios With Two Composite Clocks

Matthias Suess (DLR)

Demetrios Matsakis (USNO)
United States Naval Observatory (USNO),
Washington, D.C., USA

***Abstract*— The performance of the GPS constellation is modeled using four possible ensembles of monitor site clocks and two different versions of the composite clock algorithm. The analysis of our previous paper [1] is scrutinized; the conclusion remains that the improvements due to improved station clocks are minimal if the "Greenhall" algorithm is used for the composite clock. The response to a satellite and monitor station time step is investigated. Furthermore, the proportional process noise case is studied for different initial covariances.**

I. INTRODUCTION

The GPS control segment consists of 17 monitor stations. The monitor stations at USNO, Washington DC, and Schriever AFB are referenced to masers, while all other stations are equipped with HP 5071 cesium clocks **[7]**. USNO is planning to replace the maser references in Washington and Schriever with rubidium fountains. This paper uses a simplified model of the operational GPS Kalman Filter, limited to clock estimates, to investigate the impact of improved monitor station clocks on the GPS timing performance.

II. SIMULATION OF THE GPS WORKFLOW

Using the GPS toolkit software **[2]**, the positions of 31 satellites are modeled based on the GPS almanac file of week 531. The satellites are equipped with Rubidium Atomic Frequency Standards (RAFS). The measurements are simulated with a 15-minute spacing, a white Gaussian noise of 0.7 ns (1 sigma), and an elevation angle mask of 20°. The measurement noise models pseudorange measurements, which provide time information but are approximately 100 times noisier than carrier phase data.

The clock parameters computed by the Kalman Filter are uploaded to each satellite once a day as a broadcast model. In this simulation we assume the update occurs when the satellite is in view over Schriever AFB and the clock broadcast parameters are older than 1 day.
For this work, only clock parameters are solved for. In the operational filter, satellite orbit and other parameters are simultaneously included and the correlations among the full set of parameters would be expected to decrease the precision of the derived solutions. This would most likely decrease the differences we have computed between the clock models. However, double-differencing between satellite and station pairs allows one to solve for all other parameters without estimating clocks, and to solve for clocks in a second solution using the non-clock parameters as inputs.

A. Simulation of three Improved Monitor Station Clocks and Satellite Clocks

Each clock is modeled with a three-state vector X(t), which includes phase, frequency, and drift offset [3, 4].

$$\frac{dX}{dt}(t) = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix} X(t) + W(t) \qquad (1)$$

$$EW(t)W^T(t) = \begin{pmatrix} q_1 & 0 & 0 \\ 0 & q_2 & 0 \\ 0 & 0 & q_3 \end{pmatrix} = Q(0s) \qquad (2)$$

with a deterministic zero start value, $X(t_0)=0$, and W(t) is the clock process noise. The three q's measure the noise contributions from white frequency modulation (WFM), random walk frequency modulation (RWFM), and random run frequency modulation (RRFM).

Four different types of monitor station clocks are simulated: cesium, active hydrogen maser (AHM), fountain clock and optical fountain clock. Their stochastic components (q's) together with the RAFS are specified in Table 1, and were computed as in [1]. Typical Allan deviations are shown in Figure 1. The values for these q's should not be taken as authoritative by any means, nor should the associated Allan deviations be assumed as anything but a rough approximation of the clocks.

TABLE 1. CLOCK NOISE MODELS.

	q_1 WFM [s^2/ s]	q_2 RWFM [s^2/ s^3]	q_3 RRFM [s^2/ s^5]
Cesium	2.50e-23	4.44e-37	5e-53
AHM	2.8e-26	1.1e-35	4.4e-51
Fountain	2.5e-26	1.1e-37	1.1e-55
Optical Ftn	4.4e-27	1.1e-37	1.1e-55
RAFS	1.0e-24	1.1e-35	2.8e-46

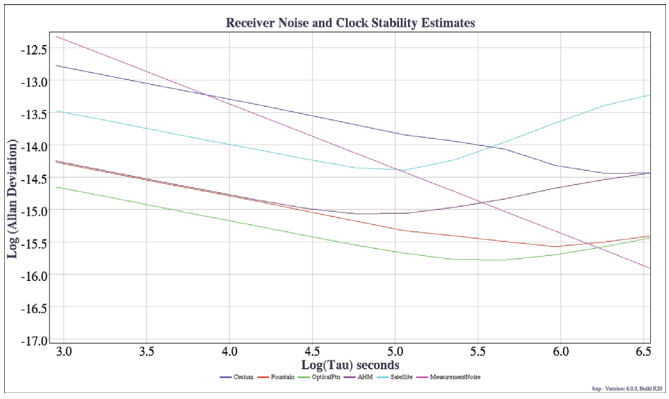

Figure 1. Allan deviation of one individual clock simulation of each modeled type. It is assumed that the necessary resources are expended to keep the masers and the optical fountains within their environmental specifications, and that the receiver's white phase pseudorange noise is diluted by 8 independent simultaneous satellite measurements.

For numerical issues it is found to be useful to change the units of the q values (Table 1), which are conventionally given in second, to nanoseconds and days:

$$\left(\frac{10^{18}}{86400^{-1}} q_1 \quad \frac{10^{18}}{86400^{-3}} q_2 \quad \frac{10^{18}}{86400^{-5}} q_3 \right) \left[\frac{ns^2}{d} \quad \frac{ns^2}{d^3} \quad \frac{ns^2}{d^5} \right] \qquad (3)$$

B. Composite Clock Algorithms – Brown and Greenhall

Two composite clock algorithms **[5,6]** are applied to estimate the three states of the satellite and control station clocks with respect to its implicitly defined time scales. Since N clocks involve maximal N-1 linearly independent measurements, each composite clock algorithm includes a method to prevent the formal covariance of the solution parameters from growing without bound.

1) The Brown Composite Clock

It can be shown **[5]** that no measured quantity is affected if the "Brown" Kalman Filter covariance estimates B(C(t)) are reduced at each iteration step as follows:

$$B(C(t)) = C(t) - \bar{H}(\bar{H}^T C^{-1}(t)\bar{H})^{-1}\bar{H}^T \qquad (4)$$

with

$$\bar{H} = \begin{pmatrix} 1_N & 0_N & 0_N \\ 0_N & 1_N & 0_N \\ 0_N & 0_N & 1_N \end{pmatrix} \in R^{3Nx3} \text{ and } 1_N = \begin{pmatrix} 1 \\ \vdots \\ 1 \end{pmatrix} \in R^N \qquad (5)$$

0_N is a vector of N zeros. Each of the nine NxN submatrices C_{ij} with $i, j \in \{x, y, d\}$ is subtracted by a NxN matrix with a common element defined by c_{ij}

$$C = \begin{pmatrix} C_{xx} & C_{xy} & C_{xd} \\ C_{yx} & C_{yy} & C_{yd} \\ C_{dx} & C_{dy} & C_{dd} \end{pmatrix} \rightarrow B(C) = \begin{pmatrix} C_{xx} & C_{xy} & C_{xd} \\ C_{yx} & C_{yy} & C_{yd} \\ C_{dx} & C_{dy} & C_{dd} \end{pmatrix} - \begin{pmatrix} 1_{N,N}c_{xx} & 1_{N,N}c_{xy} & 1_{N,N}c_{xd} \\ 1_{N,N}c_{yx} & 1_{N,N}c_{yy} & 1_{N,N}c_{yd} \\ 1_{N,N}c_{dx} & 1_{N,N}c_{dy} & 1_{N,N}c_{dd} \end{pmatrix} \qquad (6)$$

with

$$(\bar{H}^T C^{-1}(t)\bar{H})^{-1} = \begin{pmatrix} c_{xx} & c_{xy} & c_{xd} \\ c_{yx} & c_{yy} & c_{yd} \\ c_{dx} & c_{dy} & c_{dd} \end{pmatrix} \text{ and}$$

$$1_{N,N} = \begin{pmatrix} 1 & \cdots & 1 \\ \vdots & & \vdots \\ 1 & \cdots & 1 \end{pmatrix} \in R^{NxN} \qquad (7)$$

The Brown reduction results in a series of reduced covariances which are called:

$$C_B(t_k) = B(F(C_B(t_{k-1}))) \qquad (8)$$

where the matrix function F models the Kalman filter iteration. The initial values are

$$\hat{X}_B(t_0) = 0 \text{ and } C_B(t_0) = 1e^{10}Q(\tau) \qquad (9)$$

The resulting ensemble estimate and estimation error (corrected ensemble) are denoted:

$$\hat{X}_B = \begin{pmatrix} \hat{x}_B \\ \hat{y}_B \\ \hat{d}_B \end{pmatrix} \text{ and } X_B = \begin{pmatrix} x \\ y \\ d \end{pmatrix} - \begin{pmatrix} \hat{x}_B \\ \hat{y}_B \\ \hat{d}_B \end{pmatrix} \qquad (10)$$

2) The Greenhall Composite Clock

The reduction method by Greenhall is similar; however, it works only on the submatrix C_{xx} of the phase states **[6]**. Using the auxiliary matrix

$$S = \begin{pmatrix} A & 0 & 0 \\ 0 & I_N & 0 \\ 0 & 0 & I_N \end{pmatrix} \qquad (11)$$

with

$$A = (I_N - 1_N 1_N^T (1_N^T C_{xx}^{-1} 1_N)^{-1}) \qquad (12)$$

the Greenhall reduction is defined by

$$G(C(t)) = SC(t)S^T \qquad (13)$$

The matrix operation only affects the submatrixes involving the phase-parts:

$$C = \begin{pmatrix} C_{xx} & C_{xy} & C_{xd} \\ C_{yx} & * & * \\ C_{dx} & * & * \end{pmatrix} \rightarrow G(C) = \begin{pmatrix} C_{xx}^* & AC_{xy} & AC_{xd} \\ C_{xy}A^T & * & * \\ C_{xd}A^T & * & * \end{pmatrix} \qquad (14)$$

with

$$C_{xx}^* = C_{xx} - 1_N (1_N^T C_{xx}^{-1} 1_N)^{-1} 1_N^T \qquad (15)$$

Running the Kalman filter with this reduction method changes the phase estimates, but not the frequency and drift estimates. The reduced covariance of the Greenhall composite clock is defined by:

$$C_G(t_k) = G(F(C_G(t_{k-1}))) \qquad (16)$$

Analogous to the Brown filter, the Greenhall estimates and estimation errors or corrected ensemble are denoted $\hat{X}_G$ and $\tilde{X}_G$.

C. Three Ground Segment Models

Table 2 outlines three different ground segment models for the stability of the monitor station clocks.

TABLE 2. MODEL DEFINITION.

Model C	Cesiums at every station except for AHMs at Schriever and USNO
Model M	AHMs at every station
Model F	Cesiums at every station except at Schriever and USNO, where USNO will maintain rubidium-based atomic fountains
Model O	As in Model F, except that the "optical fountains" have a factor of 2.4 less WFM noise

Model C describes the current situation in GPS, Model F represents the rubidium atomic fountains which the USNO is planning to install at its two facilities in the near future, and the other models represent possible future scenarios.

D. Time Scales

Both composite clocks define their time scales within the Kalman filter. In case of the Greenhall composite clock, the time scale weights are given by

$$w_G^T(t) = (1_N^T C_{G,xx}^{-1}(t) 1_N)^{-1} 1_N^T C_{G,xx}^{-1}(t) \qquad (17)$$

with

$$C_G(t) = \begin{pmatrix} C_{G,xx}(t) & C_{G,xy}(t) & C_{G,xd}(t) \\ C_{G,yx}(t) & C_{G,yy}(t) & C_{G,yd}(t) \\ C_{G,dx}(t) & C_{G,dy}(t) & C_{G,dd}(t) \end{pmatrix} \quad (18)$$

and its time scale is

$$sys_G(t) = w_G^T(t)(x(t) - \hat{x}_G(t)) \quad (19).$$

In contrast, the time scale of the Brown composite clock is the phase of the implicit ensemble mean (IEM). Using the Brown time state weight of all states

$$w_B^T(t) = ((\bar{H}^T C_B^{-1}(t)\bar{H})^{-1}\bar{H}^T C_B^{-1}(t))(1,:) \quad (20),$$

the IEM is defined by

$$sys_B(t) = w_B^T(t)\begin{pmatrix} x(t) - \hat{x}_B(t) \\ y(t) - \hat{y}_B(t) \\ d(t) - \hat{d}_B(t) \end{pmatrix} \quad (21)$$

Unlike the Greenhall model, the Brown time scale includes the corrected frequency and drift states.

III. IMPACT OF RECEIVER NOISE

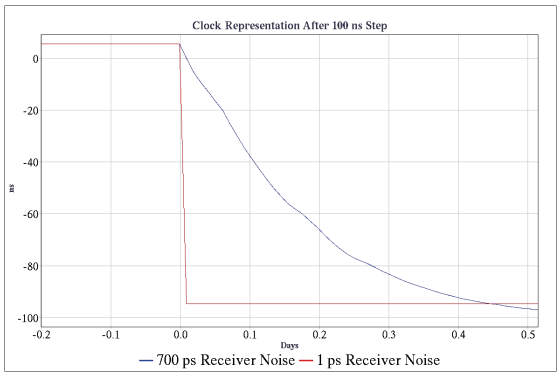

Figure 2. Impact of receiver noise on Kalman filter estimate.

It is well known that the Kalman Filter acts as a smoother to balance the noise in the data against the process noise in the parameters. The impact of this smoothing upon impulse response is shown in Figure 2.

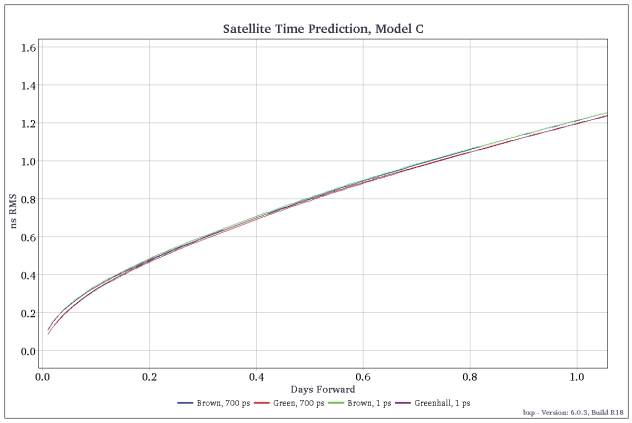

Figure 3. Impact of receiver noise on prediction error.

Figure 3 shows the accuracy of satellite prediction as a function of age of data. Lower curves are 700 ps receiver noise; upper are 1 ps noise case; the apparent discrepancy is due to the smoothing.

IV. TIMESCALE RESPONSE ON PHASE JUMPS

In order to investigate the impact of a phase step on the time scales a phase step test is performed:

- Monitor station step of 100 ns at 8 day (clock type depends on model)
- Satellite clock step of 100 ns at 10 day

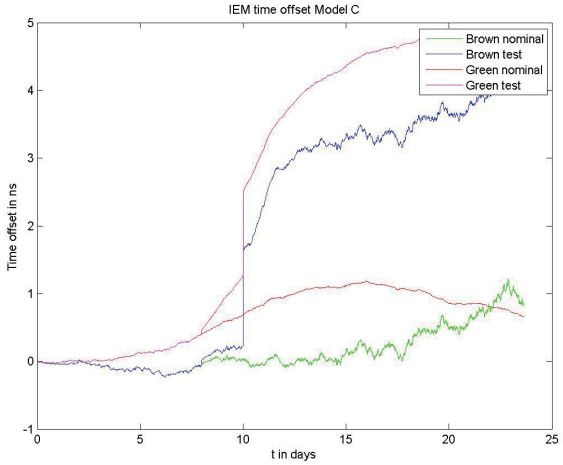

Figure 4. Phase step impacts on Model C.

Figure 4 compares the resulting IEMs of Model C to the nominal scenario. The impact of the monitor step at day 8, which is a cesium, is almost insignificant (~<0.5 ns) and at the receiver noise level. However, the result of satellite clock step is around (~2 ns). The different step size is due to the different weighting of the clock phases. Both algorithms act in a similar manner.

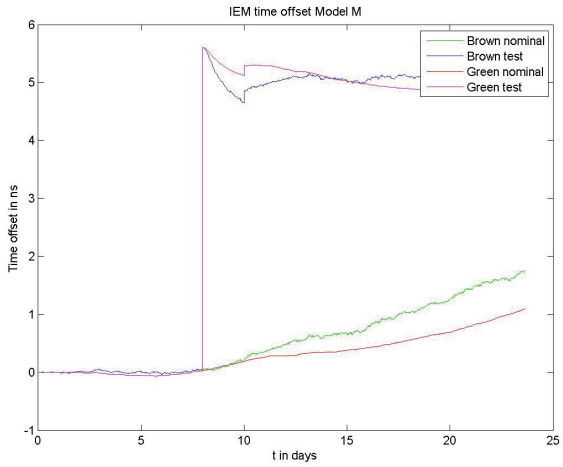

Figure 5. Phase step impact on both IEMs of Model M.

Figure 5 shows the phase step impact on Model M. The monitor station step (AHM) is significant and of size ~6 ns which is reflects the weighted step size 100ns/17=5.88ns using the fact that the 17 AHM carry all the weight. Vice versa, the satellite clock step is less, and ~0.5 ns. The Model M situation is switched relative to the Model C situation which again is due to the different weighting of the ensemble clocks. In the case of Model M the monitor stations carry the most weight, which is not the case for Model C.

V. Comparison of Brown And Greenhall assuming the PPN Case And Its initalizationi dependency

Our previous paper [1] empirically showed that the two covariance reduction methods of Brown and Greenhall can be commutatively combined without affecting the clock difference, frequency, or drift estimates. Within [5] Brown studied a special type of ensemble which is called the proportional process noise (PPN) case. Each clock noise covariance can be expressed by a scalar value and a 3x3 covariance:

$$Q_i = s_i Q_0 \tag{22}$$

It is shown [5] that the phase of the Brown IEM is identical to

$$sys_B(t) = w_B^T(t)\begin{pmatrix} x(t)-\hat{x}_B(t) \\ y(t)-\hat{y}_B(t) \\ d(t)-\hat{d}_B(t) \end{pmatrix} = \left(\sum_i \frac{1}{s_i}\right)^{-1} \sum_i \frac{1}{s_i} x_i \tag{23}$$

However, the Brown method weights corrected time, frequency and drift states as well:

$$w_B^T(t) = (w_{B,x}^T(t) \quad w_{B,y}^T(t) \quad w_{B,d}^T(t)) \tag{24}$$

In case of PPN, the frequency and drift weights are zero:

$$w_{B,y}^T(t) = w_{B,d}^T(t) = 0_N^T \tag{25}$$

By simulation the impact of the PPN case on the Greenhall and Brown algorithm is studied. Identical Q_i values of the clock process noises are used, but with a smaller system. The ensemble consists of seven clocks and two clocks of the ensemble observe the remaining five clocks at each measurement epoch. Different initialization values of the ensemble covariance are tested. The starting values are multiplies of the ensemble noise covariance

$$C(t_0) = kQ \tag{26}$$

with

$$k \in \{1e2, 1e4, 1e6, 1e8, 1e10, 1e12\} \tag{27}$$

Figures 6 and 7 show the time and frequency state weight of a observed clock 1: $w_{B,x,1}^T(t)$ and $w_{B,y,1}^T(t)$.

The time state weights fall on each other for k <=1e8. However, in case of k=1e10 and k=1e12 the weights converge to the same final value (Figure 6). Focusing on the frequency state weight (Figure 7), these values are close to zero for k<=1e8, however there are biases for k=1e10 and k=1e12. Recalling that the frequency weights are zero in the PPN case, we see large differences for k=1e10 and k=1e12. In contrast, the Greenhall time weight of observed clock 1 is not affected by the different initial covariances. Figure 8 shows the difference of an observed clock 1 between the time estimates of both algorithms. The time differences are numerically zero for k<=1e8, while the remaining two values (k=1e10 and k=1e12) result in biased differences.

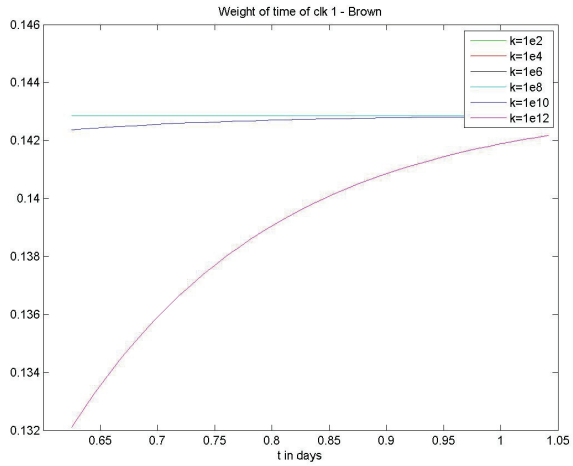

Figure 6. Weight of observed clock 1 time in Brown IEM phase, for 7-clock ensemble.

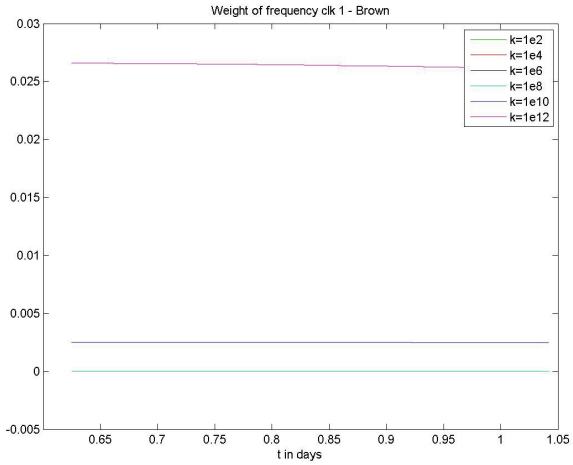

Figure 7. Weight of observed clock 1 frequency in Brown IEM phase, for 7-clock ensemble

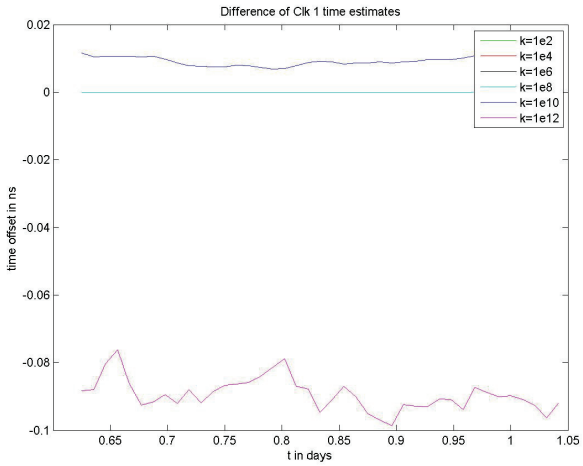

Figure 8. Differences between time estimates of Brown and Greenhall for observed clock 1 in 7-clock ensemble.

The results suggest that both algorithms generate identical estimates using proper initial values of the covariance (k<=1e8).

VI. Conclusion

The improvements due to improved station clocks are minimal if the "Greenhall" algorithm is used for the composite clock. Greenhall is generally superior, although the two algorithms respond differently to unanticipated clock variations. It is also noted that several other timescale algorithms have great merit, but have not been tested in this work. The study of the PPN case shows the sensitivity of the Brown algorithm to the initial values. It is suggested that the PPN case results in identical estimates of both algorithms. Simulations verify this behavior for a smaller ensemble using proper initial covariances.

Supression of collisional frequency shifts in an optical lattice clock

***Abstract*— By strongly confining atoms in a two-dimensional optical lattice, we have suppressed collisional frequency shifts in a ^{87}Sr optical lattice clock.**

I. Suppression of collisional frequency shifts

Optical clocks based on atoms confined in optical lattices provide a unique opportunity for precise study and measurement of quantum many-body systems. The state-of-the-art optical lattice clock has reached an overall fractional frequency uncertainty of 1×10^{-16} [1]. This uncertainty is dominated by two contributions – atomic collisions and blackbody radiation-induced frequency shifts. The density-dependent frequency shift arises from collisions between initially identical fermionic Sr atoms that are subject to slightly inhomogeneous optical excitations during clock operation [2]. We have recently implemented a seemingly paradoxical solution to the collision-shift problem: with a strong atomic confinement in one-dimensional tube-shaped optical traps, we dramatically increase the atomic interactions. Instead of a naively expected increase of collisional frequency shifts, these shifts are increasingly suppressed [3]. The large atomic interaction strength creates an effective energy gap in the system such that inhomogeneous excitations can no longer drive fermions into a pseudo-spin antisymmetric state, and hence their collisions and the corresponding frequency shifts are suppressed. We demonstrate the effectiveness of this approach by reducing the density-dependent frequency shift to the level of 10^{-17}, representing more than a factor of ten reduction from the previous record [2, 3]. In addition, we have observed well-resolved interaction sidebands separated from the main peak of the clock transition, giving direct evidence for the removal of the interaction energy from the clock carrier transition [4]. Control of atomic interactions at the level of 1×10^{-17} is a testimony to our understanding of a quantum many-body system and it removes an important obstacle for building a high accuracy optical atomic clock based on such systems.

***Abstract*— We present here experimental result showing that an collisional shift that cannot be explained by mean-field effects. We demonstrate that the latter results from subtle interaction scheme in our cold atomic cloud, mathematically equivalent to a fermionic collisional shift. We show agreement between theory and experiment, and extract the relevant energy scales implied in the collision process.**

A new definition of the SI second will built on optical transitions. The interrogation of neutral fermionic atoms is performed to increase the clock stability while controlling the collisional shift. Theoretical efforts have been made in order to predict and model a fermion collisional shift [1] [2] [3]. For Ramsey interrogation, K. Gibble predicts a non-zero collisional shift due to an energy-dependent Rabi frequency of the driving pulse [2].

We apply his formalism to atoms in a harmonic trapping potential and extend the theory to the case of a position-dependent Rabi frequency. The case of an energy-dependent Rabi frequency can be viewed as the sideband-resolved limit of our calculation. We numerically solve the equations of motion for a complete Ramsey sequence. Just like in [2], we show that during the first Ramsey pulse, the inhomogeneous Rabi frequency coherently populates singlet and triplet states. Their populations beat at the frequency corresponding to the singlet state interaction energy. The time varying populations manifest themselves through the so-called spin waves [4]. The second Ramsey pulse reveals signature of multiple interfometers paths, whose beating is governed by this interaction energy alongside with the trap frequency and its multiples in the non-resolved sideband regime. This multiple path interference, direct consequence of the Rabi frequency inhomogeneity, results in a significant non-intuitive collisional shift when varying the second pulse area. Furthermore, the shift is highly non-linear at high atom density.

We verify our model by measurements of the $|F = 1, mF = -1\rangle$ to $|F = 2, mF = 1\rangle$ transition in magnetically trapped 87Rb atoms [5]. Because all scattering lengths coincide within 5%, this boson is mathematically equivalent to the fermion case. Spatial inhomogeneity of the Rabi frequency is obtained by using the evanescent field 150m above a microwave stripline. We indeed observe spin waves and a collisional shift that depends on the area of the second Ramsey pulse. We find excellent agreement between model and data. Thereby the data give evidence for the predicted fermion collision shift and suggest that it should be considered when designing future primary clocks.

***Abstract*—This paper describes an acoustic tweezers consisting of a multi-foci Fresnel lens on 127 μm thick PZT sheet, designed to capture micron-sized particles. The multi-foci Fresnel lens was designed to have similar working mechanism as that of an axicon lens to generate an acoustic Bessel beam and, correspondingly, to generate negative axial radiation force capable of trapping one or more microparticle(s). The fabricated acoustic tweezers successfully trapped lipid particles ranging in diameter from 50 to 200 μm and microspheres ranging in diameter from 70 to 90 μm at a distance of 2 to 5 mm from the tweezers without any contact between the transducer and microparticles.**

I. INTRODUCTION

Contactless particle trapping is an emerging research topic in biology, physical chemistry and bio-medical research. Among the various approaches of contactless tweezing techniques, optical tweezers is the most well developed and most commonly investigated technique [1]. However, particle trapping using optical manipulation has several limitations: first, the high energy of a highly focused laser can damage living cells. Secondly, optical tweezers cannot trap large particles due to the short wavelength of the light source. The size of the largest particle which can be trapped by an optical tweezers is limited to tens of micrometers or smaller. Finally, the use of optical tweezers is confined to optically transparent objects or shallow region of opaque medium.

Ultrasonic tweezers is a relatively young field, and seeks to provide an alternative to optical tweezers. Ultrasound is more attractive than light, because it imparts much higher energy (or impact force) and also offers greater spatial range, consequently providing the ability to capture larger particles over a wider range. However, ultrasonic tweezers is not well established or researched, possibly due to lack of good focusing technology. Control and manipulation of microparticles offer a wide range of applications ranging from the study of cells and molecules to the construction of labs on a chip, from cancer treatments to DNA studies.

Limited ultrasonic manipulation of microparticles has already been achieved. The systems used for the said manipulation, however, are not as versatile as are optical tweezers. One such system is the "acoustical tweezers" pioneered by Wu [2], a device capable of stably capturing latex particles of diameter 270 μm. The tweezers utilized two counteracting acoustic transducers to create a force potential well that could capture and manipulate different microparticles. Another device used for ultrasonic manipulation of microparticles used one highly focused transducer to hold a lipid droplet that was already confined to a mylar sheet in water [7].

This paper describes microparticle trapping in a 3-D space by a single ultrasonic transducer. We designed and fabricated transducers that could generate a Bessel beam containing a region of a negative axial radiation force [3]. In general, Bessel beams are generated by an axicon lens [4]. However, fabricating an axicon lens in small size can be challenging due to the steep lens angle required. Thus, we fabricated both an axicon lens and a Fresnel lens employing an air-reflector [5] that has wide tolerance to manufacturing imprecision. Both of the fabricated lenses were shown to generate a Bessel beam through particle trapping. The trapping by the Fresnel lens device was strong and stable, that there was no limit to moving range of the trapped particles in plane of the water surface.

II. THEORY

When a Fresnel lens is designed to have multiple focal points, the acoustic waves passing through the lens produces a Bessel beam with a micron sized region where the radiation force is negative, and microparticles can be trapped. The wave equation ψ_B for a scalar-wave Bessel beam is an axisymmetric solution of the free-space wave equation [3].

$$\psi_B(x,y,z) = \psi_0 \exp(i\kappa z) J_0(\mu\sqrt{x^2+y^2}) \quad (1)$$

where ψ_o, κ, J_o, and μ are the wave amplitude, axial wave number, zeroth-order Bessel function, and radial wave number, respectively.

Marston mathematically proved that negative axial radiation force exists in a Bessel beam under certain conditions [3]. To explain the condition for the negative axial radiation force, Marston defined parameter domain (k, a, β)

where k and a are the wave number and radius of trapping particle, respectively, while β is a cone angle. The cone angle β is an important parameter in the characterization of a Bessel beam, and linked to the parameters of Eq. (1) by

$$\beta = \arccos(\kappa/k) = \arcsin(\mu/k) \quad (2)$$

The square of the wave number k, i.e., k^2, is equal to $\kappa^2+\mu^2$, and also equal to $(\omega/c_0)^2$, where ω and c_0 are angular frequency and the phase velocity of the acoustic wave in the liquid, respectively.

III. Design and Fabrication

Observing the working mechanism of an axicon lens, we can see that the wave closer to the lens center is focused at a shorter distance from the lens. In the other end, the wave farther from the lens center is focused at longer distance from the lens as shown in Figure 2. A Bessel beam is formed in the region where the focused wave is uniformly distributed.

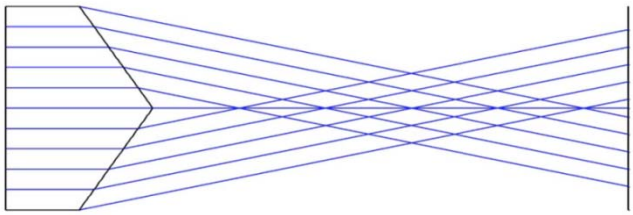

Figure 2. Ray trajectories of the acoustic waves going through an axicon lens.

To simulate the behavior of an axicon lens described above, a multi-foci Fresnel lens with an air-reflector was designed. The Fresnel lens has 7 rings in total. The 2 inner most rings, the next 2 rings, and remaining 3 rings have focal lengths of 830 µm, 860 µm, and 890 µm, respectively (Figure 4). As a control experiment, an acoustic tweezers with Fresnel lens having only one focal length of 800 µm and same number of rings was fabricated. When the control transducer was actuated, particles above the control transducer were immediately expelled from the region due to positive axial radiation force and the stirring effect, and no particle was trapped.

An acoustic tweezers with an aluminum alloy axicon lens also designed and fabricated to compare the performance. To have the cone angle β=60°, the axicon lens angle α was set to 63° (Figure 3)

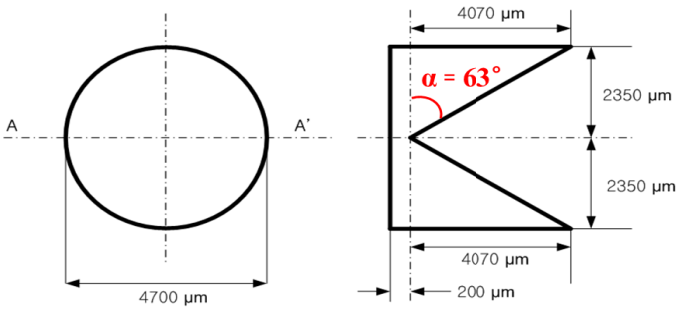

Figure 3. Top-view (*left*) and side-view (*right*) schematics of the Aluminum-Alloy Axicon Lens.

We fabricated the multi-foci Fresnel lens as follow. After delineating the top and bottom electrodes on a 127 µm-thick PZT sheet, we patterned Fresnel lens with photoresist as a sacrificial layer, on which 3.5 µm-thick parylene D layer was deposited as a lens structural layer. The sacrificial photoresist was then released through release holes to form air gaps, and additional 7 µm-thick parylene D layer was deposited to seal the release holes. Finally, a bulk micro-machined silicon was glued to the transducer as a structural support layer.

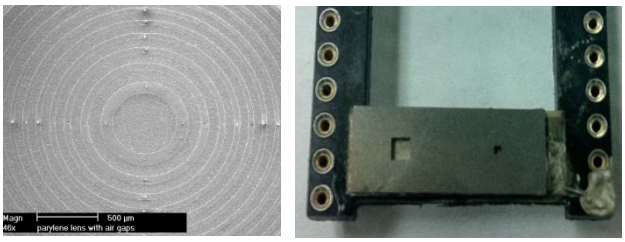

Figure 7. (Left) SEM photo of the fabricated multi-foci Fresnel lens on a PZT sheet. (Right) Photo of a packaged acoustic tweezers with the multi-foci Fresnel lens.

IV. Measurement Setup and Results

For a low energy in trapping microparticles, a pulsed 17.9 MHz sinusoidal signal, instead of continuous sinusoidal signal, was applied to the fabricated acoustic tweezers with 10 – 20 kHz pulse repetition frequency. The pulse width was 2 µsec, and the sinusoidal signal had 160 $V_{peak\text{-}to\text{-}peak}$ amplitude. The tweezers submerged in water was fixed to a manual XYZ moving stage, and lipid particles or microspheres were freely floating on and in the water. The movement of the microparticles was observed through a CCD attached a long range microscope, and the images and videos captured by the CCD were recorded with a computer (Figure 9).

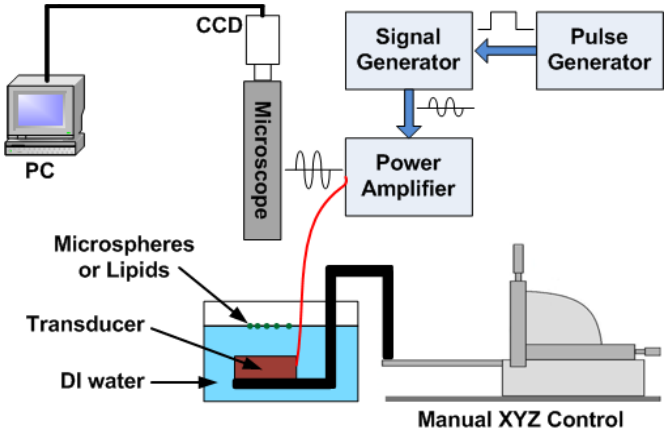

Figure 9. Schematic of the setup to observe the trapping of microparticles by the fabricated acoustic tweezers.

The fabricated tweezers, both the one based on the multi-foci Fresnel lens and the aluminum-alloy axicon lens were tested to trap lipid particles ranging from 50 – 200 µm in diameter and microspheres ranging from 70 – 90 µm in diameter. As the actuated tweezers produced acoustic waves and stirred the water as well as the microparticles in/on the water, the microparticles circled around the tweezers. Once a lipid particle hit the location where the Bessel beam was generated, the lipid particle firmly trapped to the spot and held there even when another lipid particle hit the trapped lipid particle (Figure 8). And we were able to move the trapped particle by moving the transducer over a wide range (limited only by the movable range of the transducer in the test apparatus).

Of the two devices tested, only the multi-foci Fresnel lens device demonstrated consistent success in capturing and manipulating both the lipid droplets (50 - 200 µm in diameter) and the polystyrene microspheres (70 - 90 µm in diameter) at a distance from of 2 to 5 mm from the lens surface without any contact between the transducer and microparticles.

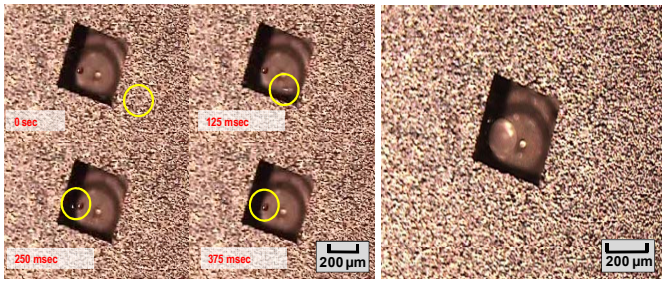

Figure 8. (Left) Photos taken at different times showing that a 72-µm-diameter lipid particle was being trapped by the multi-foci Fresnel transducer that was situated below the square opening. Another lipid particle (circled for clarification) that was being drifted by the stirring effect of the transducer hit the trapped lipid at 250 msec, but the trapped lipid was unmoved by the impact from the other lipid, as shown in the photo taken at 375 msec. (Right) Photo of a large 200-µm-diameter lipid particle being trapped by the same Fresnel transducer.

V. DISCUSSION

Axicon Lens Tweezers

The reason for the axicon lens transducer's ineffectiveness as a tweezers was the level of imprecision that was undeniably present in the making of the axicon lens. The machine shop which constructed the axicon lens was not able to build it to the high level of precision, and the performance of the axicon lens transducer was compromised. The interior surface of the lens had many imperfections and rough patches, which although very small, impacted the axicon lens transducer's performance. The axicon lens transducer was indeed able to capture one particle at the beginning of our tests, but quickly lost the particle and was not able to retain it for any significant period of time. With better fabrication at the machine shop, the axicon lens transducer should be able to produce consistent trapping and manipulation of microparticles. One major reason of going through this approach, and possibly continuing this approach, in spite of the success of the multi-foci Fresnel tweezers, is that the axicon lens is so much simpler in design and construction (than the multi-focus array) that the tests with it provides a very clear and solid understanding of principles behind the ultrasound-based particle trapping/cooling.

Multi-foci Fresnel Lens Tweezers

The multi-focus annular ring array was very successful in capturing particles, as it focused the waves very well over a multiple spots along the focal axis. This device merits further research, in an effort to possibly optimize the design and increase its capabilities in handling multiple particles on demand, moving the particles without involving the transducer movement, etc.

VI. CONCLUSION

A single ultrasonic transducer has been shown, for the first time, to capture microparticles (both lipid and polystyrene) in 3-D space. The microparticle trapping by a single focused-ultrasonic-beam transducer is very exciting, since the transducer (or an array of multiple such transducers) can pick up solid particles (ranging from a few microns to several hundreds in diameter), and move and place them at precise locations for diagnostics, construction, etc.

***Abstract* — We report on an experimental exploration of *ex vivo* measurements and *real-time* monitoring of the motions of heart wall for perfused rat hearts, by employing a surface-contact type of electromechanical probes based on piezoelectric transduction. In a hybrid experimental apparatus consisting of a conventional heart perfusion system and external electromechanical probing devices and circuitry, prototyped piezoelectric cantilever devices are calibrated and tested. We demonstrate that the external piezoelectric cantilevers are capable of monitoring the dynamic behavior of the isolated heart *ex vivo*, by measuring the motions of the heart wall. For typical rat hearts with heart rates in the range of ~150–250bpm (beats per minute), cantilevers with dimensions of $t \times w \times L \approx$ 130μm × (0.3–8)mm × (1–19)mm yield electrical signal of ~50–400mV. Measured data can also help identify signatures of various regimes (*e.g.*, from healthy to fatigued, to expiring) in the dynamical evolution during the perfused heart's lifetime. Preliminary tests on parallel multi-channel monitoring with probes positioned at multiple locations on heart surface prove to be valid and useful in obtaining information of regional displacement of heart wall.**

I. Introduction

Heart is the foundation of advanced lives including human being. Heart health and function monitoring are critical, especially for patients who suffer from heart diseases. Heart diseases are the top one cause of death in the United States and several other countries (*e.g.*, a total death of ~600,000 per year in 2007–2009 in US means one death due to heart disease every ~50 seconds) [1], and are the top reason for disease-based deaths throughout the world. This drives researchers to push the limits in advancing heart healthcare technology. We perceive at least the following major challenges: (i) *early detection* of alarms of heart diseases for apparently healthy people – it is desirable to develop devices that are wearable or implanted (with very low pain), especially for old people, athletes, and those who may have family history of heart diseases; (ii) *post-surgery* chronic heart monitoring for patients who are already receiving surgery and other treatment – what is desired includes low-pain implantable solutions that are small, light, enduring, and compatible with telemetry.

To date it has been well recognized that regional strain and stress on heart wall are related to development of disease [2], and studying the electromechanical properties and monitoring heart wall motion can help for heart diseases diagnosis [3]. From an engineering perspective, the heart is an amazing *electromechanical* device with exquisitely elegant functions and structures (Figure 1) enabled by soft materials and tissues – this causes some of the fundamental issues that are challenging the devices and instruments to be interfaced with heart for diagnosis and treatment. The prevalent electrocardiography (ECG) today is easy to use but only retrieves crude signals of overall heart function. Magnetic resonance imaging (MRI) is a powerful tool for studying heart structural and motional details and disease mechanisms. However today's MRI systems are bulky, highly complicated, and expensive, and often suffer from limitations in speed and resolution. We have been exploring a new, low-cost approach of directly probing heart wall motion by using distributed, surface-mount, and miniaturized (*e.g.*, micro and nanoscale) *electromechanical* devices for regional strain/stress and motion sensing. Here we report our initial effort toward this goal, and describe our first experimental results.

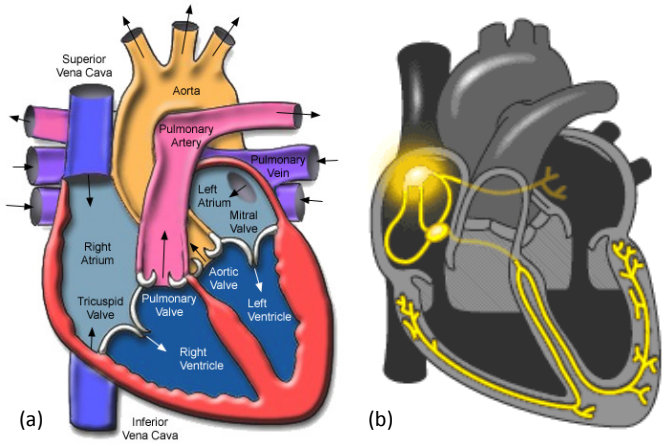

Figure 1. A glance of the heart structures and functions from an engineer's viewpoint. (a) Illustration of the anatomy of the heart, showing the heat chambers, vessels and valves. (b) Illustraton of the *pacemaker* and *distal conduction system*.

II. Heart Wall Motion

The heart is an electromechanical organ with great structural and functional complexities. Its wall motion is depending upon the compromised coronary arterial supply. Myocardial wall motion defects are essential and sensitive markers for coronary artery disease and myocardial ischemia. The capability of directly probing regional or highly localized heart wall motion may also have critical impact on arrhythmia,

restoring synchronization between asynchronous chambers or regions, early alarm of regional muscle fatigue or failure, *etc.*

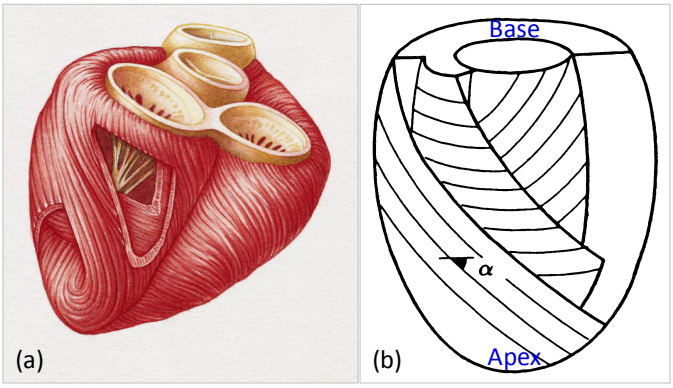

Figure 2. Simplified illustration of the complexity of the heart wall muscle structure and organization – the *basket-weaving* arthitecture of cardiac muscle cells and the myrocardial fibers. (a) A perspective view of the weaving fibers in layers at various depth in the heart wall. (b) A simplified model showing the weaving structure and orientation.

There are several types of muscle cells that participate in and coordinate the complex motions in concert. The most important of these include: (i) the cardiac muscle cells making the weaving myocardial fibers (see Figure 2a), (ii) the vascular smooth muscle cells (abundant in the coronary arterial tree), (iii) the conduction system muscle cells (*e.g.*, in the pacemaker region shown in Figure 1b). For this 'weaved basket', advanced MRI techniques including tagging, harmonic phase, and diffusion tensor MRI (DTMRI) have been developed for regional wall motion and strain assessment [4-7]. This work describes our initial effort and preliminary results toward a convenient electromechanical monitoring and diagnosis system using piezoelectric (PZE) devices, which, with computer aid, can automatically detect and monitor local heart wall motion *ex vivo*.

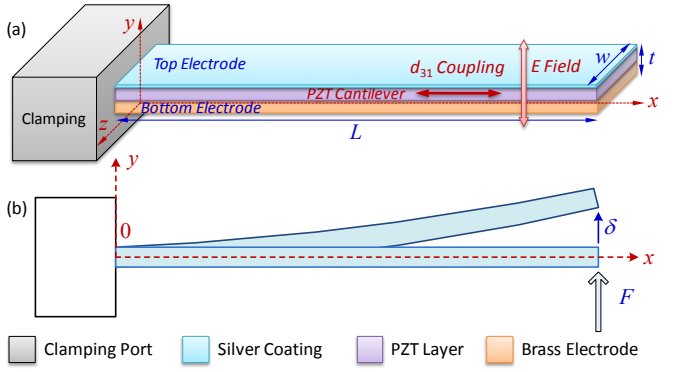

Figure 3. Piezoelectric (PZE) cantilever devices for electromechanical signal transduction. (a) Illustration of a prototypical composite cantilever with an active PZT layer sanwiched between two thin electrodes (metallic coating layers). (b) Simplified illustration of cantilever bending upon application of external force at the cantilever tip.

III. Piezoelectric Cantilever Sensors

A. Piezoelectric Cantilevers

We explore piezoelectric (PZE) device technology because of the direct electromechanical coupling effect in PZE transducers. A PZE device as simple as a singly-clamped cantilever beam (Figure 3) can be conveniently maneuvered to probe static deflections and dynamic motions of other mechanical systems. We have been exploring two scenarios for a PZE cantilever device to interface with a beating heart: (i) making contact between the free end of the cantilever and regions of interest on the heart wall, while keeping the other end of cantilever clamped on a solid (not moving) substrate; (ii) mounting the base (clamped end) of the cantilever on the beating heart's surface and having the cantilever body free to move and vibrate. The former is suited for *ex vivo* studies; the latter is attractive for packaged implanted systems.

Figure 3 illustrates a generic cantilever device based upon a ~65μm-thick PZE lead-zirconate-titanate (PZT) thin film sandwiched between two metal electrodes, a bottom ~65μm-thick brass layer, and a top ~1–5μm silver coating. We exploit the d_{31} coupling in such structures – transverse (out-of-plane) motion of the cantilever tip (free end) induces in-plane strain in the PZT layer and causes surface charge and electrical potential between the two electrodes which is read out for monitoring of motion. Within the scope of this work – cantilever tip in contact with heart wall with quasi-DC movements (beating frequency much lower than the fundamental resonance of the cantilever), the displacement, force, and the voltage signal are in convenient linear relationship, *i.e.*, $V_{PZE} \propto d_{31} \cdot \delta \propto d_{31} \cdot F/k_{eff}$, in a simple lumped parameter model [8].

TABLE I. Piezoelectric Materials of Interest

Material	**Piezoelectric Coefficients** [pm/V or pC/N]	**Young's Modulus** [GPa]	**Density** [g/cm^3]
PZT	d_{33}~100–600, d_{31}~50–300 d_{15}~100–800	~40–150	~7.5–7.8
ZnO	d_{33}~10, d_{31}~4, d_{15}~3	~30–140	~5.6
AlN	d_{33}~5.6, d_{31}~2.6, d_{15}~2.5	~330–410	~3.26
PVDF	d_{33}~20–30, d_{31}~20, d_{15}~10–40	~2–15	~1.76

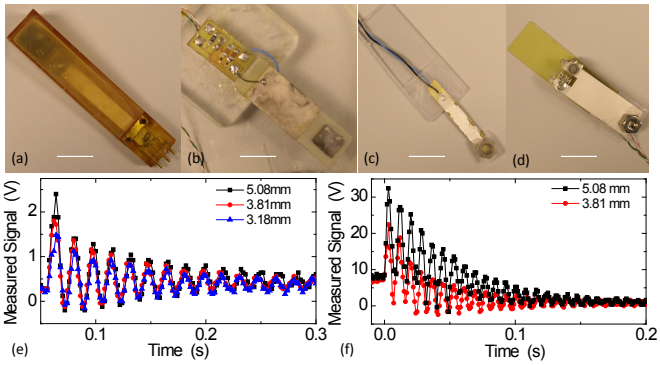

Figure 4. The first generation of our prototyped piezoelectric (PZE) devices based upon flexural-mode cantilevers using PZE thin film materials (*e.g.*, PZT and PVDF). (a) A vibration energy converter in plastic package with complementary dual PZT layers, easily generating ~10V level voltage signals from human body movements. (b) A PZT-based device with on-board energy conversion and harvesting circuit. (c) A much thinner PZT-based device. (d) A PZE cantilever based on flexible PVDF material. Scale bars: 1cm. (e) Measured time-domain voltage waveform (peak voltage ~2V) due to ring-down oscillations of a ~30Hz resonanst mode. (f) Voltage (peak voltage ~32V) measured from ~110Hz oscillations. Legend: initial tip deflection.

B. Materials of Choice

We choose PZT as the active material for its large PZE coefficient and easy availability for this study. Table I displays a short list of materials that we find interesting for employment in our studies. We have also been exploring devices made of polyvinylidene fluoride (PVDF) because of its attractive and promising properties for implants on flexible substrates. Other

materials of potential interest include zinc oxide (ZnO) and aluminum nitride (AlN), particularly for recent developments in engineering them into micro and nanoscale functional devices that could be integrated and packaged in implanted microsystems.

C. Prototyped Devices

We first demonstrate several prototyped PZE cantilevers using PZT and PVDF. The prototyped devices (see examples in Figure 4) are first calibrated in DC/static operation, and are then extensively tested in pulse and resonant modes. Early generations of cantilevers are on the few-mm- to 1cm-scale in size, with fundamental flexural resonance frequencies in the ~0.1kHz to ~1–100kHz ranges, and easily generates voltage signals up to ~10V. Our preliminary data and estimation show that these devices and their performance can be suited for both quasi-DC and resonant-mode applications, operating at atmospheric pressure, either in customized macroscopic plastic packages, or in micro polymeric thin film packages.

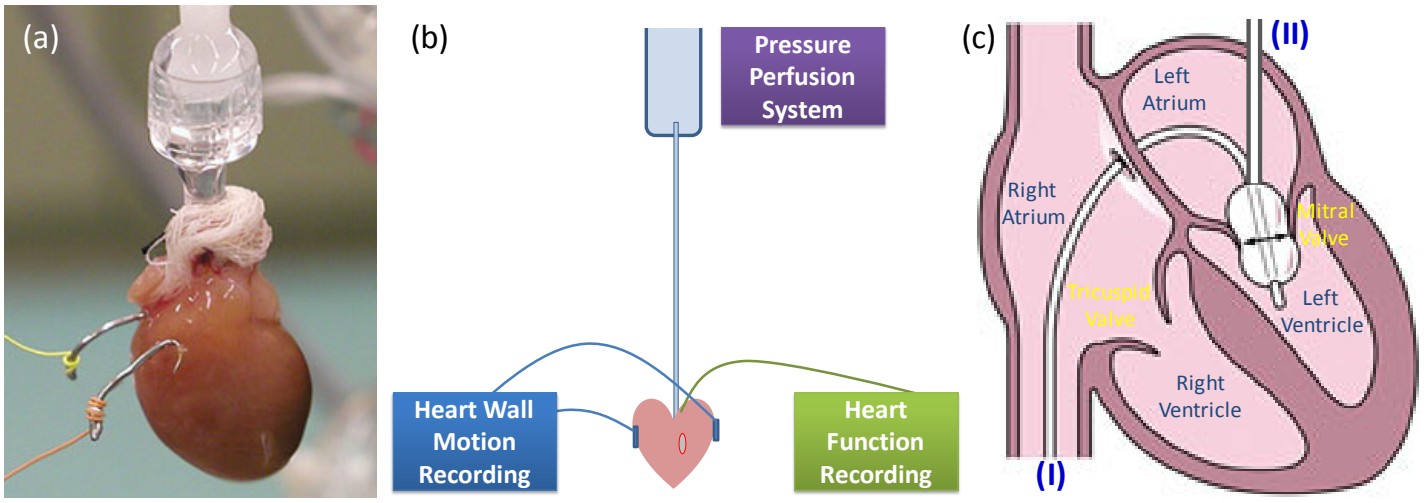

Figure 5. The heart perfusion system for *ex vivo* experimental studies with the isolated live rat heart. (a) Picture of a prototypical perfused rat heart with surface-mount external bulky electrodes for physiological measurements (*e.g.*, see http://vflab.org). (b) Highly simplified schematic of our experimental approach – using both the external piezoelectric (PZE) devices on heart wall, and the conventional approach for heart function recording system in a canonical rat heart perfusion system. (c) Illustration of the scheme of using a balloon (*i.e.*, simiar to *balloon valvuloplasty*) and its associated external perssure sensor for heart function recording. (I) and (II) are two specific options for implanting the balloon; we use option (II) in all the tests presented in this work.

IV. Experimental Techniques

In this early-stage effort of our exploration, as illustrated in Figure 5, we combine the piezoelectric (PZE) cantilever monitoring technique with well-established (commercially available) heart function recording systems. This helps to reliably evaluate the new approach and calibrate the measurements and the devices, both qualitatively and quantitatively, against today's standard protocols.

A. Heart Perfusion System and Heart Function Recording

The conventional *real-time* heart function recording is realized in a heart perfusion system, as illustrated and shown in Figure 5 and Figure 6. The system is based on the classical Langendorff technique for isolated heart perfusion [9]. This allows for convenient and prompt *ex vivo* studies, and many 'brute-force' (*e.g.*, Figure 5a) experiments, on isolated hearts. In the particular case of this study, the perfusion system greatly facilitates the continuous tests with the piezoelectric cantilever probes in a considerably long time (depending on the heart lifetime in the perfusion system, ~1-3 hours typically). It provides not only the live heart, but also a parallel monitoring option as a control experiment.

Male Sprague-Dawley rats of 10–12 weeks old are heparinized (1000 units/kg, i.p.) and anesthetized by sodium pentobarbital (85 mg/kg. i.p.). The heart is excised, cannulated, and perfused with Krebs-Henseleit (KH) buffer containing (in mM) 118.5 NaCl, 4.7 KCl, 1.2 $MgSO_4$, 1.2 KH_2PO_4, 1.5 $CaCl_2$, 11.1 glucose, and 25 $NaHCO_3$. Isolated hearts are perfused at a constant pressure in the Langendorff-type perfusion system. The perfusate was maintained at 37°C and equilibrated with 95% O_2-5% CO_2.

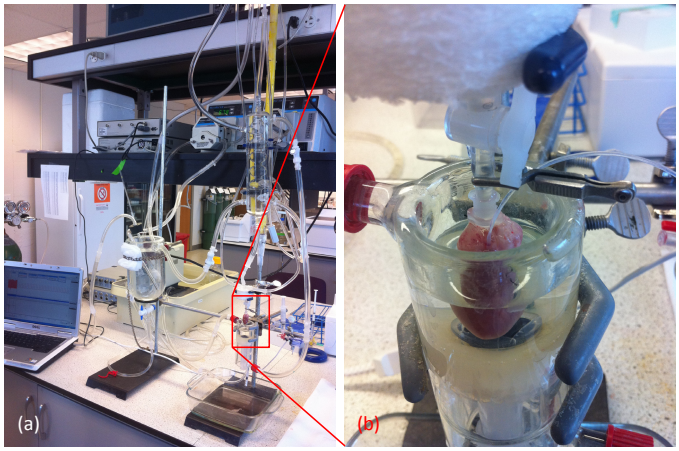

Figure 6. Pictures of the rat heart perfusion system employed in this work. (a) The overall Langendorff perfusion system with rat heart, pump, circulation lines, the implanted balloon sensor and its data acquisition system (vendor: ADInstruments). (b) Close-in view of the rat heart in the perfusion buffer.

Embedded in the heart perfusion system, as shown in Figure 5c, we insert a water-filled latex balloon into the left ventricle (*i.e.*, similar to *balloon valvuloplasty*). The balloon is connected to an external pressure transducer to record the left ventricular developed pressure (LVDP) and heart rate (HR). The heart's rate-pressure-product (RPP), *i.e.*, the product of LVDP and HR, is then calculated as an index of the workload.

The measured rat heart rate can typically be in the range of ~150–250 bpm (beats per minute) at the beginning of the experiment (with a fresh and healthily perfused rat heart). The heart rate decreases gradually as the time elapses. The temperature of the perfusion buffer is a critical factor for keeping the heart alive. When temperature deviates, the heart function could degrade, and the amplitude of heart wall movement may decrease dramatically. Figure 6 demonstrates pictures and details of the rat heart perfusion system we have been implementing in this study.

B. *Piezoelectric Cantilever Monitoring System*

We have built a convenient desktop apparatus for interfacing the piezoelectric cantilever probes with the rat heart in the operating perfusion system. Cantilever probes can be positioned and adjusted by moving the arms (to which the cantilevers are clamped) on the stage with control in all three directions. Figure 7 demonstrates a picture of an early generation of the implementation.

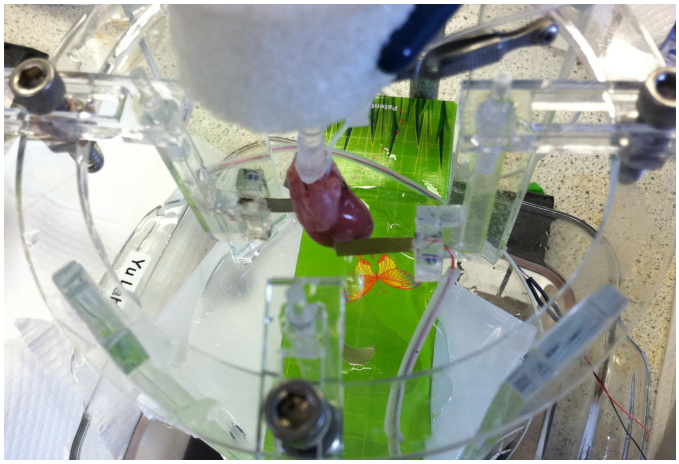

Figure 7. Picture of first-generation exprimental implementation of *ex vivo* monitoring of rat heart wall motion, by using surface-contacting piezoelectric (PZE) cantilever probes. For each cantilever, its one end is clamped, and the other end (tip) is in contact with the heart wall muscle. In paralle, the perfused rat heart's basic function is also being monitored using the balloon valvuloplasty technique. In this particular picture, the free ends of a pair of cantilevers are gently contacting the left and right ventricle of the heart.

TABLE II. PARAMETERS OF SELECTED TESTED DEVICES

Cantilever Device ID	**Length** [mm]	**Width** [mm]	**Resonance** [Hz]
(I)-A	18.0	7.0	222.0
(I)-B	19.0	7.3	214.0

As we expect these cantilever devices to operate while interfacing with perfused hearts in physiological solutions, we need to package the devices so that their electromechanical performance would not be compromised by any corrosion or contaminants. Prior to testing, every device is coated by a thin layer of parylene C (thickness on the order of ~5μm).

We note that in Figure 7 the liquid solution for nurturing the heart is temporarily moved away. In the present generation of setup, both the heart and all the cantilevers and device arrays (all micropackaged with ~5μm parylene C thin layer) are immersed in the fluid. Basic parameters of two generations of devices tested in this work are summarized in Table II.

V. EXPERIMENTAL RESULTS AND DISCUSSIONS

Extensive experimental observations and measurements have been performed. First, the heart function is recorded using the balloon implanted in the left ventricle, which provides a reference and calibration for the performance of the perfused rat heart. Then the piezoelectric cantilevers are applied to make contact to the heart wall for direct electromechanical probing.

A. *Heart Function Recorded by Balloon in Left Ventricle*

Without engaging any piezoelectric devices, real-time heat function is recorded by the left ventricular balloon and its associated pressure sensor. Typical data traces of LVDP and left ventricular pressure changing rate *dp*/*dt* are recorded for ~1–2 hours or even longer, throughout the whole lifetime of the perfused heart. Figure 8 shows the measured data in a very short 12s time interval. Table III summarizes the results from a few repeated measurement runs by only using the implanted balloon for monitoring and recording.

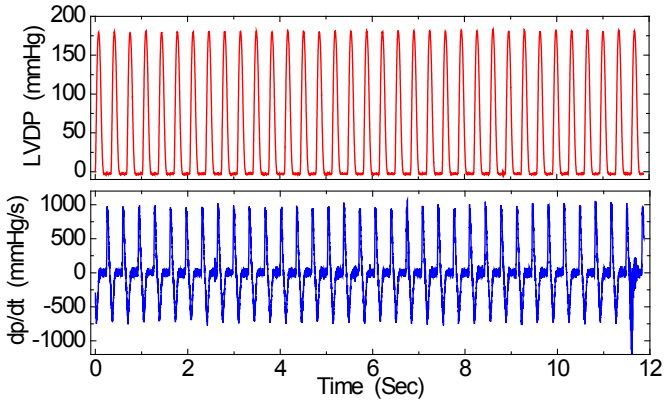

Figure 8. Representative data of the perfused rat heart under healthy condition, measured in real time by only the balloon implanted in left ventricle (no any external cantilever probes touching the heart wall). (a) Left ventricular developed pressure (LVDP, in mmHg) as a fundtion of time. (b) Measured pressure changing rate *dp*/*dt* as a function of time.

TABLE III. MEASURED HEART PARAMETERS WITHOUT CANTILEVERS

Test Run ID	**Heart Rate (HR)** [beats per minute, bpm]	**LVDP** [mmHg]	**RPP** [mmHg·bpm]
1	153 ± 3	135 ± 2	20655 ± 710
2	150 ± 3	120 ± 2	18000 ± 666
3	184 ± 5	102 ± 2	18765 ± 890

B. *Measurements with Piezoelectric (PZE) Cantilevers*

Prior to using the cantilevers for perfused heart wall motion probing, we first perform a 'dry-run' test by using air-filled balloons to mimic simplified heart motions. Because the fundamental flexural-mode resonance frequencies of the PZT cantilevers in this work are usually in the range of ~200Hz to ~100kHz range, the rat heart motions are well in the close-to-DC or quasi-DC range. Because in all our tests, the cantilevers are in contact with the air balloon (*i.e.*, heart model) or perfused heart at the cantilevers' tips, the tip motions closely follow the contractions and heart beat cycles. The heart motion does not drive the cantilever into its flexural-mode resonance.

Such quasi-DC operations of the cantilever probes lead to a simple linear relation between the piezoelectric voltage output and the detected displacement of heart wall motion. The 'dry-run' test (using air balloon to simulate a beating heart) indicates that for the early generations of devices (relatively large), *e.g.*, both (I)-A and (I)-B (listed in Table II), have high conversion *responsivity* (*i.e.*, gain), ~3V/mm (voltage per unit cantilever deflection at its tip). In both the 'dry-run' with heart models and the perfused heart tests, the output voltage signals are directly recorded and monitored by the oscilloscope using Labview/DAQ software.

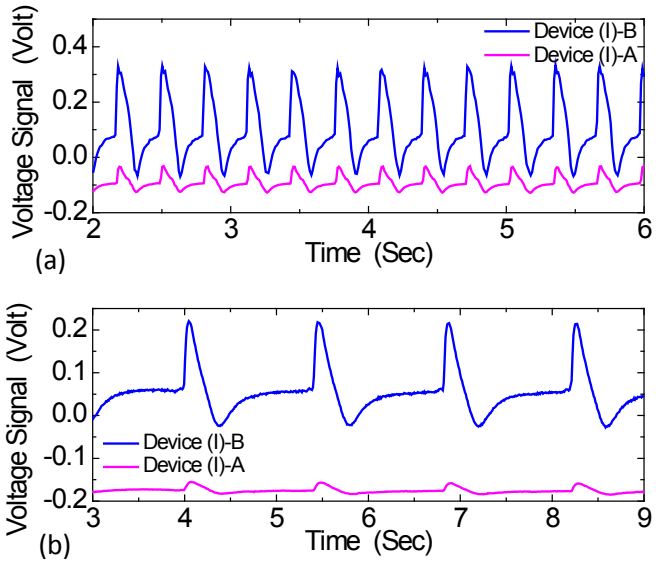

Figure 9. Voltage signal measured from a pair of PZT cantilevers touching the heart wall. (a) The free ends (tips) of the two cantilevers touching the heart wall of the left and right ventricle, respectively. (b) The free ends of the cantilevers are touching the base and apex of the heart wall, respectively.

Figure 9 demonstrates the voltage signals representing the local heart wall motions, probed by a pair of PZT cantilevers. In all these cases, the free ends of the cantilevers just barely touch the heart wall. When the cantilevers tips make contact to the left and right ventricles (Figure 9a) respectively, the extracted heart rate is HR~229bpm. Measured voltage signal is V_{pp}~150mV, and ~350mV, for device (I)-A and (I)-B respectively. The asymmetry in the data amplitude from this pair of devices is due mainly to the fact that one cantilever device has been pre-bent (with a transverse crack developed but not yet broken, at ~1/3 length near the clamped end), and thus has much less strain developed given the same displacement at the tip. When the devices' tips are placed against the base and the apex at a later time, the data show a lower HR~43bpm, and lower V_{pp}~50mV and 150mV, respectively, mostly due to the heart degradation during the time of transition.

The effects of probing the heart wall motion by making contacts with different depths and strengths are also explored. A second generation (group (II) listed in Table II), smaller cantilevers, in small parallel fingers-alike arrays, are used. With control of the positioning arms, the devices are first carefully placed to just barely touch the heart wall, and then gradually move toward the heart center to start gently pressing the heart wall. Figure 10 displays the measured data from a pair of small cantilevers, (II)-B1 and (II)-B2, in contact with the heart wall under three different depth/strength conditions.

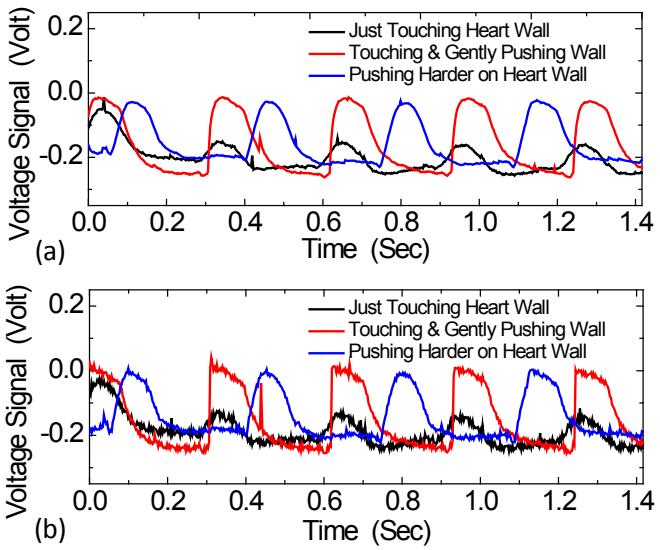

Figure 10. Voltage signal measured from a pair of smaller cantilever devices with varying the depth of the cantilever tip touching the heart wall. (a) Data from device (II)-B1. (b) Data from device (II)-B2. The data shown are truncated from much longer traces. For each device, data for three contact conditions are taken at three time intervals in series. Throughout these time intervals, the implanted balloon recording ensures that the heart functions are normal and stable. The offsets on the time axes are not adjusted among the different traces.

In case of just touching but not pressing the heart wall, larger devices (group (I) in Table II) yield larger V_{pp}, which is evident from Figure 9 and Figure 10. As cantilever tips get to press against the heart wall gradually, the signals first increase as expected, and then there is no more appreciable signal increase observed with further pressing of the devices against the heart surface. Such information can help us better understand the strength of the heart wall motion, especially with more advanced future generations of devices. We also note that the data traces from larger devices (gently touching heart wall, Figure 9) appear to be proportional to the *dp*/*dt* data in Figure 8, while the voltage signals from the smaller devices (under all contact conditions, see Figure 10) seem to have the shape similar to that of the LVDP curve in Figure 8. We are currently making more effort to investigate this intriguing phenomenon.

As we aggressively miniaturize these devices by using micromachining techniques, their apparent signal levels decline. Nonetheless, with significant volume reduction they become better suited with flexible substrates [10,11] and packages that are more amenable to 'harsh' environments for implants in living bodies. We envision that it is also possible for us to take advantage of the resonant operations of the PZE devices, combined with air-cavity packages possible in flexible substrate, cantilever- and membrane-structured micro/nano resonators in various frequency ranges can be exploited for local heart wall motion monitoring. Further, the same types of PZE devices in micropackages can also be employed for energy conversion from heart beats [12], which could be exploited for self powering low-power implants. Moreover, for miniaturized devices and chip-scale implants, the signal transmission could be not only wired but also wireless. As all these technical components are getting ready, the approach of using miniaturized PZE devices explored in this work can lead to both external heart function monitoring systems in research and clinic labs (*e.g.*, supplementing the

conventional implanted balloon recording), and implanted systems for surgery and patients' chronic heart monitoring – and in all these applications, capable of offering high sensitivity and high spatial and temporal resolutions for parallel readout of heart wall motion at various locations.

VI. Concluding Remarks

In summary, we have shown that using external surface-contact or surface-attached piezoelectric (PZE) cantilevers can probe the rat heart wall motion and the heart function *ex vivo*. The cantilevers in the present work are made of PZT thin films with strong PZE effect. The d_{31} coupling effect in the cantilever is exploited to transduce the flexural mechanical motion of the cantilever into electrical signal for readout. The cantilevers have been limited to quasi-DC operation (heart beating rate much lower than cantilever's resonance frequency) with their tips closely following the movements of the regional heart wall. Devices with sizes in the mm-scale and sub-mm-scale are tested. The preliminary tests verify the feasibility of monitoring heart wall movements with good resolutions in the time domain, and at different locations on heart surface. The heart wall displacement extracted from the measurement is typically ~0.1–0.3mm, which is consistent with MRI measurement. The output power level of typical PZE cantilevers we have tested is in the range of ~1–10μW. Combined with advances in PZE materials at micro and nanoscale, implantable and flexible materials, and micropackaging techniques, this approach is expected to have the potential of being implanted, as well as offering very high spatial and temporal resolutions by employing further miniaturized devices.

Among the most promising sensing platforms are resonating microcantilevers due to their high sensitivity and wide application range. A key parameter of the device implementation is the predicted value of the resonant frequency that depends on the modeling and considerations of relevant physical phenomena. In fact, the estimation based on the conventional, perfectly clamped, Bernoulli-Euler cantilever beam does not lead to satisfactory accuracy in certain cases. Hence this work investigates two system characteristics that may affect the resonant frequency (a support effect and a so-called rim effect) and provides solutions for a straightforward estimation of rim dimension using resonance behavior of the cantilevers.

I. INTRODUCTION

Among the most promising sensing platforms are resonating microcantilevers due to their high sensitivity and wide application range for chemical sensing. A key parameter of the device implementation is the predicted value of the resonant frequency, which depends on the modeling and considerations of relevant physical phenomena. The classical expression used for the first transverse resonant frequency of a clamped-free microcantilever is obtained from the solution of the Euler-Bernoulli equation for a cantilever in vacuum [1]:

$$f_0 = \frac{\lambda_0^2 h}{2\pi L^2}\sqrt{\frac{E}{12\rho}} \qquad (1)$$

With $\lambda_0 = 1.875$, h the cantilever thickness, L the cantilever length, E and ρ the Young's modulus and mass density of the cantilever material, respectively. In fact, when compared to measurement, this equation does not lead to a satisfactorily accurate result in certain cases. For example, in the case of a silicon cantilever 504µm x 100µm x 20µm, with the cantilever length parallel to the <110> direction of the silicon <100> wafer, the measured resonant frequency is 94.4kHz, whereas the theoretical resonant frequency using (1) with the mechanical properties of silicon in this configuration (E = 169GPa, ρ = 2330kg/m^3) leads to 108.3kHz (15% higher than the measured value). Assuming that the geometry of the cantilever and the boundary conditions are not the error sources, two possible reasons for the difference between the theoretical and measured resonant frequency may be envisioned: the presence of the air as the surrounding medium instead of vacuum and the shear strain which is not considered in the Euler-Bernoulli equation.

The presence of the surrounding medium can be taken into account by considering the hydrodynamic force per unit length exerted by the air on the cantilever. This force per unit length is composed of both a viscous part proportional to the cantilever velocity (term noted g_1) and an inertial part proportional to the cantilever acceleration (term noted g_2) [2]. Equation 1 has to be modified by taking into account this force, resulting in [3]:

$$f_r = f_0 \frac{\sqrt{1-\frac{1}{2Q^2}}}{\sqrt{1+\frac{g_2}{m_L}}}; \qquad (2)$$

with m_L the cantilever mass per unit length and Q the quality factor defined by [3]:

$$Q = \frac{2\pi\sqrt{1+g_2/m_L}}{g_1/m_L} f_0 \qquad (3)$$

Using these equations and appropriate values for g_1 and g_2 [3], the resonant frequency in air (107.1kHz) is smaller than in vacuum but the difference is not sufficient to predict the measured resonant frequency.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

The Timoshenko beam theory [4] allows taking into account the shear strain and rotational inertia effects which are not considered in Eq.1. Again, these effects are not significant enough to account for the decrease in the resonant frequency that is seen in the measurements.

This leads one to consider that frequency discrepancy may be due to variations in the geometry and/or the boundary conditions. As detailed in the following section, the fabrication process may result in cantilever and support geometry that is not exactly the same as the one considered in the solution of the Euler-Bernoulli equation for a perfectly clamped cantilever. In this context, the work presented in this paper investigates two system characteristics that may affect the resonance mode and associated resonant frequency: the elasticity of the support which doesn't clamp ideally the supported end of the cantilever and the effect of a fabrication-induced silicon undercut that can occur during the release process of the suspended structures by Deep Reactive Ion Etching (DRIE).

II. MOTIVATION

Classically, silicon microcantilevers are fabricated by means of silicon standard micromachining techniques using a process in which release of the structures is based on a backside etching of the wafer. For this, Silicon-On-Insulator (SOI) substrates are commonly used in which a thin silicon dioxide layer insulates the backside silicon etching, either using a wet or dry etching process. This results in free-standing microcantilevers clamped on a thick silicon support. An example of silicon microcantilevers with silicon support is shown on figure 1. From this figure, a free-standing microcantilever is clearly visible, but a silicon undercut at the clamped end of the cantilever is also visible, due to silicon over-etching during backside etching. (In the present case, silicon backside etching is provided by means of DRIE.) A consequence is a loss of rigidity at the supported end of the cantilever, resulting in possible mechanical deformation of the undercut part, which in this paper will be referred to as the "rim" (Fig. 1).

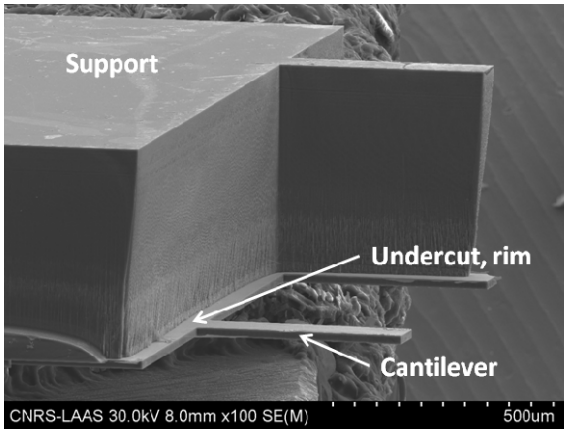

Figure 1: SEM picture of a microcantilever released by DRIE on a SOI wafer. Visualization of the silicon support and over-etching (rim).

In the present analysis, two origins in the discrepancy between theoretical and experimental values of resonant frequency of microcantilevers have been identified: a support compliance effect and an effect due to silicon over-etching, i.e., the so-called rim effect. First, the impact of both effects on the resonant frequency has been simulated using COMSOL. For this, a cantilever with ideal clamping (no rim, rigid support) has been simulated and the results compared to resonant frequency predictions for the case in which the structure is supported by an elastic rim attached to a rigid support block (rim length = 35µm in the simulation). Then, the impact of both effects (combined) has been simulated. The comparison of results is indicated in the schematic diagram of figure 2. This figure shows that the combined effect of rim and support is significant: the simulated resonant frequency is 11.3% lower than for the ideally-clamped cantilever. The results also show that the rim effect dominates the support compliance effect since a decrease of resonant frequency of 10% is due to the rim and thus, 1.3% due to the support elasticity. In this context, the systematic and direct (i.e. without the need of a backside observation of the chip) estimation of the rim length is of particular interest. This will lead to an appropriate use of the structures in the broad range of applications covered by resonant microcantilevers. The objective for the present work is thus to develop a method for using the resonance behavior of microcantilevers to determine the rim length at the supported end of the structures. Future work will include the development of an analytical expression for the cantilever resonant frequency which takes into account the rim effect.

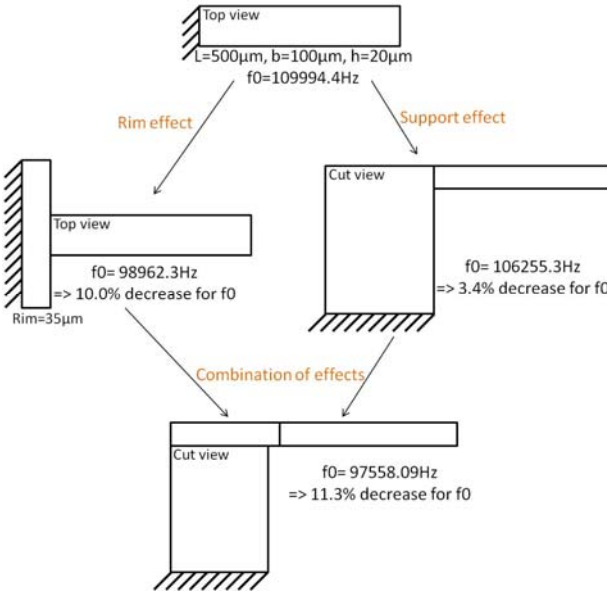

Figure 2: Microcantilever geometries and resonant frequencies obtained by COMSOL simulation in the case of a) ideal clamping, b) rim effect, c) support effect, d) combination of effects.

III. Experimental Section

A. Cantilever fabrication

Free-standing microcantilevers have been fabricated by standard micromachining techniques. Cantilevers are rectangular shaped with a length of 500µm and a width of 100µm. Each cantilever can be actuated individually by means of a Laplace force by incorporating both a patterned gold layer allowing a local current flow and an external magnet.

The main steps of the fabrication process are as follows. The starting substrate is a 100 mm-diameter, <100>, N-type Silicon-On-Insulator (SOI) wafer, with a 1 µm-thick buried oxide and a 20 µm-thick top silicon layer (resistivity of 4-6 Ω.cm). A first step consisted in the deposition of 300 nm of Plasma Enhanced Chemical Vapor Deposition (PECVD) silicon dioxide on the entire SOI wafer before the sputtering of Ti/Au (100 nm / 700 nm) for the electrode used for electromagnetic actuation. The film was lifted off with an AZ nLOF negative photoresist to define the electrode characterized by a width of 10 µm. A passivation silicon oxide film (300 nm thick) was then deposited by PECVD. Contact pads were opened by wet etching of oxide using HF buffer. To finish, the microcantilever shapes were defined by a front Reactive Ion Etching of silicon, followed by vertical sidewalls etching on the backside of the SOI wafer using the Deep Reactive Ion Etching technique to release the structures. The 1 µm-thick SiO_2 acts as an etch stop layer for the dry silicon etching. This layer was then removed by Reactive Ion Etching. The cantilever chips were then mounted on a PCB by gluing the silicon support (figure 1) with epoxy glue. Wire bonding ensures communication between the chips and the PCB.

Figure 3 shows a close-up view of one cantilever obtained by dual-beam optical interferometry (Veeco NT9080). As shown in this figure, the rectangular geometry of the cantilever is clearly defined with respect to the design, as is the gold electrode used for integrated actuation. Also, as shown in figure 1, the release of the cantilever is clearly visible.

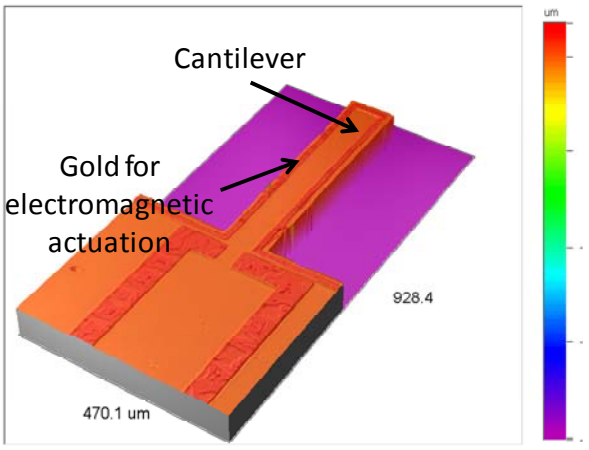

Figure 3: Geometry of the chip obtained by optical profilometry.

B.Rim pre-estimation by means of optical profiler

Prior to the development of methods for estimating the rim length using the resonant behavior of microcantilevers, the value of rim dimension is estimated by means of a dual-beam interferometry profiler. This optical tool was found to be the best compromise to achieve a balance of simplicity, accuracy and minimal time consumption. Concerning the measurement set-up, the cantilever chips were placed vertically under the objective of the profiler, so that the sidewall etching profile of the backside of the SOI wafer could be studied. An example of a profile acquired is shown in figure 4. From this figure, one sees that the verticality of the sidewall is not perfect, and the silicon over-etching is clearly visible. An undercut below the top silicon layer is evident, from which the rim length may be determined. For the different chips tested, the values of rim length that were measured are summarized in table 1. From this table, it can be seen that the rim lengths range from 15 to 35 µm. The values obtained are consistent with the position of the chips on the wafer, since silicon over-etching decreases as one moves from the center to the periphery of the SOI substrate. (Chip A7 is at the periphery of the wafer while chips A100 and A102 are close to the center of the wafer.)

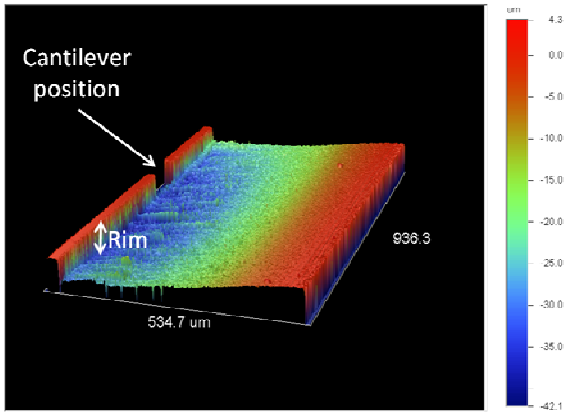

Figure 4: Sidewall etching profile measured by optical profilometry.

Table 1: Measured rim length (optical profiler).

Chip #	Measured rim length (µm)
A100	34.7 ± 0.8
A102	32.2 ± 1.1
A63	35.5 ± 1.4
A7	15.6 ± 0.5
A28	26.7 ± 3.2

C. Rim length evaluation by means of cantilever resonance

In the present work, two methods based on the resonance behavior of microcantilevers are proposed to estimate the dimension of the rim, whose existence is primarily responsible for the inaccuracy of the conventional method for

estimating resonant frequency (1). The first method uses the value of the microcantilever resonant frequency, while the second one uses the deflection profile at resonance (i.e., the deformed beam shape) of the actual cantilever. For both methods, the first out-of-plane flexural resonant mode has been studied using a Polytec MSA-500 optical vibrometer. Actuation of the structures is performed by electromagnetic forces, while the deflection spectrum is acquired via the laser vibrometer, allowing a precise determination of resonant frequency (<1 Hz resolution). Also, the vibrometer system allows a specific meshing of the vibrating structure, so that a specific resonant mode shape can be studied quantitatively. Making use of this capability, the cantilever deflection profile at resonance has been acquired. A resulting ratio (R) between deflection at the tip of the cantilever and the deflection at the clamped-end (i.e. at the beam/rim interface) has been calculated and compared to a calibration curve obtained via Finite Element Modeling (FEM) using COMSOL. For the resonant frequency method, a similar approach is proposed, but the values that are compared are those of resonant frequency. Using both methods, a rim value is determined by comparison between experimental data and the calibration curve.

IV. Results and Discussion

By utilizing the resonance behavior of the cantilevers, the two methods outlined above have been employed to obtain estimates of the rim length, i.e., without the need of a backside (or side) observation of the chip. In the following, the details of the methods are given in addition to the results.

A. Resonant frequency method

The resonant frequency method is based on the fact that the resonant frequency clearly depends on the value of rim length because the presence of the rim induces a different mechanical rigidity at the supported end of the cantilever. Indeed, in figure 5 a calibration curve has been established via FEM where the simulated structure corresponds to the one designed, composed of bare silicon, PECVD SiO_2 and a gold electrode. As expected, the figure shows a decrease of resonant frequency when the rim length increases. This is mainly due to the loss of rigidity at the clamped-end of the cantilever when rim length increases. Also, in this figure has been plotted the value of resonant frequency measured on chips A7, A28, A100, A102., These chips, composed of cantilevers characterized by the same geometry, provide different resonant frequencies ranging from 92.5 kHz to 97.9 kHz. This indicates that different values of rim length are present for the tested chips. Indeed, by comparison between the calibration curve and the experimental values, rim length values ranging from 20.4 µm and 49 µm, have been determined. However, these values do not perfectly fit with values determined with the optical profiler, as shown in table 2. Note that in all cases, the proposed method overestimates the rim length, indicating that there exists other "softening effects" (e.g., support compliance) that the proposed method does not include. A discrepancy between 14.4% and 30.8% in rim length estimation is observed for three of the four chips. The remaining chip (A28) has an 83.5% difference because the measured values of the frequency and rim length do not follow the trend of the other data (i.e., larger rim length should result in lower frequency). Thus, this data point may be suspect. Note that a slight loss of accuracy may result from other parameters not considered in the simulation, such as the exact thickness of the top silicon substrate or the thickness nonuniformity of the gold electrode. However, with the resonant frequency method, a simple and rapid estimation of rim has been demonstrated.

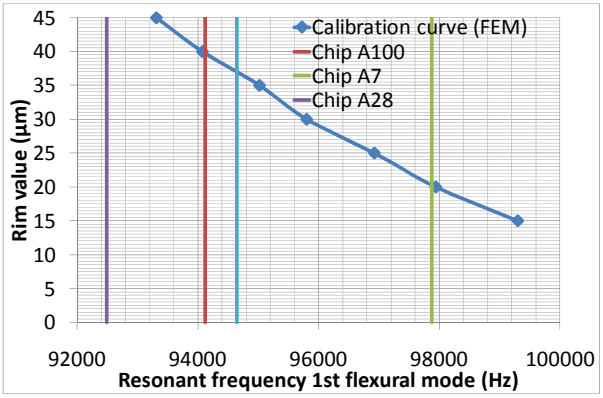

Figure 5: Determination of the rim length value using the resonant frequency measurement and the one obtained by COMSOL simulation.

Table 2: Comparison of the rim length estimation using resonant frequency measurement and the one obtained by optical profilometry.

	A100	A7	A28	A102
estimated rim length (optical profiler) (µm)	34.7	15.6	26.7	32.2
measured resonant frequency (Hz)	94116.2	97877.9	92492.1	94648.4
estimated rim length with resonant frequency (µm)	39.7	20.4	49	37

B. Resonant profile method

Since the rim influences the rigidity of the supported end of the cantilever, the large deflection obtained at resonance can induce a deformation in the rim structure and this deformation will, of course, depend on the rim length. With this in mind, the influence of the rim length on the deflection profile of the cantilever at resonance has been studied. In figure 6, the normalized resonant profiles of cantilevers for different values of rim length have been simulated by FEM. From this figure, the dependence of the resonant profile on rim length is evident, so that the ratio between tip deflection and deflection at the clamped-end (rim/cantilever interface) is proposed as a metric for rim length estimation. By comparison with the calibration curve obtained by FEM, values of rim length have been estimated, ranging from 18.3 µm to 26.7 µm as shown in table 3. With this method, it is observed that the rim length tends to be underestimated (in contrast to the frequency method) with the discrepancies being larger (between -30.7% and 17.3%) than those obtained

with the resonant frequency method (Again, the largest difference (-30.7%) corresponded to Chip A28).
However, given the simplicity of the method and the possible error sources, mainly the difficulty in determining the exact position of the clamped-end of the cantilever for the determination of the deflection ratio, the values of rim length obtained give an approximate estimation of this important parameter.

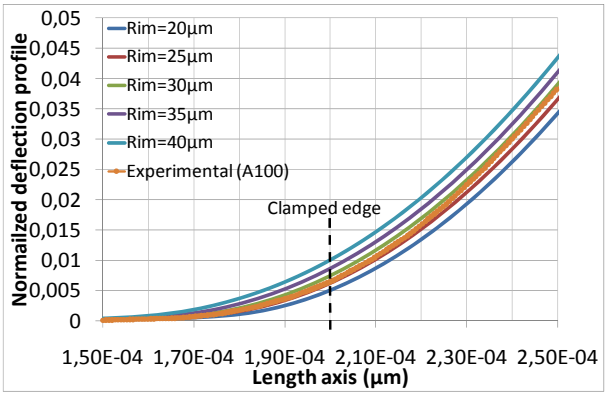

Figure 6: Deflection profile at resonance obtained for different values of rim length (COMSOL simulations).

Table 3: Comparison of the rim length estimation using the resonant profile method and the one measured by the optical profiler

	A100	A7	A28	A102
estimated rim length (optical profiler) (µm)	34.7	15.6	26.7	32.2
measured deflection ratio (w_tip/w_clamp)	151.24	220.87	213.2	176.6
estimated rim length with ratio (µm)	26.7	18.3	18.5	22.7

C.Summary

The values of rim provided by optical profilometry (reference method) and the ones obtained with the alternative methods proposed for the four tested chips are summarized in figure 7. From this figure, it can be seen that the resonant frequency method tends to overestimate the rim length, while the resonant profile method tends to overestimate it (the exception being chip A7). Thus, by combination of both methods, a rim length range for each chip can be determined, while the average value gives an approximate value of rim length with a discrepancy magnitude as low as ~4%, as obtained for the chip A100. These results are encouraging in that they provide some motivation for (a) further development of a combined method based on the resonant frequency and resonant profile methods, and (b) development of analytical models that show how various system parameters, including rim length, influence the resonant behavior of a microcantilever/rim system. We envision the successful development of these types of models as being of paramount importance when using single or multiple (coupled) cantilever devices in sensing applications.

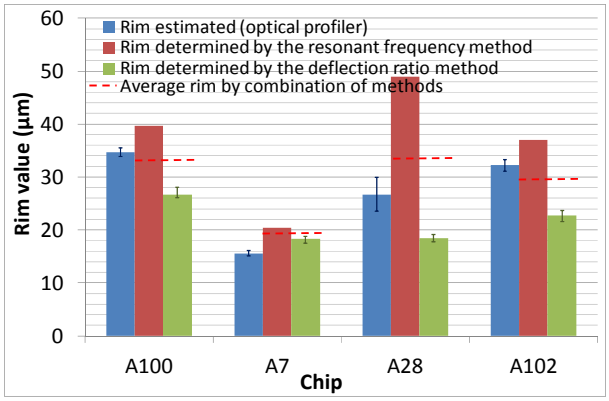

Figure 7: Summary of rim length estimation for the different methods investigated.

V. CONCLUSION

In the present work, two straightforward methods based on resonance behavior of microcantilevers have been proposed and evaluated for the systematic determination of rim length due to silicon over-etching that can occur during DRIE. Using both the cantilever's observed resonant frequency and its deflection profile at resonance, the rim length was determined via comparisons with calibration curves obtained via FEM simulations. By combining both methods, good estimates of the rim length value have been achieved. However, due to the time-consuming nature of performing the requisite FEM simulations, the development of analytical solutions to the problem is desirable. Such analytical models are now under development, so that a better understanding of the complex interplay of system parameters may be obtained for resonating microcantilevers having non-standard support conditions.

***Abstract*—In this work, we develop a radio-frequency oscillator operating near the 434MHz-centered ISM band to validate the temperature compensated capability of HBAR based on combining $LiNbO_3$ and Quartz single crystal plates for such purposes. Electrical and thermoelectric characterizations have shown QF product in excess of 10^{13} and a third order frequency-temperature behavior. A phase noise better than -160dBc/Hz at 100kHz has been measured as well as a -165dBc/Hz level at 1MHz from the carrier. First results showing that the resonator stability is better than 10^{-9} under room conditions. Further work is expected to lower that level well below 10^{-10}.**

I. Introduction

Radio-Frequency (RF) oscillators can be stabilized by various resonating devices. Their stability is mainly conditioned by the spectral quality of the resonator even if the oscillator loop electronics must be optimized to lower the generated noise as much as possible. For mid-term stability, temperature compensation as a key point and allows for notably improving the corresponding figure of merit. In a previous work [1], we have shown the possibility to build temperature compensated High overtone Bulk Acoustic Resonators (HBARs) combining $LiNbO_3$ and Quartz single crystal plates for the excitation of high order modes exhibiting cubic frequency-temperature behavior. In this work, we develop a radio-frequency oscillator operating near the 434 MHz-centered ISM band to validate the capability of the above-mentioned HBAR for such purposes. The composite substrate have been built using a 3-inch (YX*l*)/163° $LiNbO_3$ cut wafer bounded and thinned down to 15 µm onto a 350µm thick (YX*lt*)/34°/90° quartz base.

Single-port resonators operating near 434 MHz (exploiting the third harmonic of the thinned niobate plate as the HBAR transducer) have been then manufactured. Electrical and thermoelectric characterizations have shown quality factor of the resonance in excess of 25000, yielding a QF product in excess of 10^{13} and a third order frequency-temperature behavior. A SAW filter was used to select the ISM band and to filter the high spectral density HBAR response. The oscillator then has been measured using a phase noise automatic bench (R&S FSUP26 spectrum and phase noise analyzer). A phase noise better than -160dBc/Hz at 100kHz has been measured as well as a -165dBc/Hz level at 1MHz from the carrier. Mid term stability also have been achieved, first results showing resonator stability better than 10^{-9} under room conditions. Further work are expected to lower that level well below 10^{-10}.

The first section of the paper discusses the design of the resonator based on thermoelastic computation of the temperature coefficients of frequency (TCF) of each mode of the structure. The basic theory is first recalled and general relations are provided to select the material stack thicknesses for a given mode order/frequency operating condition. A very brief description of the device fabrication is provided and experimental characterization of the resonators is reported. The oscillator architecture is depicted and the stability measurements detailed. As a conclusion, comparison with SAW-based oscillator is achieved and possible improvements of the oscillator is discussed

II. Device analysis and design

A. HBAR Temperature Coefficient of Frequency (TCF)

The celebrated Campbell&Jones method [2] is used here for predicting the TCF of any mode of a given HBAR. As it has been reported hundred times in previous papers, only the main basic equation is reported below:

$$f=\frac{V}{2e} \rightarrow \frac{df}{f}(T)=\frac{dV}{V}(T)-\frac{de}{e}(T) \qquad (1)$$

which means that the frequency changes due to temperature variations are computed as the difference between the development of the velocity and of the stack thickness vs temperature. As discussed in [1], Lithium Niobate and Quartz have been associated for the fabrication of shear-waver based HBARs. $LiNbO_3$ provides crystal orientations for which very strongly coupled shear waves exist (k_t^2 in excess of 45%) whereas AT cut of Quartz allows for compensating second order frequency-temperature effects [3]. Although this idea was already proposed using other material combinations [4], no real design process was presented until now and therefore the possibility to actually determine structures allowing for high frequency operation with first order TCF smaller than 1ppm.K^{-1} was quite hypothetic. Second order compensation was even not imagined in [4]. Figure 1 shows the evolution of the TCF_1 of almost all the modes of thinned (YX*l*)/163° $LiNbO_3$ layer atop a (YX*lt*)/36°/90° Quartz plate for various Niobate/Quartz thickness ratios, always assuming a Niobate layer much thinner than the Quartz substrate (which allows for neglecting the differential thermoelastic stress within the stack). One can see that depending on the harmonic number, the TCF_1 changes from +1 to -14ppm.K^{-1}. Furthermore, depending on the harmonic of the transducer alone, the TCF_1 may notably change and thus it cannot be considered as a simple periodic function vs harmonic number. Therefore, it is mandatory to accurately consider all the actual feature of the structure for an accurate design of a resonator, i.e. the operation frequency, the harmonic number and the thickness ratio for a given structure. To complete this, one should also account for the actual thickness of the device as this parameter will control the possibility to select one (frequency/harmonic number) couple. Finally, it clearly appears that the analysis of such HBAR TCF requires a numerical analysis and that if an intuitive approach allows for a first order definition of crystal orientations, the complicated distribution of energy within the stack vs all the structure parameters induces more intrication in the design process.

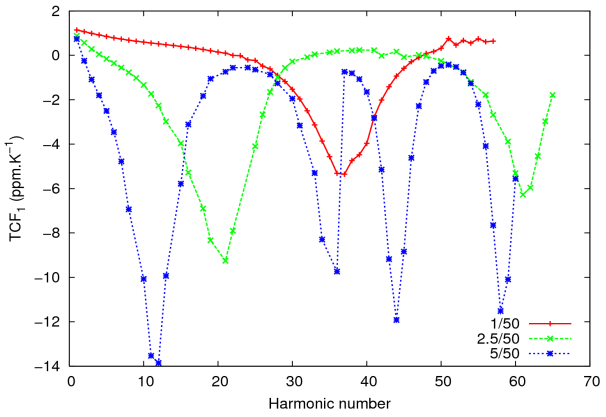

Figure 1. Plot of the TCF of a HBAR built on a (YX*l*)/163° $LiNbO_3$ thinned plate bonded on (YX*lt*)/36/90 Quartz substrate for various Niobate/Quartz thickness ratio (Quartz thickness arbitrary fixed to 50µm)

As an illustration of these considerations, the evolution of the TCF of the most strongly coupled mode of the structure (coinciding with the fundamental mode of the niobate plate alone) has been plotted vs niobate thickness (Fig.2). A TCF_1 vs Niobate/Quartz ratio law has been derived from this curve, yielding the following expression:

$$TCF_1 = 42.5 \times R_t + 3.2 \times \log(200\, R_t) \quad (2)$$

where R_t is the Niobate/Quartz ratio, thicknesses and TCF_1 being expressed in µm and in ppm.K^{-1} implicitly.

Considering now the TCF_1 evolution vs quartz cut angle θ (rotation around X axis), one can set the following complementary law:

$$TCF_1 = (\theta - 35.) \times 5.10^{-6} \quad (3)$$

Using these relations allows one to show that the most coupled mode of the structure is temperature compensated for R_t=1/50 for the (YX*lt*)/34°/90° quartz cut, whereas the (YX*lt*)/33°/90° and (YX*lt*)/32°/90° cuts will be selected for R_t respectively equal to 2.5/50 and 5/50.

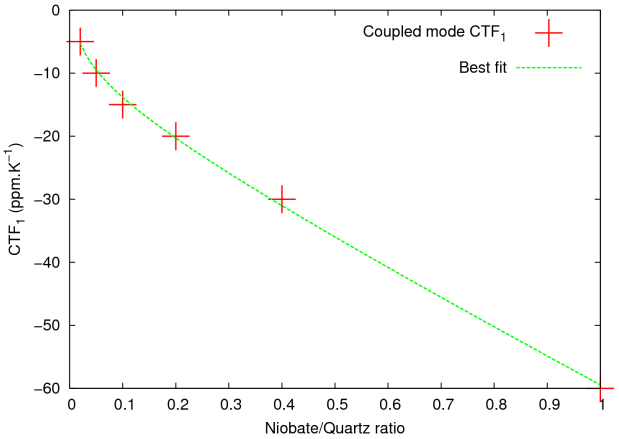

Figure 2. Plot of the TCF of a HBAR built on a (Yxl)/163° $LiNbO_3$ thinned plate bonded on (Yxlt)/36/90 Quartz substrate for various Niobate/Quartz thickness ratio (Quartz thickness arbitrary fixed to 50µm)

B. 434 MHz resonator design

The design of the 434 MHz centered resonator has been done considering our capability to thin down $LiNbO_3$ wafers. A typical thickness of 15µm±2µm then must be considered, the Quartz thickness being deduced along the theoretical analysis presented above. Assuming a phase velocity of the shear mode in the $LiNbO_3$ layer near 4000m.s^{-1}, the third harmonic of the fundamental mode then is easily excited at the expected frequency. To achieve the temperature compensation of the mode, the quartz cut angle and plate thickness then has to be fixed. A R_t value of 2.5/50 is considered as a trade-off between the spectral density of modes and the ease to manufacture the material stack.

Consequently, the quartz thickness is found near 270µm for a cut angle corresponding to (YX*l*)/34°/90°. Once again for manufacture simplicity, standard quartz wafer thicknesses are considered, yielding a value of 350µm.The $LiNbO_3$ thickness then is adjusted to 14µm according to the above considerations (R_t actual value 2/50). Validation of such a configuration has been achieved theoretically by computing the admittance of the corresponding device and then its theoretical TCF. An equivalent quality coefficient Q of 20,000 has been considered for Quartz whereas a Q of 100,000 was affected to $LiNbO_3$. Au electrodes are used at the interface (t = 300nm, Q~1000) and Al ones at the top surface (t = 250nm, Q~2000). An effective Q value slightly larger than 20,000 then is predicted for a k_s^2 of 1,9‰ (Fig.3). Temperature compensation is checked by plotting both TCF_1 and second order TCF_2 for each resonance near 434MHz, as shown in Fig.4. For such a configuration, one can see that TCF_1 smaller than 1ppm. K^{-1} can be obtained together with TCF_2 of less than 5ppb.K^{-2}.

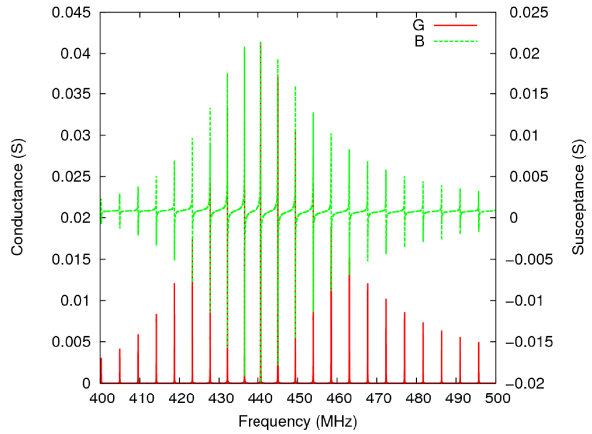

Figure 3. Theoretical admittance of a HBAR built on a 14µm thick (YXl)/163° $LiNbO_3$ plate onto 350µm thick (YXlt)/34°/90° Quartz

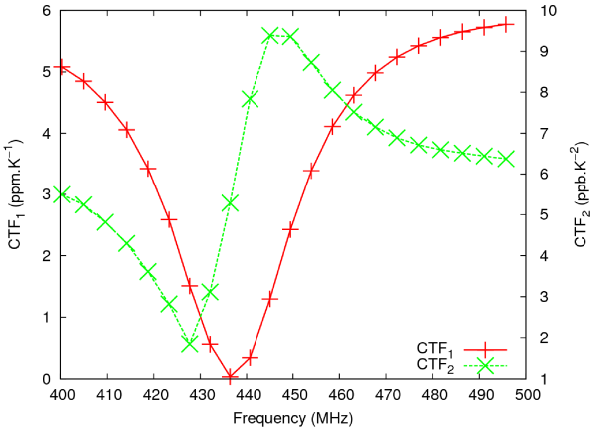

Figure 4. 1st and 2nd order TCF of the above $LiNbO_3$/Quartz HBAR, temperature compensation achieved between 430 and 440MHz.

III. Experimental implementation

A. *HBAR fabrication*

As mentioned above, only some information is reported here as most of the process has been already presented in details [1]. $LiNbO_3$ and Quartz are bonded together using thin Cr/Au films deposited on both wafer sides to be bounded and therefore used both as diffusion layers and interface electrode. A pre-bonding is first achieved using either an EVG bounder or a Suss Microtech CL200 megasonic cleaner. The bounding then is reinforced by applying a quite strong homogeneous pressure during a few tenth minutes, yielding then an almost perfect acoustic adhesion between both material. Top electrodes are then deposited using standard lithography processes.

B. *Resonator characterization*

Conforming to the above design and manufacturing process, several devices have been fabricated and tested to select the most appropriate one for frequency stabilization in the ISM band. Figure 5 shows one example of resonator admittance from which electromechanical coupling k_s^2 and Q factor are deduced, respectively at about 0.2‰ and 25,946, yielding a Q factor of 1.13×10^{13}, much better than Rayleigh wave based resonators on Quartz considering the same frequency. One can note that Q factor in excess of 30 000 also were measured (QF products in excess of 1.3×10^{13}), but for frequencies slightly out of the ISM band. The TCFs have been again tested to demonstrate the predicted compensation effect.

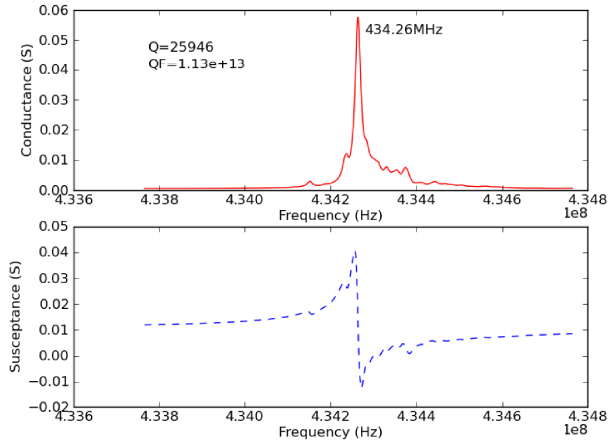

Figure 5. Experimental measurements (admittance) of a HBAR based on (YXl)/163° $LiNbO_3$ plate onto 350µm thick (YXlt)/34°/90° Quartz

C. *Oscillator stabilization*

The implemented oscillator once again is very similar to what has been already presented for SAW devices [5] and therefore will not be detailed here. It is a Colpitts-type negative resistance circuit to which a buffer stage has been

added to isolate the oscillating loop and provide sufficient signal for the oscillator characterization. Figure 6 shows the characterization of the oscillator output using a spectrum analyzer, showing the definition of the resonance and also proving the possibility to actually select the ISM band by filtering.

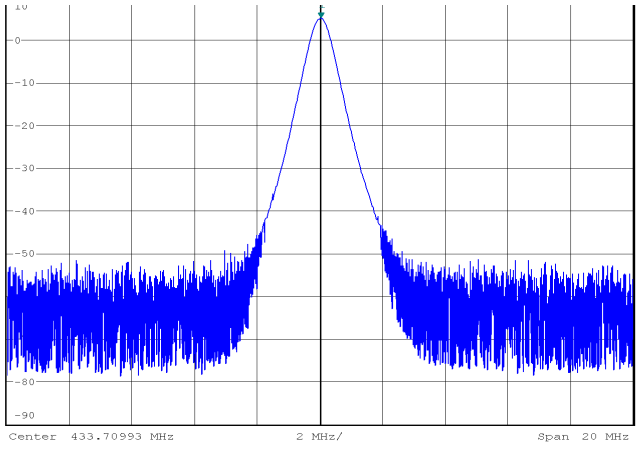

Figure 6. Spectrum of the oscillator output signal, close to the ISM center (433.7MHz)

Figure 7 shows the phase noise of the oscillator. The noise floor is at -165dBc/Hz and the phase noise at 10kHZ is -140dBc/Hz.

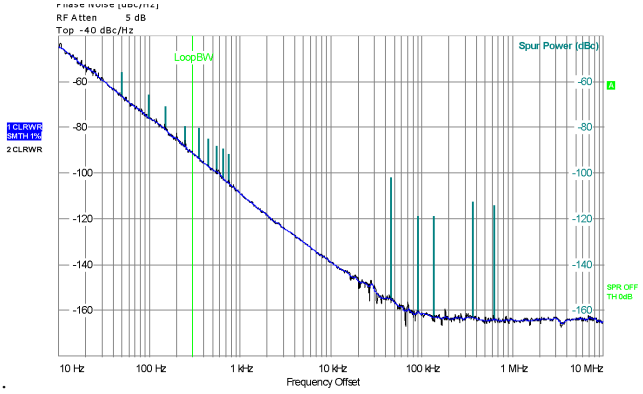

Figure 7. Phase noise of the Colpitts oscillator.

Figure 8 show Allan variance of the oscillator output signal. The oscillator based on HBAR temperature compensated presents a relative stability of near 2×10^{-10} over 2 seconds of integration at room conditions.

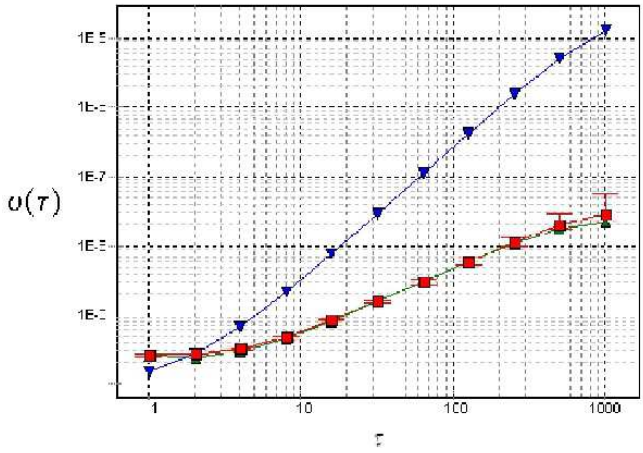

Figure 8. Allan Variance of the oscillator output signal, yielding a relative stability near 2×10^{-10} over 2 seconds of integration at room conditions

IV. Conclusion

In this work, we develop a radio-frequency oscillator operating near the 434MHz-centered ISM band to validate the temperature compensated capability of HBAR based on combining LiNbO3 and Quartz single crystal plates for such purposes. Electrical and thermoelectric characterizations have shown QF product in excess of 1013 and a third order frequency-temperature behavior. A phase noise better than -160dBc/Hz at 100kHz has been measured as well as a -165dBc/Hz level at 1MHz from the carrier. First results showing that the resonator stability is better than 10-9 under room conditions over 2 seconds. Further work is expected to lower that level well below 10-10. To achieve this objective, excitation of resonator will be increase, test will be done under controlled temperature condition, and electromechanical coupling coefficient will be increase. Towards ultimate stability allows us competition with SAW based oscillators.

Passive Tuning in Lateral-Mode Thin-Film Piezoelectric Oscillators

Mohsen Shahmohammadi, Derya Dikbas, Brandon P. Harrington and Reza Abdolvand
Department of Electrical and Computer Engineering, Oklahoma State University, Tulsa, Oklahoma, USA
mohsen.shahmohammadi@okstate.edu

Abstract — **In this paper, for the first time frequency tuning in lateral-mode thin-film piezoelectric resonators is demonstrated through varying the termination load connected to an isolated tuning port. The dependency of frequency tuning on the design features of the resonator is studied as well. More than 4300ppm tuning range in a thin-film piezoelectric-on-silicon (TPoS) resonator and more than 9000ppm tuning range in a pure piezoelectric resonator is achieved at ~29.5MHz and ~31.5MHz respectively. Also, an oscillator tuning range of more than 2700ppm is reported which shows a great potential for temperature compensated oscillators.**

I. Introduction

Quartz crystal resonators have been widely employed in clock generators in communication systems since they offer high quality factor (Q) and excellent temperature stability. However, the drawback of such resonators is that they are not compatible with CMOS fabrication process, which complicates the integration of the high-performance oscillators with the rest of electronics. This issue will be of much greater importance for realization of future generations of data and communication systems in which oscillators at different frequencies are demanded in a very small footprint area.

MEMS resonator technology has gradually become popular as a solution for the integration problem. Many researchers and companies have presented high-performance MEMS-based oscillators so far [1, 2]. In the past, our group has shown that thin-film piezoelectric-on-substrate (TPoS) MEMS resonators can yield superior power handling and Q (in air) due to the excellent power density and low acoustic loss of their silicon resonant body [3, 4]. Such advantages make TPoS resonators as great candidates to be employed in low-noise oscillator circuits.

Although, lateral-mode piezoelectric resonators such as TPoS devices have been successfully incorporated in low-power and low-noise oscillators, they have limited frequency stability versus temperature (relatively large temperature coefficient of frequency, TCF). Also, methods of frequency tuning have not yet been studied extensively for such devices. Simple and effective tuning schemes can be exploited in temperature compensated oscillators.

In capacitive resonators, frequency tuning is usually pursued through altering the effective stiffness of the resonator by varying the bias voltage across the parallel plate capacitive transducer [5, 6]. In these resonators effective tuning at high frequencies (10's of MHz and above) is only achievable with very small transduction gaps and large tuning voltages, rendering the technique impractical. Tuning based on heating the resonant structure has also been studied in the past [7, 8]. The drawback is that although the frequency stability achieved in such scheme can be considerable, but the large power consumption is prohibitive for all battery-powered applications. In this paper we exploit the well-known concept of altering the mechanical stiffness of a vibrating piezoelectric film through varying the electrical impedance connected to the conducting electrodes. The novelty in this work is in separating the tuning port from the signal port which will be included in the oscillation loop. This way the termination impedance can be altered to the extremes (open and short) without largely affecting the oscillation loop and therefore the tuning range is expanded. We will experimentally investigate the effect of the resonator design features such as tuning electrode position, relative electrode sizes, and relative thicknesses of the layers in the resonant structure on the maximum achievable tuning.

II. Overview of TPoS Technology

As shown in the schematic of Fig. 1, a TPoS resonator consists of a thin piezoelectric film (e.g. aluminum nitride, AlN) sandwiched between two metal electrodes (e.g. molybdenum, Mo) stacked on top of the device layer of a silicon-on-insulator (SOI) substrate [9]. The bottom Mo is patterned to reduce the parasitic capacitor of the input and output traces. The top and bottom Mo are dry etched in SF6 and O2 plasma to form the top electrodes and the traces while the AlN is wet etched to clear access to the bottom electrode. The resonator body is defined in a plasma etching step. The backside handle layer silicon is etched in a deep reactive ion etching chamber, which creates the cavity below the resonator. The final release step is done in buffered oxide etch (BOE) solution to remove the buried silicon dioxide layer and create the free-standing structure. TPoS resonators can be designed in either one-port or two-port configurations. In a two-port design (Fig. 1) usually one port is used to excite the resonance and the second port is used to sense the vibration. The electrode pattern is designed to yield a minimum series impedance (maximum output current) at the mode-shape of interest. For example the pattern of Fig. 1 can be used for both

This work was funded by Integrated Device Technology Inc.

fundamental and the third harmonic bulk width-extensional modes of the structure.

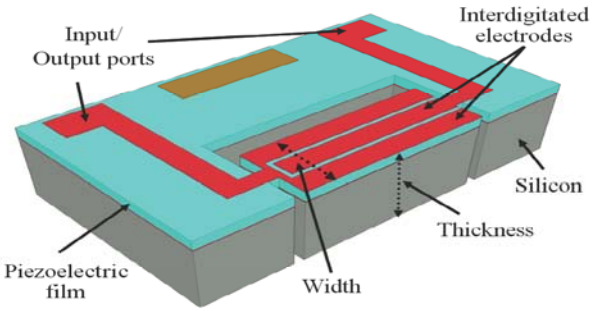

Figure 1. The schematic of a TPoS resonator

Using the TPoS technology we have successfully demonstrated very high quality factor, low motional impedance, and high power handling in air. A frequency response of an optimized fundamental-mode TPoS resonator similar to the schematic picture of Fig. 1 and designed for operation at 27MHz is shown in Fig. 2. The combination of 44500 unloaded quality factor and 200Ω motional impedance in air as demonstrated in this figure is a unique feature not reported by other technologies. Also, there are no significant spurious resonance peaks in the vicinity of the main peak as captured in the 20MHz span of Fig. 2.

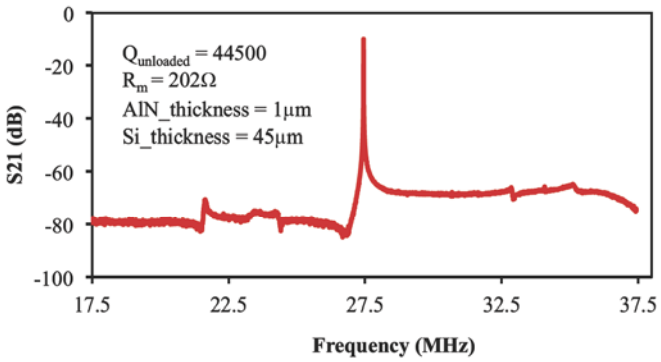

Figure 2. The frequency response of a typical TPoS resonator in air

III. Passive Frequency Tuning in TPoS Resonators

It is known that the effective modulus of a piezoelectric layer (and consequently the resonance frequency) can be altered by varying the shunt impedance connected to a pair of conductive electrodes that cover the surfaces of the film [10]. As shown in Fig. 3 the modulus will change between a minimum at short termination and a maximum at open termination as the parallel impedance is varied. For a short termination the effective modulus (E_{Short} in Fig. 3) depends only on the material compliance (S^E) while for other terminations it is a function of not only the material compliance but also the piezoelectric properties and the shunt impedance (d, ε_p, Z_T and Z_p). In Fig. 3, E is the effective modulus, d is piezoelectric constant, ε_p is the permittivity of piezoelectric material and Z_T and Z_p are shunt impedance and the capacitive impedance of conductive electrodes respectively.

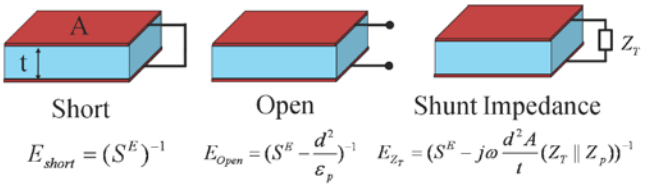

Figure 3. Dependency of the effective modulus of a metalized piezoelectric film on the electrical termination [10]

We have exploited this concept in the lateral-mode TPoS resonators. The proposed configuration for the frequency tuning purpose is shown in Fig. 4. One of the two terminals in the two-port resonator (port 2) is designated to tuning. Varying the shunt impedance (Z_T) connected to this port changes the effective modulus of the resonant body and the minimum and maximum impedance determines the resonance frequency limits. The other port (port 1) will then be connected to the oscillator circuit. To investigate the tuning range the reflection S-parameters (S11) are measured from port one as the second port is either floating (creating open termination) or connected to a 50Ω terminated probe (mimicking close to a short termination). The resonator impedance is then calculated from the measured S11 data.

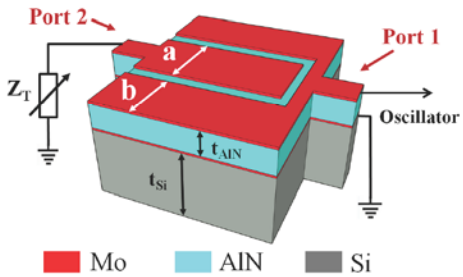

Figure 4. The proposed TPoS resonator electrode configuration for passive tuning purposes

IV. Measurements

A. Tuning in TPoS Resonators

TPoS resonators with variable electrode pattern were fabricated on SOI wafers with different silicon thicknesses for characterization of the tuning range. Two sets of pure AlN devices [11] were also fabricated on bare silicon wafers with 1.5 and 2μm thick AlN film for comparison. The frequency response of a 29MHz fundamental-mode resonator is shown in Fig. 5. This design is fabricated on a SOI wafer with 5μm silicon and 2μm AlN. The impedance vs. frequency plot is calculated from the measured reflection S-parameter (S11). Measurement is repeated for two cases; 50Ω (close to short) and open termination at port two. The results are plotted in Fig. 6. As seen in this figure the resonance frequency is shifting more than 116kHz at ~29MHz (4000ppm) between short and open case. It is observed that the attributes of the measured frequency response other than the resonance frequency are also affected by the termination on the tuning port (e.g. the Q is higher for the open termination). However, the change is not significant to an extent that could disrupt the operation of an oscillator circuit.

As we will discuss in the next few sections the maximum achievable tuning range is a function of electrode position, electrode size and relative Silicon to AlN thickness.

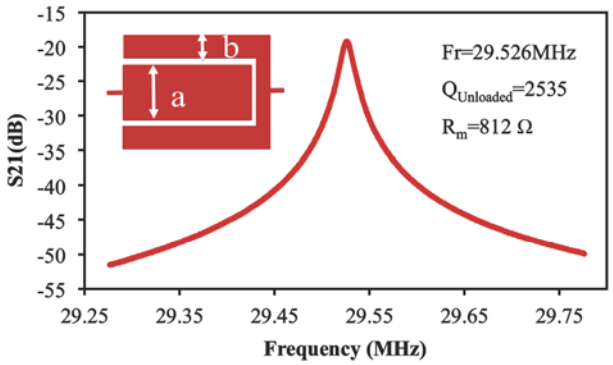

Figure 5. Measured frequency response of a TPoS resonators with a/b=4, Silicon thickness = 5µm, AlN thickness= 2µm

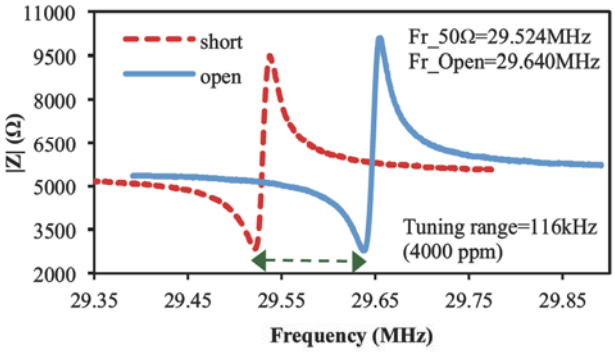

Figure 6. The measured frequency shift for the device above on probe station

1) *Effect of electrode position*

The effect of the electrode position on tuning range is studied by measuring the tuning range for two cases. First; port two is used as tuning and S11 measurement is done at port one and next; the configuration is reversed. It is observed that a larger frequency shift is achieved by utilizing the center electrode (port two) for tuning versus port one. For example the tuning results for the device tested above are shown in Table I. This observation can be explained by the fact that the center electrode covers the area that undergoes the maximum stress in fundamental mode as shown in the simulated mode-shape of Fig. 7. Therefore the contribution of the center area on the overall effective modulus of the structure is larger.

Table I. Measured frequency tuning of a TPoS resonators with a/b=4, Silicon thickness = 5µm, AlN thickness= 2µm

		Frequency(MHz)	Tuning Range(ppm)
Tuning Port: 2	Short	29.524	4000
	Open	29.640	
Tuning Port: 1	Short	29.524	340
	Open	29.534	

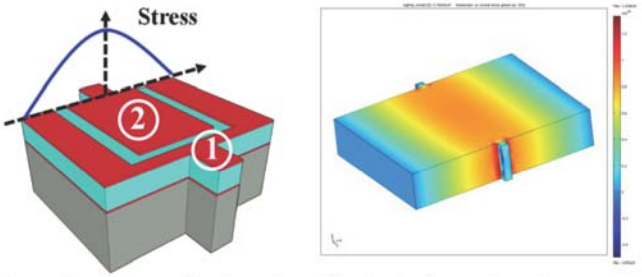

Figure 7. Stress profile along the width of a fundamental-mode resonator

2) *Effect of electrode size*

Several TPoS resonators with different ratios of the center electrode to the side electrode width (a/b) are fabricated and tested. Results show that the frequency tuning range increases as this ratio increases. As it is depicted in Fig. 8 it varies from 1000ppm to 4300ppm for "a/b" ratio of 0.7 to 10.8.

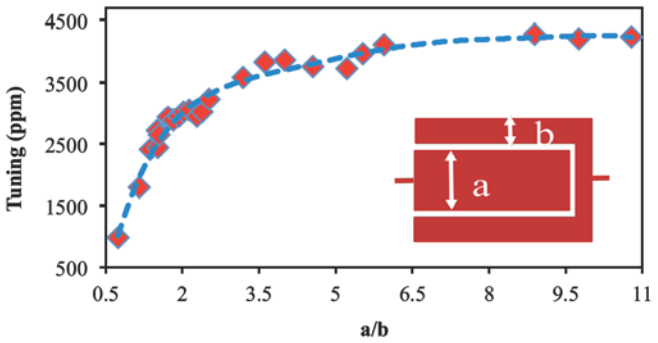

Figure 8. Maximum frequency shift as a function of a/b for TPoS resonators with Silicon thickness= 5µm and AlN thickness= 2µm

3) *Effect of relative Silicon to AlN thickness*

Several devices on different wafers were fabricated and tested in order to study the effect of the relative silicon to AlN thickness on tuning range. It is observed from Fig. 9 that the tuning range increases as the ratio of t_{Si}/t_{AlN} decreases. Table II also shows the tuning range for the same design which is fabricated on two wafers with different AlN thickness. The maximum 4300ppm tuning range at 29MHz is measured for the device with AlN thickness of 2 µm.

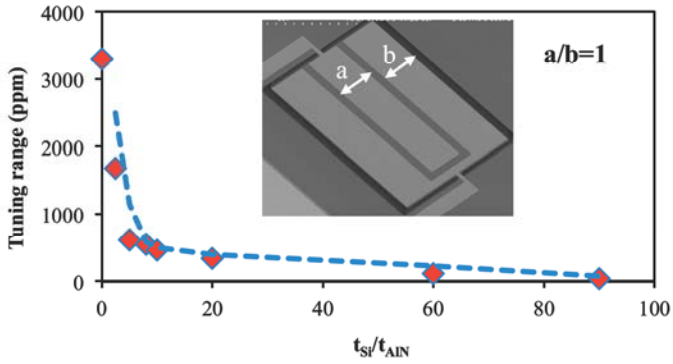

Figure 9. Maximum frequency shift as a function of t_{Si}/t_{AlN} for resonators with a/b=1

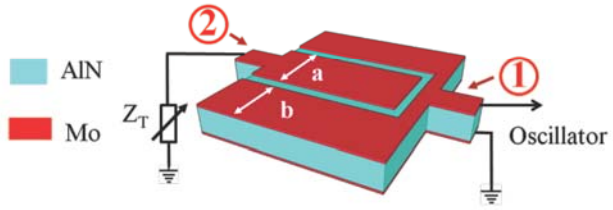
Table. II. Frequency tuning range for different AlN thickness, Si thickness=5µm

AlN	a/b	Short (MHz)	Open (MHz)	Tuning Range(ppm)
1.5µm	5.94	28.907	28.989	**2824**
2µm	5.94	29.519	29.647	**4300**

B. *Tuning in Pure AlN Resonators*

Designs are fabricated on a wafer with just AlN similar to resonators in [11]. As it is expected the tuning range increases compared with TPoS resonator since the contribution of the piezoelectric modulus on the overall effective modulus is maximized. The highest overall frequency shift is measured from pure AlN devices which is more than 9000ppm at 31.5MHz. Increasing the thickness of the AlN from 1.5µm to 2µm has also caused the tuning range to increase substantially (Fig. 10).



AlN	a/b	Short (MHz)	Open (MHz)	Tuning Range(ppm)
1.5µm	5.94	30.493	30.745	**8260**
2µm	5.94	31.571	31.860	**9150**

Figure 10. Pure AlN resonator

C. *TPoS Oscillator Characterization*

The schematic of the oscillator circuit used in this work is shown in Fig. 11 where port one on the resonator is integrated in the oscillation loop. The oscillation loop consists of two amplification stages (the second stage is mostly used for phase correction). Output signal waveform is converted to square wave through a comparator in order to enable jitter measurement. On the second port a varactor diode is used to implement the variable impedance.

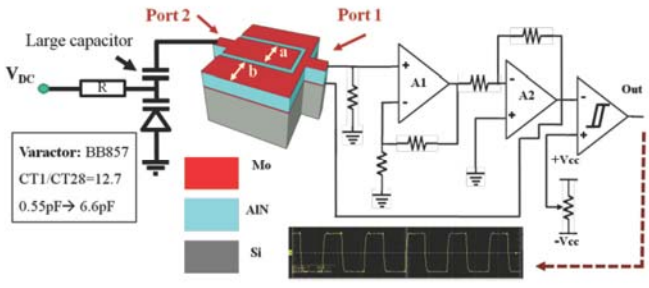


Figure 11. The schematic of the tunable oscillator circuit

Both TPoS and pure AlN resonators were employed in the oscillator. Through applying a tuning DC voltage to the varactor diode the effective shunt impedance at port two is varied. Therefore, the resonance frequency of the resonator and consequently the oscillation frequency of the circuit changes with the DC voltage. Preliminary results show oscillator tuning ranges that are less than the measured frequency shift of the resonator on the probe station. This is because the tuning range is limited by the parasitic capacitor at the tuning port generated by wire bond and PCB tracks which degrade the ideal open condition. Another limitation is the upper and lower capacitance values of the varactor diode which creates a smaller range of shunt impedance compared to what is achievable on the probe station. Maximum oscillator tuning from a TPoS oscillator was measured to be 1200ppm where as a tuning range of 2718ppm was recorded for a pure 2µm thick AlN resonator (Fig. 12) Assuming an approximate TCF of -25ppm/C for the resonator[11], 2718ppm tuning range can compensate for 110°C of temperature change.

The oscillator jitter is measured for the whole tuning range which changes from 22ps to 23ps (cycle-to-cycle standard deviation) between DC voltage of 0v to 25v showing that the jitter is not affected by the tuning impedance.

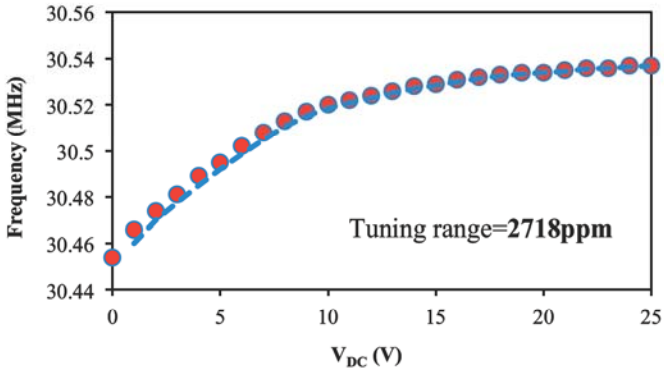

Figure 12. Pure AlN oscillator frequency as a function of DC voltage applied to the varactor

V. Conclusion

In this paper, the novel passive frequency tuning method through varying termination load connected to an isolated tuning port is demonstrated in thin-film piezoelectric lateral-mode resonators. The Effect of resonator characteristics on the frequency tuning range is also studied. Frequency tuning range of more than **4300ppm** in TPoS resonators and more than **9000ppm** in pure AlN devices are reported at ~29.5MHz and ~31.5MHz respectively. An oscillator tuning range of more than 2700ppm is reported which shows a great potential for temperature compensated oscillators.

***Abstract*— This work presents high frequency fully-micromechanical self-sustained oscillators. It has previously been demonstrated that interactions between mechanical strain and thermally generated actuation forces in micromechanical structures through the piezoresistive effect, can result in a positive feedback loop leading to self-sustained oscillation without the need for an electronic amplifier. In our previous work we demonstrated self-sustained oscillation of single-crystalline silicon dual-plate structures with frequencies up to 6.7MHz [1]. This work demonstrates higher frequency thermal-piezoresistive self-sustained oscillators with frequencies up to 36MHz using I^3-shaped resonant structures. Due to the highly nonlinear (mixed flexural-extensional) deformation of actuator/piezoresistors in such structures, they can provide two dominant output frequency harmonics. The dominant harmonic can be selected by changing the resonator bias current.**

I. INTRODUCTION

Micromechanical oscillators have a lot of potential as replacements for conventional mechanical frequency references in electronic systems. They can also be utilized as highly sensitive resonant mass sensors for chemical and biomedical applications. Such oscillators can provide lower cost, smaller size and compatibility with integrated circuit technologies. In order to use a micromechanical resonator as the frequency reference for an electronic oscillator an amplifying positive feedback loop is required. . In case of conventional electrostatic [2] and piezoelectric [3] micromechanical resonators which have been widely studied and developed over the past decade, an external amplification circuitry is required to provide such a feedback.

The other category of MEMS resonators, thermally actuated resonators with piezoresistive readout, have not been studied as intensively and thoroughly as the other conventional MEMS resonators. This is mainly due to the generally presumed disadvantages of thermal actuation, i.e. being a power hungry transduction mechanism and also its established reputation of being suitable for DC or very low frequency applications only. However it has been lately demonstrated that not only such devices can operate at very high frequencies, but also their performance can get better at higher frequencies providing that proper design considerations are met [4]. It is also shown that the power consumption for such structures can reach well below 1mW as their dimensions are scaled down to reach higher frequencies [1]. Furthermore, what is usually ignored is that the power consumption in thermal-piezoresistive resonators makes them active devices. Such devices are capable of absorbing DC power from a source and acting as an AC energy pump initiating and sustaining mechanical oscillations (i.e. playing the role of transistors in electronic circuitry). This concept has been recently demonstrated in [5] showing self-sustained oscillation capability for a thermally actuated flexural mode silicon microstructure oscillating at 1.26MHz. This is enabled by the active nature of such devices and an internal positive feedback loop resulting from the sequential interactions of electrical, thermal, and mechanical events upon passing a constant DC bias current through their structure.

In our previous work we demonstrated self-sustained oscillation of single-crystalline silicon dual-plate structures [1] with frequencies up to 6.7MHz. Furthermore, in order to reduce the power consumption of such resonators, thermal actuators were aggressively narrowed down. Although this method improves the power consumption of the oscillators but it also raises new concerns regarding their performance. Considering the fact that the in-plane extensional stiffness of the dual plate or I^2-BAR structures is determined by their thermal actuators, narrowing them down causes a decrease in the resonance frequency of the structure. Furthermore, defining such narrow features with very high precision is quite challenging leading to significant frequency mismatch between devices in the same batch.
This work demonstrates self-sustained oscillation for higher frequency extensional mode resonators.

II. OSCILLATION MECHANISM AND DEVICE STRUCTURE

The utilized structure in our previous work [1] that is shown in Fig. 1 resonates in its in-plane extensional mode. Since in this resonant mode, the two plates vibrate against each other and not against the anchors, most of the acoustic energy remains in the resonator. In addition, due to the in-plane vibration of the structure, the air damping is minimized. Moreover, the

This work was supported by National Science Foundation under grants MRI-RAPID #1061489 and MRI #0923518.

extensional resonance mode provides relatively high stiffness that keeps a lot of energy in the device and makes the energy loss through air negligible. Therefore, high quality factors and high motional conductances can be measured for such structures. This makes these devices capable of self-sustained oscillation under both vacuum and atmospheric pressures.

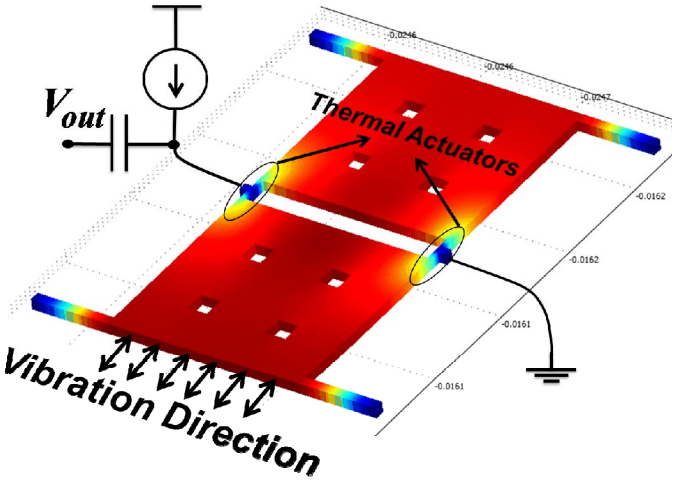

Fig. 1. COMSOL modal analysis, showing the fundamental in-plane resonance mode shape for the dual-plate 4.5MHz resonator which is bias with a constant DC current. Red and blue colors show locations with the largest and smallest vibration amplitudes respectively. The two narrow beams in the middle of this structure are also act as thermal actuators. The used electronic circuitry is to test the oscillation behavior of such resonators

The series of events that leads to self-sustained oscillation can be explained as follows: upon application of a DC bias current, the thermal actuators heat up and expand. Due to the mass (inertia) of the plates, the beams experience an over-expansion after pushing the plates and undergo tensile stress. Since the piezoresistive coefficient has a negative value, the tensile stress decreases the electrical resistance of the actuator beams. When biased with a constant DC bias current, this lowers the ohmic loss in the thermal actuators forcing them to contract. After structural over-contraction (due to the mass of the plates), the actuators will be under compressive stress and will have increased electrical resistance. This translates into a higher thermal power forcing the structure to expand again. If the resulting driving force (due to heating and cooling) in each cycle is large enough to compensate for mechanical losses of the structure, the same sequence is repeated over and over in a self-sustained manner and the vibration amplitude keeps increasing until it is limited by nonlinearities. The 90º phase lags (Fig. 2) resulting from the mechanical and thermal response delays lead to a perfect timing for the abovementioned sequence of physical phenomena to continue.

In order to improve the performance of such oscillators, in this work a wider third bar has been added to the I^2-shaped structures (Fig. 3). In the resulting I^3-shaped structures the stiffness of the resonator is mainly determined by the wider middle bar. Therefore higher resonance frequencies can be achieved while maintaining very narrow actuator beams. For the same reason fabrication induced changes in the dimensions of the narrow thermal actuators will not have a significant effect on the frequency of the resonator. Therefore, it is also expected that fabrication induced frequency variations between similar devices of this types will be highly suppressed.

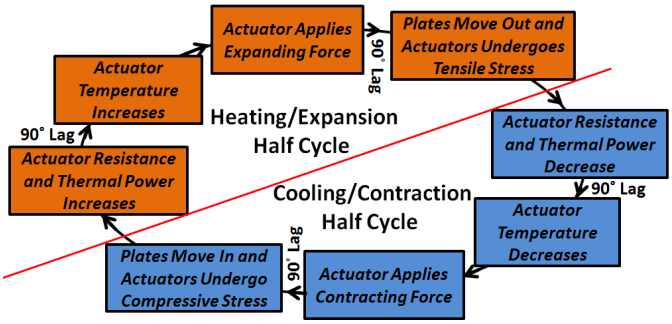

Fig. 2. Sequence of phenomena causing an internal positive feedback loop in thermal-piezoresistive resonators biased with a constant current that lead to self-sustained oscillation.

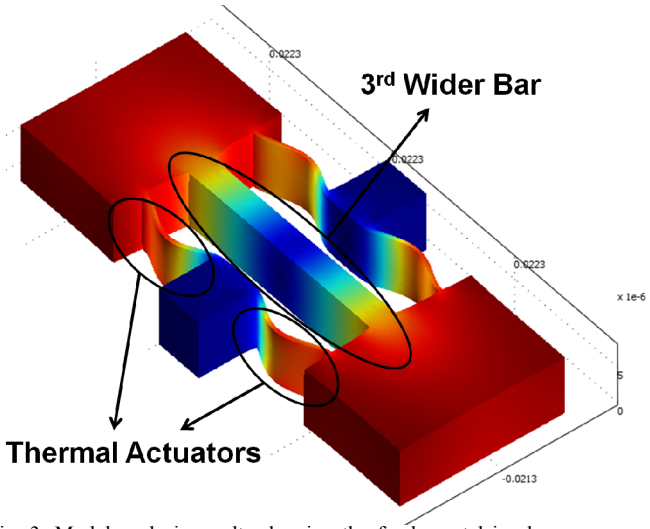

Fig. 3. Modal analysis results showing the fundamental in-plane resonance mode shape for an I^3 resonant structure. In this structure a third wider bar has been added in the middle of the structure to further increase the resonance frequency of the resonator. Red and blue colors show locations with the largest and smallest vibration amplitudes respectively.

III. Fabrication and Measurement Results

Single crystalline silicon I^3-shaped structures were fabricated using the standard single mask SOI-MEMS process [3] on a low resistivity N-type SOI wafer with device layer thickness of 10µm. Since longitudinal piezoresistive coefficient of silicon reaches its maximum value along the <100> direction [6], the resonator actuator beams were fabricated along that direction for optimized transduction. Figure 4a shows the SEM view of a fabricated resonator as well as the schematic view of the required bias current and electrical connections for oscillator operation and measurement.

For this resonator a series of thermal oxidation steps followed by oxide removal in hydrofluoric acid were carried out to narrow down the thermal actuators. Instead of current sources relatively large resistors with values a few times (up to 10X) larger than the electrical resistance of the resonator, were used to provide the resonator bias currents. The AC output

was connected to a high frequency digital oscilloscope. By gradually increasing the bias current, after passing a threshold, the waveform in Fig. 4b with oscillation frequency of 36.54MHz emerged on the oscilloscope. As it can be seen in Fig. 4b, the output signal shape is far from a sinusoidal due to existence of different frequency harmonics. Since the tested resonator has its first in-plane resonance mode at

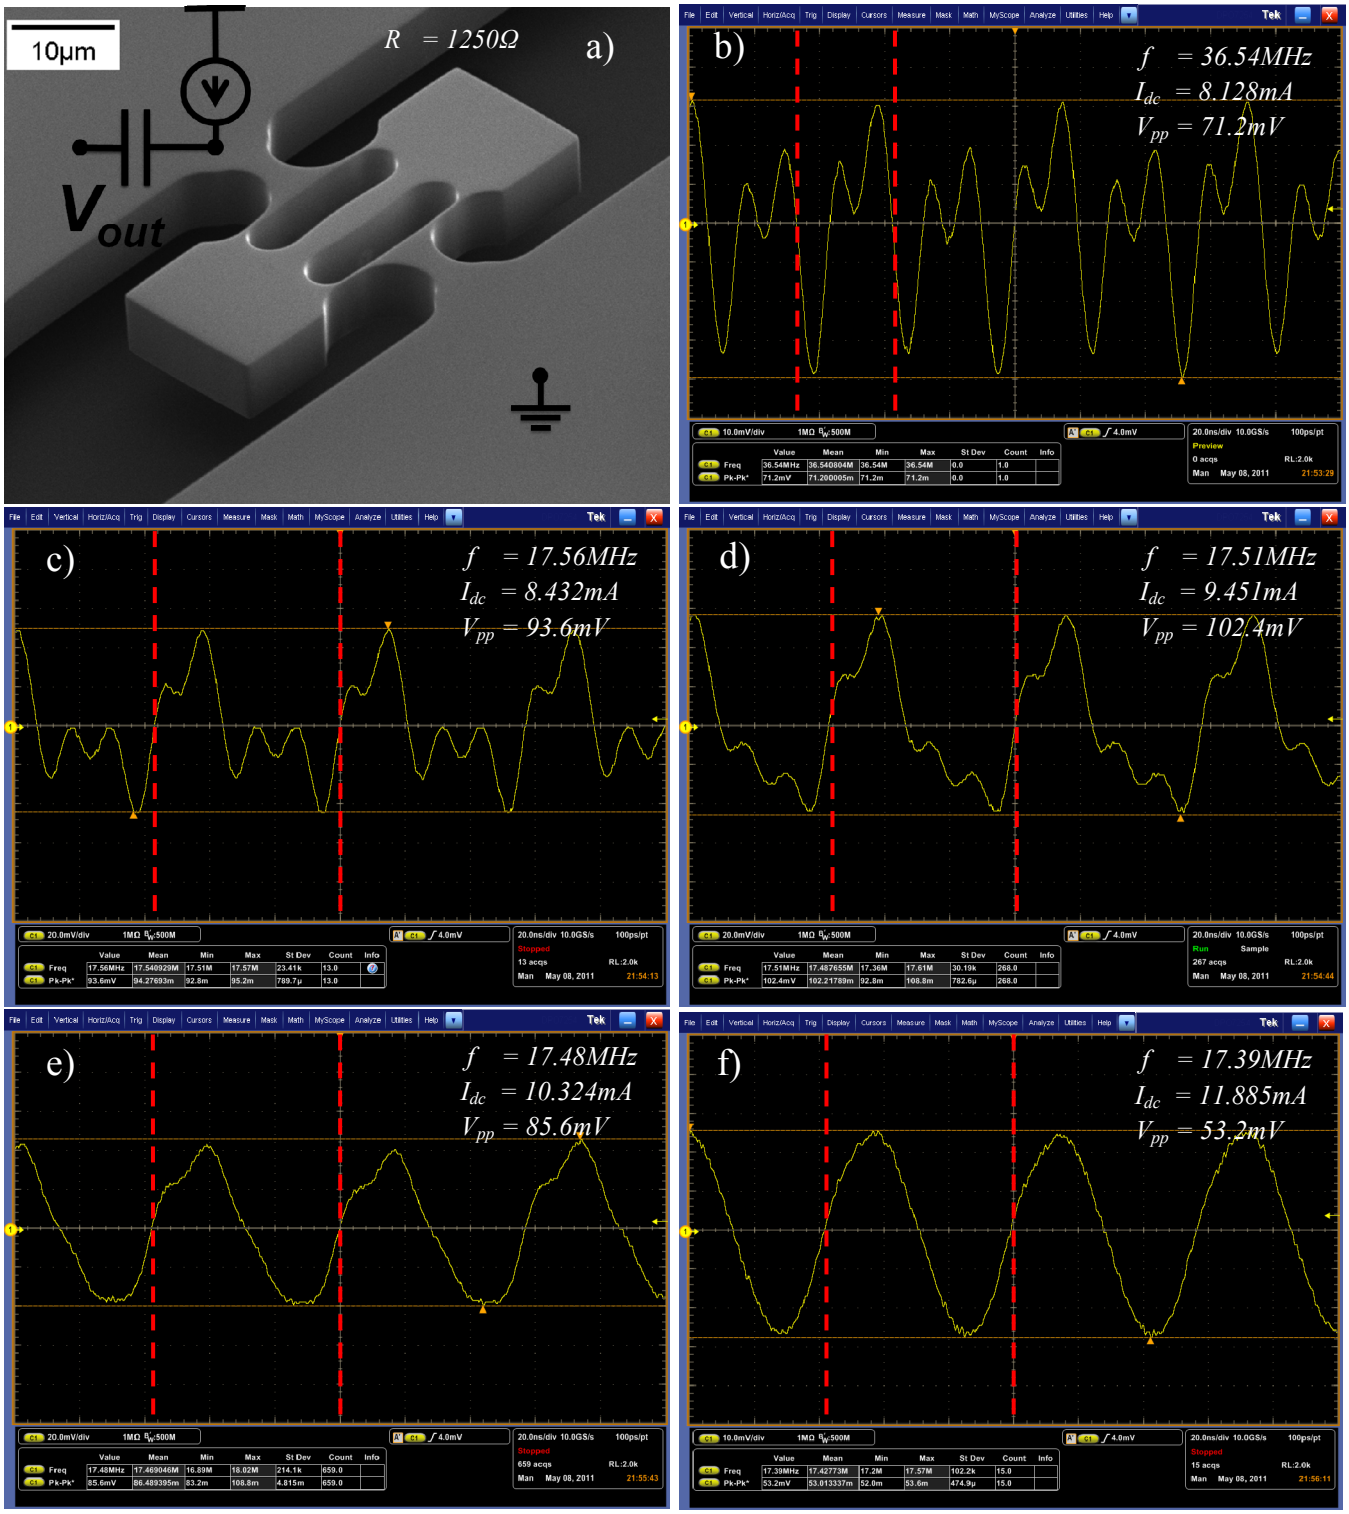

Fig. 4. a) SEM view of a fabricated dual-mode silicon I^3 resonator with oscillation frequencies of b) 36.54MHz at I_{bias}=8.128mA, c) 17.56MHz at I_{bias}=8.432mA, d) 17.51MHz at I_{bias}=9.451mA, e) 17.48MHz at I_{bias}=10.324mA and f) 17.39MHz at I_{bias}=11.885mA both under atmospheric pressure. All the waveforms have the same time interval

17.4MHz, it can be concluded that the second harmonic is the dominant component. The first harmonic shows itself as uneven level of the consecutive peaks in the output waveform. In addition, the small ups and downs in the waveform can be blamed on higher frequency harmonics. It was noticed that by further increasing the bias current, the output voltage waveform constantly changes and at some point the first frequency harmonic with frequency of ~17.5MHz becomes dominant. Figures 4c-4f show how the output waveform changes by increasing the bias current. Figure 4f shows a close to sinusoidal waveform at the same frequency as the mechanical resonance frequency of the structure.

A closer look at the mode shape for the fundamental in-plane resonant mode of the structure reveals that the deformation of the narrow actuator beams is a combination of both extensional and flexural deformations. Figure 5 shows that as the resonator moves from its fully extended state to its fully compressed state in half of the resonance cycle, the narrow support beams go from a fully bent state to their normal straight shape and back into another bent state. Each time the beams flex there will be an increase in their length leading to a frequency component at twice the vibration frequency of the resonator.

As shown in Fig. 4, by changing the applied DC bias current each of these frequency components can become the dominant component determining the output frequency of the oscillator.

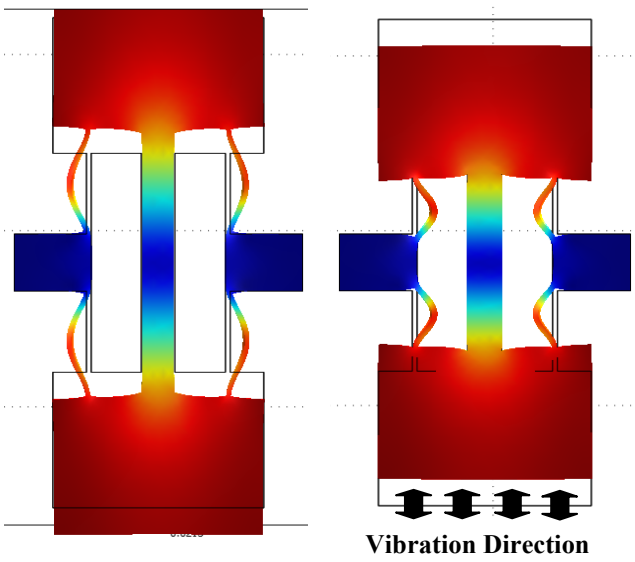

Fig. 5. COMSOL modal analysis results showing the fundamental in-plane resonance mode-shape for an I^3 resonator at its maximum expansion and compression points. It demonstrates that the deformation of narrow thermal actuators is a combination of flexural and extensional deformations and the frequency of the longitudinal deformations of the narrow beams due to flexural deformation is twice the resonance frequency of the resonator.

IV. Conclusions and Future Works

High frequency thermal-piezoresistive I^3-shaped resonators capable of self-sustained oscillation were demonstrated. It was shown that such structures can self-oscillate at higher frequencies compared to the previously demonstrated structures. This design also lowers the fabrication induced frequency variations. Such devices have monolithic crystalline silicon structures and can be fabricated using a very simple CMOS compatible process.

Future work includes further characterization of other versions of such devices and understanding of the factors limiting their oscillation amplitude and long-term as well as short-term frequency stability. Achieving lower power consumptions and higher frequencies are among other future goals.

Although relatively large bias currents were needed leading to relatively high power consumptions for the oscillators, however the power consumption of such structures could be easily lowered to values below 1mW. To do so the resonators should be fabricated on SOI wafers with thin device layer thicknesses rather than using a 10µm thick structure, which is the case in this paper. In addition, the thermal actuators can be further narrowed down to lower their power consumption.

Regarding the stability of such oscillators, phase noise and jitter characteristics could be measured. It is believed that the main source of instability would be the short-term fluctuations in the resonator temperature due to the electronic noise in the bias current and the used bias resistor. Therefore, even higher oscillator stabilities are expected to be achievable via passive temperature compensation of the resonators (e.g. using degenerate doping) [7, 8].

***Abstract*— Recent advances in temperature-compensation for FBAR (Film Bulk Acoustic Resonators) have brought this technology forward as a serious contender in the oscillator marketplace. As with any mechanical resonator oscillator, a cost-effective hermetic package combined with circuit technology are critical for commercial application. Billions of FBAR duplexers have been fabricated using Avago Technologies' wafer-scale packaging process, whereby a silicon lid wafer is Au-diffusion-bonded to a base FBAR wafer to make a robust, hermetic package. This paper presents a method for integrating circuitry into the lid wafer to form a sub-0.1 mm^3, sub mW, 1.5 GHz temperature-compensated chip-scale oscillator. Circuit integration, testing and performance will be discussed.**

I. INTRODUCTION

For over 20 years, FBAR or SMR-BAW (Solidly-Mounted Resonator – Bulk Acoustic Wave) with its high f•Q product has been proposed as an attractive alternative to conventional approaches for timing applications [1,2]. Like other mm-scale mechanical resonators, FBAR requires a hermetic package in order to maintain frequency stability. The FBAR is also not readily integrated with circuit technologies for the simple reason that the processing that produces the FBAR – high resistivity, high impedance electrodes; high dielectric constant for the piezoelectric material, and highly variable thicknesses depending on the frequency target – does not produce a viable electronic device. Although integrating a Bulk Acoustic resonator or filter on the same substrate as an IC has been demonstrated [3,4,5], there are three problems with this approach: 1) compromises between technologies must be made to eliminate interference between processing steps (e.g. temperature limitations), 2) the economics for integrating the two technologies on the same wafer is unfavorable [6], and 3) none of the previous work addressed the issue of how to create an open-air cavity around the BAW device while simultaneously providing a hermetic and robust package.

Our previous work demonstrated the potential value of an FBAR [7], a wafer scale hermetic package [8], and a modified FBAR demonstrating temperature stability comparable to quartz (referred to as Zero Drift Resonators, or ZDR [9]). We have also demonstrated low noise sub-mW oscillators using FBAR [10]. The work presented here is the culmination of those advancements. We now present a technique for integrating active circuitry into the lid of the wafer-scale hermetic FBAR package while the FBAR resonator, ZDR, or filter resides on the base wafer. Both sides of an opened and "unfolded" module are shown in Figure 1. The 285µm x 330µm active circuit area is clearly visible, as is the location for the FBAR resonator. This strategy is IC technology "agnostic". Besides an area limitation, there are no special circuit design rules required for our technique, and process modification for the lid/IC wafer is minimal compared to a full SOC (system-on-a chip) implementation.

II. PROCESS DESCRIPTION

The wafer fabrication uses existing processes where possible, which has the advantages both of simplicity and of maintaining native device performance. In the Avago microcap process, the FBAR is fabricated on one wafer while a second "lid" wafer contains through-wafer vias, Au pads, sealing structures, and a recessed air cavity above the FBAR.

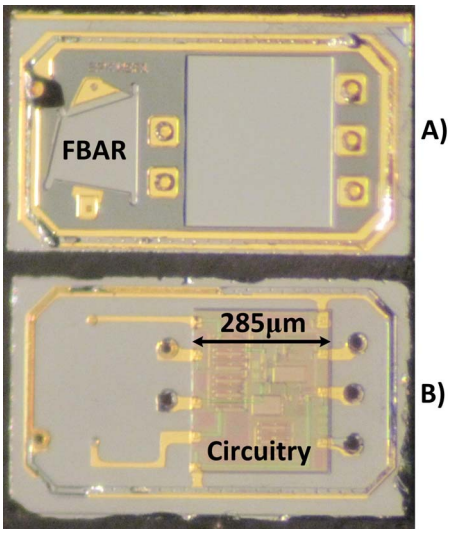

Figure 1. Photograph of disassembled hermetic oscillator package containing A) FBAR die B) lid with integrated active circuitry.

Figure 2 contains a simplified process flow for a standard FBAR/micro-cap part. On the FBAR wafer side, the cavity under the FBAR ("swimming pool") is defined and filled with a sacrificial oxide, the resonators are processed, followed by the patterning of the Au interconnect and sealing material and, finally, the removal of the sacrificial oxide. The Si micro-cap lid is then Au-diffusion bonded to the FBAR wafer and pads patterned on top. The lid wafer is manufactured with standard micromachining processes and through-wafer vias are etched to make external pad connections. Both the FBAR and lid wafers are high-impedance Si to minimize cross-talk and capacitive losses.

Figure 3A contains a schematic flow of the circuit-containing lid wafer. The process flow proceeds as normal with minor modifications for pattern density. Inter-layer dielectric is left in the field until the devices are complete, after which they are removed down to Si. At that point the lid micro-machining can be completed. The cavity etch that leaves a gap above the FBAR removes any remaining epi-Si between contact pads. The final oscillator die with integrated circuitry is shown in Figure 3B. We retained the Au-Au wafer bond that has proven to provide a robust hermetic seal [6]. The circuitry on the lid aligns with a corresponding depression in the FBAR wafer to provide clearance for wafer bonding. Since the depression is patterned along with the depression under the FBAR, no additional masking steps are required. Once the lid is bonded to the FBAR wafer, the lid Au metallization forms the interconnect between the circuitry and the FBAR. Figure 3C contains a SEM cross-section of a bonded die showing the relative position of the FBAR and the lid circuitry (reversed from the schematic). For this demonstration, our circuits used Avago's HP25 silicon bipolar process.

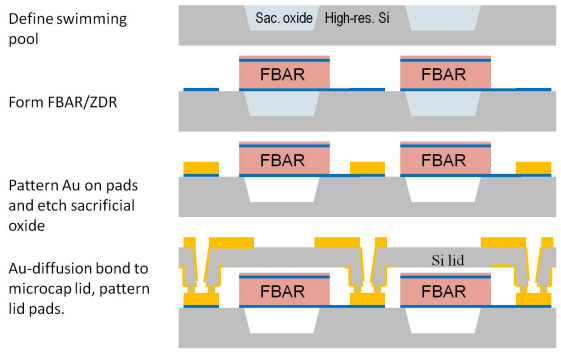

Figure 2. Schematic description of normal FBAR/micro-cap process flow.

III. CIRCUIT IMPLEMENTATION

The concept of integrating active circuitry into the lid has the economic advantage of reusing the lid wafer area for the electronics' pads and from eliminating external connections between the FBAR and the circuit. The size can be further reduced by placing the FBAR directly above the circuitry, which we hope to demonstrate in future iterations. Further economic advantage is gleaned by forcing the circuit size and the resonator (or filter) size to be comparable. The number of external connections is limited by via size; a reasonable via count would be ten or less. In this work, we have six external pads and two internal connections from the lid electronics to the FBAR resonator.

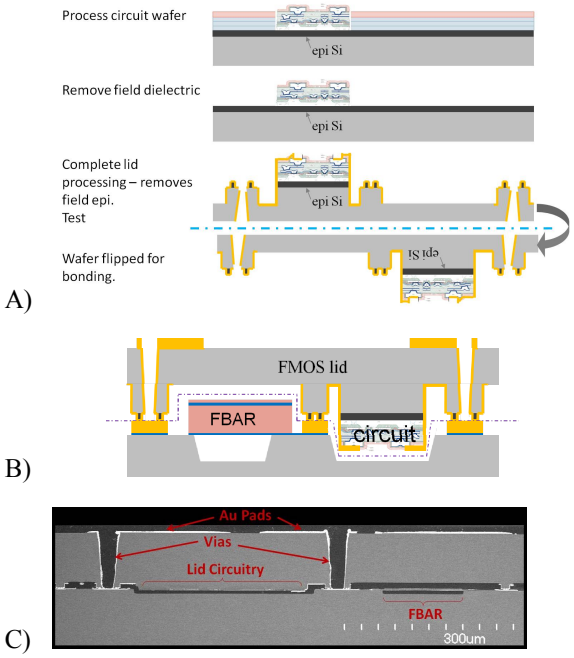

Figure 3. A) Schematic circuit lid flow, B) micro-capped oscillator die, C) cross-section SEM of FBAR/bipolar process showing completed die.

Figure 4A shows the Pierce oscillator and divider that are integrated into the lid. All bias circuitry is integrated and derived internally. The oscillator and bias consume 150µA from a 2V supply. Emitter/Base diode varactors are used for tuning, and a temperature-sensing diode is included for on-die temperature monitoring. The oscillator is AC-coupled to an on-chip divide-by-64 circuit comprising six cascaded stages of divide-by-two bipolar current mode logic (CML). The oscillators operate at 1.5 GHz, yielding a divided clock source of 23.4 MHz. Each divide-by-two circuit includes two cross-coupled D-latches, with the clock input of each latch driven by a level shifter to set the proper DC bias of the input transistors. The maximum operating frequency of the divider-by-two circuit is a function of the D-latch delay and level-shifter delay. The bias currents of the latch and of the level shifter are set accordingly. Because each stage works at half the frequency of the previous one, the bias current of subsequent stages are scaled to reduce power consumption without degrading maximum operating frequency.

A fully-differential Colpitts oscillator was also designed and fabricated in this process. Figure 4B shows the simplified schematic. The Colpitts oscillator has superior cyclostationary noise properties and is thus a good candidate for low jitter reference clocks. However, the Colpitts oscillator requires a higher initial loop gain for oscillator startup. We utilize a gm-boosting technique to reduce power consumption by improving the oscillator startup characteristic. As shown in

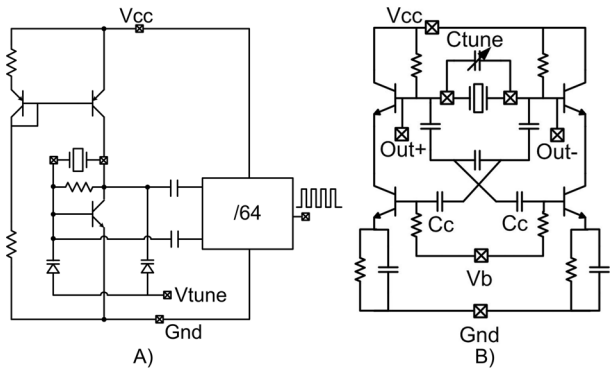

Figure 4. A) Schematic of Pierce oscillator with divider. B) Differential Colpitts oscillator with gm-boosting

Figure 4B, the FBAR resonator is connected between the bases of the top transistor pair. The center point of the FBAR resonator can be viewed as a virtual ground. Differential operation is sustained when the two sides oscillate at opposite phases. By cross-coupling the oscillator output and AC-coupling the signals to the base of the foot transistor pair, the effective loop gain of the oscillator is increased to reduce the bias current requirement. Frequency-dependent emitter degeneration is used to suppress a parasitic mode of oscillation that is not present in typical LC versions of this topology. The differential architecture minimizes common-mode noise introduced power supply and substrate coupling, and thus can further reduce the overall phase noise of the oscillator.

IV. Experimental Results

A. Oscillator Performance

Figure 5 shows the measured transient waveforms from the oscillator at the RF carrier and the divided output. The measured oscillator phase noise at the 1.5 GHz carrier is -118 dBc/Hz @ 100 kHz offset. Although we typically achieve quality factors (Q) of over 2000 for temperature compensated resonators [8], our first devices had a fixable design error limiting the Q of these devices to about 500 to 800. The differential Colpitts oscillator consumes 300µA from a 1.8V supply and provides a phase noise of -124 dBc/Hz @ 100 kHz offset.

These chips integrate temperature compensated FBARs (zero drift resonators, or ZDR) which remove the linear temperature drift around a fixed turn-over temperature (TOT), yielding a residual 2nd order temperature dependence on the order of -15 ppb/˚C^2. The ZDR in these devices have a TOT of approximately -120˚C, which will be moved to 50˚C in subsequent runs. To improve oscillator temperature stability to below 100ppm (over a 100˚C temperature range), a feedback loop measuring temperature is necessary. The on-die temp sensing diode provides a nearly instantaneous read-out of the temperature that closely matches the FBAR temperature. Fig. 6 shows the temperature and frequency as measured by the integrated diode thermometer and a reference sensor placed 10 mm away from the oscillator. A 2W resistive heater on the board was activated for roughly 1 minute to simulate a PA or other heat source. Clearly, the integrated diode will greatly shorten the feedback cycle time and improve temperature compensation accuracy. To test the aging of the wafer-scale packaged resonator, the oscillator frequency shift was measured after 168 hours at 125˚C and again after 336 hours at 125˚C. Less than 1ppm of frequency drift was observed.

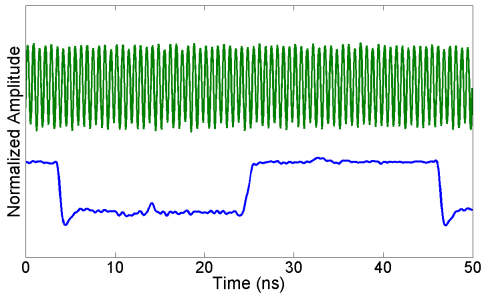

Figure 5. Measured signal at 1.5 GHz RF output (top) and 23.4 MHz divide-by-64 output (bottom)

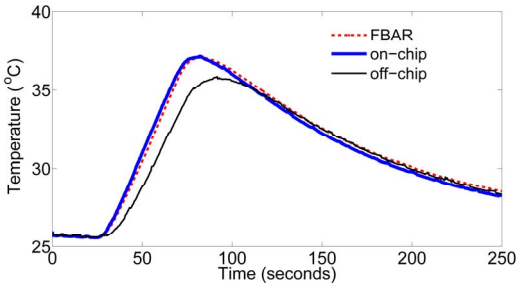

Figure 6. Measured temperature response as measured by the ZDR frequency response, an integrated diode thermometer, and a reference diode placed 10 mm away from the oscillator.

The on-die varactor is used to pull the resonant frequency of the oscillator to compensate for temperature drift as well as any frequency variation due to processing uncertainty. Figure 7 shows the measured pulling range of the oscillator using the integrated varactor (+/- 500 ppm).

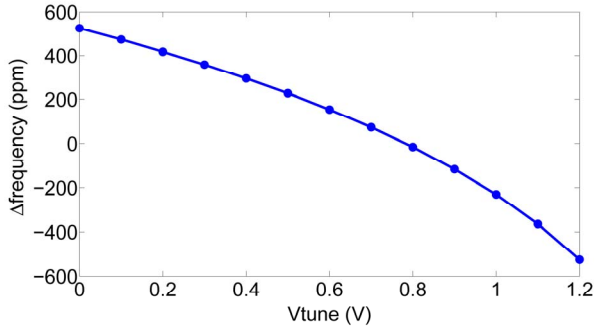

Figure 7. Measured tuning curve of FBAR oscillator.

We used bipolar devices in our first demonstration of this process for three reasons. First, this process has a higher f_T than comparable legacy inexpensive CMOS processes. Secondly, the lower 1/f noise of BJTs provides a significant improvement (6-8dB) in close-in phase noise. Finally, the gm/I_d ratio is 2-3x higher than a MOSFET biased for high f_T.

The properties of this bipolar process thus complement the CMOS circuitry of any accompanying chip.

Different applications of this technology will lead to different optimal partitioning. For example, a high-performance PLL could use the FBAR/bipolar chip as a low noise VCO while the digital functionality were integrated onto a separate CMOS chip. Table 1 is a performance summary of both oscillators implemented in this process. Figure 8 shows the measured phase noise profile of both oscillators.

TABLE I. TABLE 1. DESIGN AND PERFORMANCE SUMMARY

	Pierce	Differential	ISSCC '06 [3]
Integrated FBAR	Yes	Yes	Yes
Hermetic	Yes	Yes	No
Freq (GHz)	1.5	1.5	5.4
Icc (µA)	150	300	1700
Vcc (V)	2.0	1.8	2.7
Tempco (ppm) (0-80˚C)	+/- 200	+/- 200	> +/- 1000*
L(100 Hz) dBc/Hz	-49	-51	-33
L(1 kHz) dBc/Hz	-76	-80	-63
L(10 kHz) dBc/Hz	-98	-104	-93
L(100 kHz) dBc/Hz	-118	-124	-118
*Based on theoretical uncompensated BAW tempco of ~-27ppm/˚C			

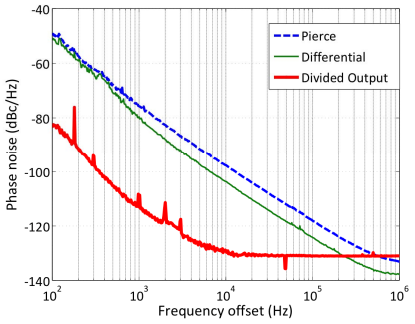

Figure 8. Phase noise of both oscillators measured with an Agilent 5052 signal source analyzer. The 1/f corner for the Pierce is 800 Hz, while the Differential Colpitts is 3 kHz. The phase noise of the ÷64 output is also shown, indicating a 20·log(64) improvement in phase noise. The phase noise floor at 10kHz is the instrument noise floor of the divided output due to a low output signal level. This is not a fundamental limitation.

B. Wafer-level Test

One key benefit of the wafer-scale packaging, as opposed to 2-chip, approach to making FBAR oscillators is the ability to perform wafer-level testing on completed oscillators. Resonator frequency testing with a network analyzer is limited to 5-10 ppm accuracy due to limitations of the measurement and even to parasitic inductance introduced by small variations in probe placement. Oscillator testing reproducibility is <0.2 ppm in initial testing, making it suitable for evaluation of aging effects as well as die screening. Figure 9 shows a map of one of the first wafers made, with the functional ÷64 (23.4 MHz) die shown in green.

V. CONCLUSIONS

We have presented the first circuits implemented in a new single-chip FBAR/Bipolar process. An ultra-low power

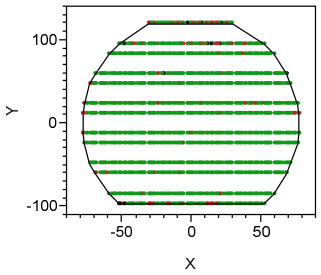

Figure 9. Wafer map showing functional oscillators (in green) from one of the first chip-scale packaged oscillator wafers.

150 µA Pierce oscillator was realized, which achieves a phase noise of -118 dBc/Hz at 100kHz offset. A low noise differential Colpitts oscillator was also implemented, achieving a phase noise of -124 dBc/Hz at 100kHz. The single-chip hermetic package contains all necessary components for a miniaturized frequency reference, including oscillator, high Q resonator, dividers, temperature sensing diode, and frequency tuning varactor.

ACKNOWLEDGMENT

We would like to thank Duane Fasen, Andy Weilert for integrating all of our design rules into reticle services, Mark Dumke and Mark Urfer for their support on the bipolar process, the management team of the Wireless Semiconductor Division of Avago, and Julie Hu for layout/testing assistance.

Abstract— **A low phase noise, 5 MHz, quartz BAW oscillator has been developed for space applications. Considerable effort has been made to optimize the quartz resonator design used in this oscillator. Both SC and LD resonator cuts have been studied. Although promising results have been achieved with LD cut resonators, the best results have been achieved with 5 MHz, fifth overtone, SC cut resonators. Single sideband phase noise of -133/f ^{3} dBC/Hz for offsets from 0.1 to 2 Hz (equivalent to $\sigma_y(\tau)$ = 7E-14, for τ = 1 sec) has been achieved. This performance is within a factor of two of what is generally accepted as the theoretical phase noise limit for BAW quartz oscillators at this frequency. Details of resonator design, and circuitry are discussed, and phase noise data are presented. Although the results presented have been achieved using commercial electronic parts in the oscillator, the fundamental oscillator architecture is such that it can be implemented using readily available space qualified parts.**

I. INTRODUCTION

The work described here is inspired by a desire to push the envelope of short term frequency stability performance of precision quartz oscillators; with an ultimate goal of implementing this improved performance in quartz oscillators designed for space applications. In order for any results of this effort to be applicable to space applications, it is in general necessary that:

1. All circuit components must be capable of meeting space quality and reliability guidelines (e.g. hermetically sealed packages, space radiation tolerant, etc.)
2. Oscillator and all components must be capable of surviving launch vibration and shock environments

Specific space applications typically impose additional design constraints, however, it is not the purpose of the work described here to meet specific space program requirements, but rather to develop oscillator capability which does not involve any circuit components or mechanical structures which would preclude use in space applications.

With these constraints in mind, the focus of this effort is improvement of short term frequency stability, as defined by the Allan deviation, for averaging times of 0.1 to 100 seconds. Based on the material properties of quartz, the best performance in this domain is expected from oscillators utilizing quartz resonators with the lowest feasible resonant frequency, f_0, since $S_\varphi(f) \propto f_0^4$ ($\sigma_y(\tau) \propto f_0$) [1], [2], [3]. In practice, 5 MHz is the lowest feasible frequency, because lower frequency resonators which can meet the above criteria for space applications are difficult to manufacture. For this reason, the work described here focuses on 5 MHz quartz oscillators and resonators.

More specifically, this work has focused primarily on oscillators using SC cut quartz resonators, given the proven track record and many advantages of such resonators [4]. Accordingly, most of the results shown below are for oscillators employing SC-cut resonators. Recent work, however, has suggested some potential advantage to LD-cut, or Low isochronism Defect, quartz resonators. These resonators are in the same doubly rotated family as the SC cut, but with a somewhat larger φ angle, shown to result in a minimum sensitivity to resonator drive current (amplitude-frequency effect) [5], [6], [7]. Therefore some preliminary effort has been devoted to investigation of oscillators using LD-cut quartz resonators, the results of which are reported below.

For well designed oscillators at this frequency, the quartz resonator in general determines the output noise, and hence the frequency stability. Therefore, this effort has focused mainly on the design of the quartz resonator. Some effort is required to insure that the noise of the sustaining amplifier can be maintained below the level at which it contributes to the oscillator noise within the resonator bandwidth, but the primary effort is to improve the resonator noise performance.

One of the impediments to progress in this arena is the relatively long time required to make meaningful measurements. The introduction of the SC-cut actually improved this situation, since it requires considerably less warm-up/stabilization than comparable performing AT-cut resonators. Nonetheless, given the necessity of tight oven

978-1-61284-110-6/11/$26.00 ©2011 IEEE

control, stabilization times of several hours to several days are required to get meaningful results regarding the underlying performance of these devices out to 100 seconds averaging time. The authors have found that it is generally most efficient to gauge performance of such devices by measuring the phase noise at 1 Hz offset, with attention to the slope of the phase noise vs offset frequency plot.

The frequency stability of the best 5 MHz quartz oscillators, for averaging times of 0.1 to 100 seconds, is determined almost exclusively by 1/f *frequency* noise [3]. This being the case, the *phase* noise is proportional to $1/f^3$, and is related to the Allan deviation, $\sigma_y(\tau)$ (which is independent of averaging time for 1/f *frequency* noise), by [8]:

$$S_\varphi(\mathrm{f}) = \frac{(f_0)^2}{2\,\mathrm{Ln}(2) f^3}\sigma_y^2(\tau\ = 1\ \mathrm{sec}). \qquad (1.)$$

Thus a phase noise plot exhibiting a slope of $1/f^3$ at an offset frequency of 1 Hz represents a fairly reliable indication of underlying performance capability throughout the $\tau = 0.1$ to 100 second range. Since equipment capable of measuring phase noise very efficiently now exists, it is possible in this way to obtain a good indication of oscillator performance in a matter of hours rather than days.

II. Oscillator Design

A block diagram of the basic oscillator used for these studies is shown in Figure 1. The device is designed to allow relatively easy access for removal/replacement of quartz resonators. It utilizes a double oven enclosure for the quartz resonator, with the oscillator circuitry contained within the outer oven. Although the device is not intended for use in space, care has been taken to utilize only oscillator circuit components which are generally acceptable for use in space applications. A photograph of the device is shown in Figure 2.

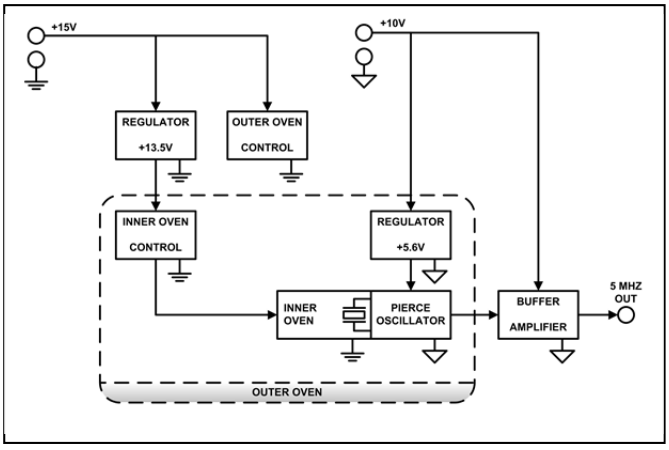

Figure 1. Block diagram of oscillator used for resonator tests

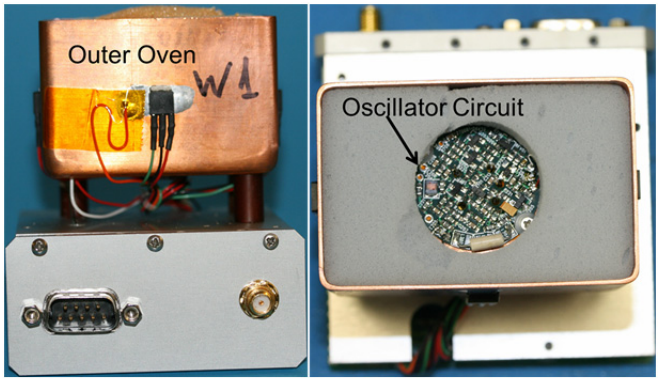

Figure 2. Oscillator used to test quartz resonators

III. SC-Cut Resonators

The work reported here has so far involved the testing of over one hundred 5 MHz, fifth overtone, SC-cut quartz resonators in oscillators like the one shown in Figure 2. These resonators have been made to a variety of specifications in which φ angle, contour, electrode diameter, and electrode metallization are varied as a means of optimizing performance. In order to draw meaningful conclusions from this work it is necessary to accumulate considerable statistics, as inevitably a number of un-controlled variables can obscure the real cause and effect associated with performance observations. This is an on-going effort, with initial results being reported here.

Although no definitive, simple recipe leading to improved noise performance has been identified to date, some useful preliminary conclusions are possible, and performance within 3 dB of what is generally considered to be the material limit of quartz has been observed in some resonators. The manufacturing yield for resonators with this level of performance is low, but reproducible.

A. Activity Dips – "Sweet Spot"

One working hypothesis at the start of this effort was that noise performance can be limited by the presence of activity dips, a problem more closely associated with AT-cut crystals. The idea is that at the oven set point temperature (typically the turn-over temperature or zero-slope of frequency vs. temperature) one or more competing modes may get partially excited in addition to the desired c-mode, and that this excitation is highly temperature dependent in comparison to the dominant c-mode [4]. It is postulated that it could be possible to improve the noise performance significantly in this case by offsetting the temperature slightly; thus strongly attenuating the competing temperature dependent modes, while affecting the dominant mode only slightly. In fact it has been suggested that "sweet spot" temperatures may exist at which the noise is dramatically improved over that observed at the presumed optimum (turn-over) temperature. In some cases it is indeed observed that SC-cut resonator series resistance shows significant variations near the turn-over temperature, and this could well be due to the presence of activity dips. The question is, in cases where little or no measured resistance variations near the operating temperature are observed, can performance be improved by slight changes

in oven operating temperature. Although documentation regarding this is sketchy, claims to this effect do exist, and therefore some effort was devoted to studying this idea.

Typical results are shown in Figure 3. , which shows phase noise at 1 Hz and 10 Hz offsets as a function of quartz resonator oven temperature, over a narrow window of 5°C around the turn-over temperature. Some small variations in phase noise are observed, but these are within the error bars of the measurement. This measurement has been repeated with a number of different resonators. In spite of concerted effort, no evidence of the existence of a "sweet spot" temperature has been found.

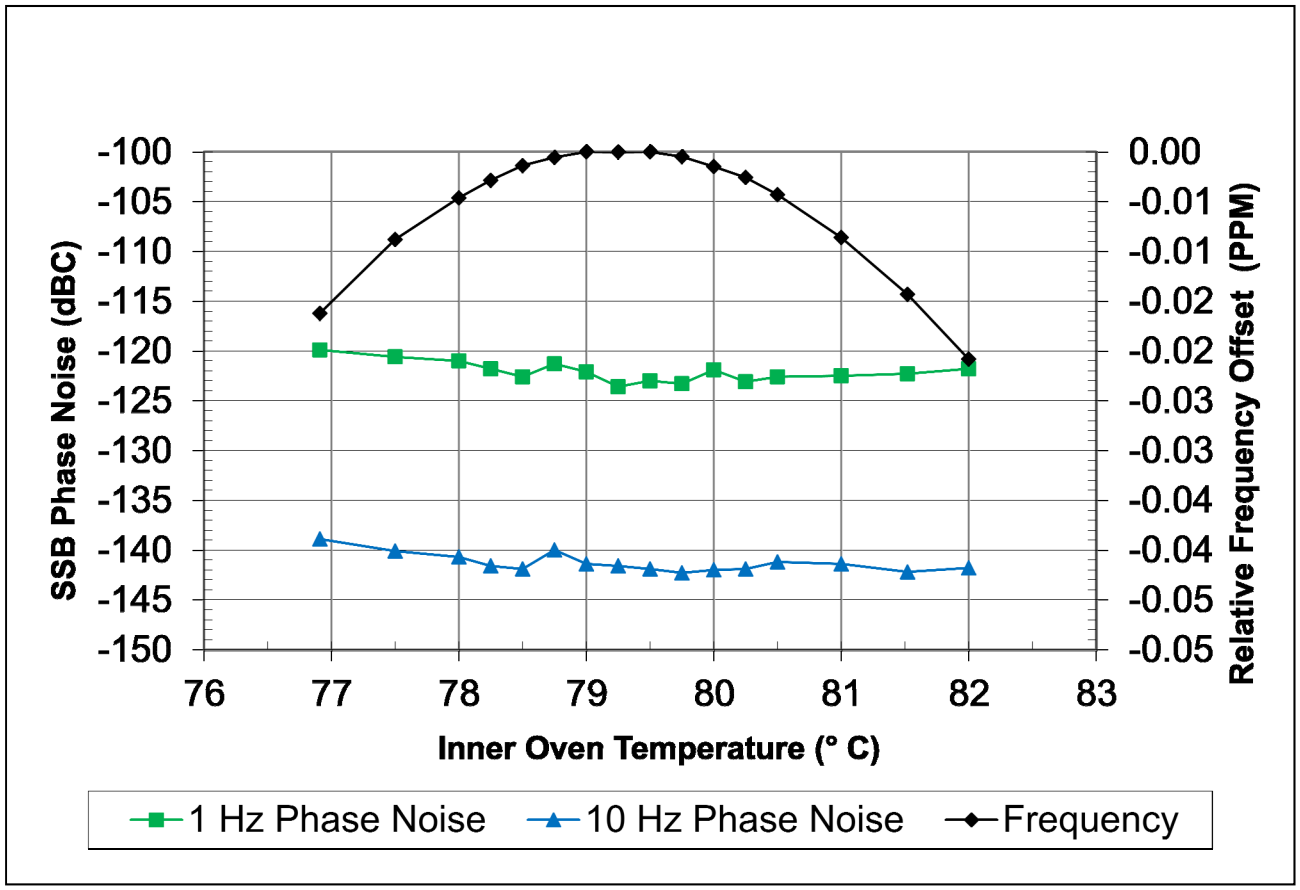

Figure 3. Single side band phase noise measured at 1 and 10 Hz offsets as a function of inner oven temperature near the resonator turn-over temperature

B. Edge Quality

The most consistent result to date has been the correlation between the visual quality of the quartz resonator edge (which is attached to the mounting structure) and noise performance. Those resonators which have edges relatively free from chips and scratches consistently outperform those with more noticeable edge defects.

This was first observed as a result of reprocessing various resonators. Reprocessing resonators is an excellent way to study the effects of different contours and electrode configurations, while keeping the quartz material involved constant. The influence of variations in crystal lattice defects and impurities on the measured noise characteristics is thereby reduced or eliminated.

The critical observation was that with a large number of reprocessed resonators, re-made with a variety of different electrode materials, diameters, and thicknesses, and different contours, including some resonators which were re-made with identical design to their previous configuration; uniformly worse noise performance was observed after reprocessing. A post-mortem of these devices showed that one consistent result was that the quality of the resonator edges had been degraded during the reprocessing activity.

As a result of this observation, resonators were fabricated with greater attention to the quality of the resonator edges. This yielded consistently better performing resonators, largely independent of other variables. Phase noise results from three such resonators are shown in Figure 4. In preparing the figure, pair-wise measurements were made, one comparing each resonator to each of the other two. The results were used to

perform a three-cornered hat calculation of the individual noise contributions from each resonator. The results of this calculation are displayed in Figure 4.

It is evident from the figure that the phase noise of all three resonators is well described by a $1/f^3$ function between 0.1 and 2 Hz; the best measuring -133 dBC/Hz at an offset of f = 1 Hz. From (1), this corresponds to:

$$\sigma_y(\tau) = 7.4 \times 10^{-14} \quad (2.)$$

This is within 3 dB of what is generally presumed to be the material limit for quartz [1], [2], [3].

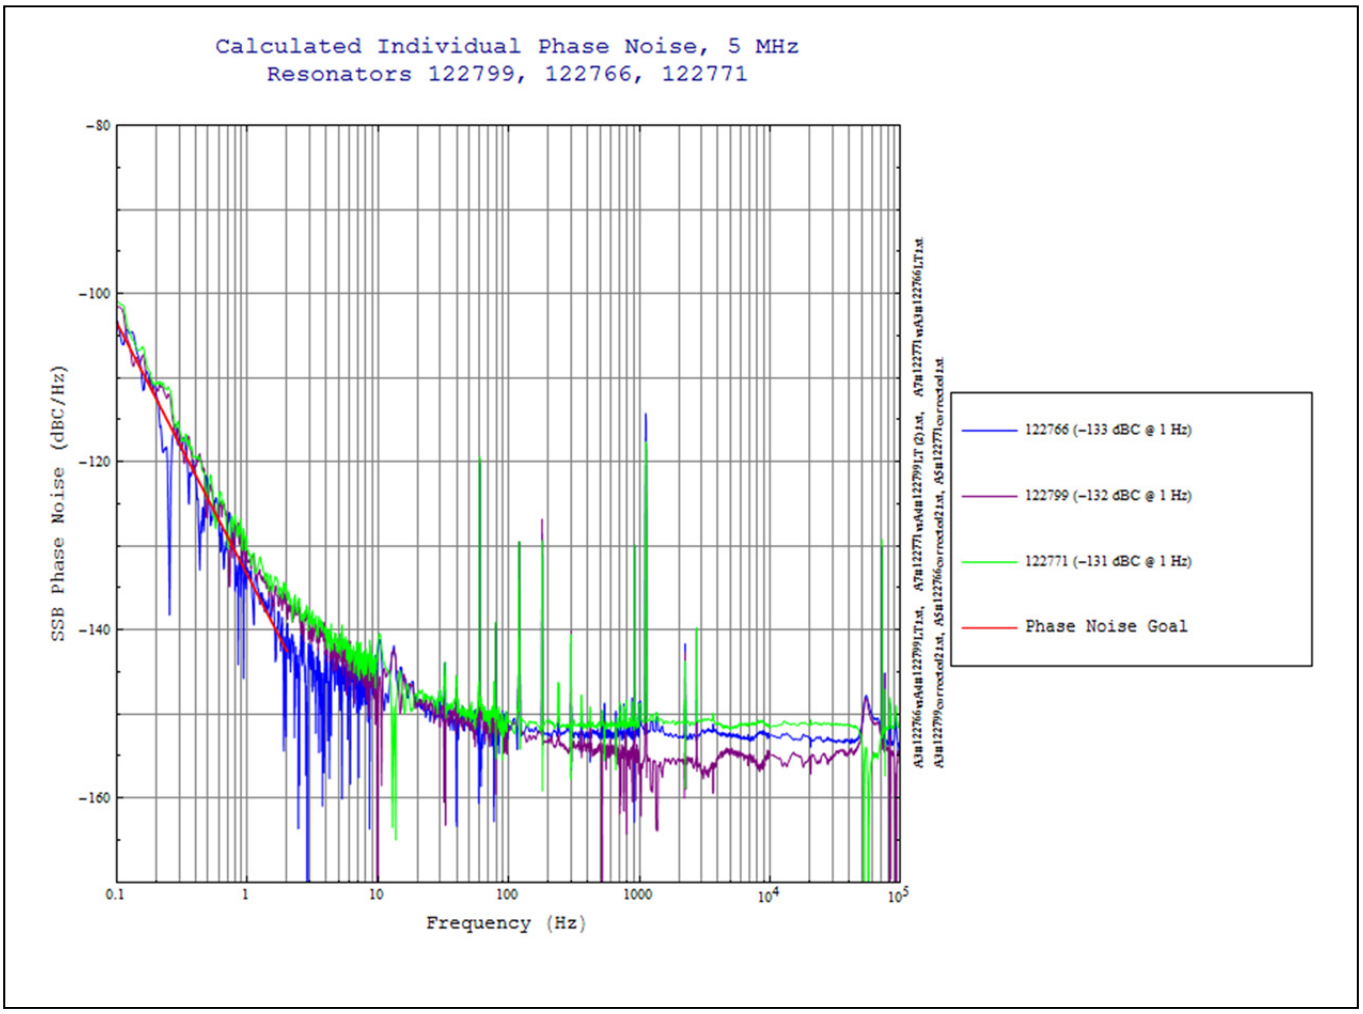

Figure 4. Single sideband phase noise calculated from individual measurements of three 5 MHz, fifth overtone, SC-cut quartz resonators. Displayed results are based on a three-cornered hat calculation of the individual noise contributions of each resonator, derived from pair-wise measurements.

IV. LD-CUT RESONATORS

The noise performance of quartz oscillators *outside* the bandwidth of the resonator is generally determined by thermal noise in the circuit elements [3]. This determines the white noise floor, for large offset frequencies, in the phase noise response. This noise can be reduced by increasing the power, or drive level in the oscillator. Unfortunately, this has the undesired effect of increasing the phase noise inside the resonator bandwidth because of the amplitude-frequency effect. This effect is the observed tendency of the frequency vs power function to exhibit an increasingly steep positive slope as power is increased. The result is that AM (white) noise in the oscillator circuit is converted into PM noise inside the resonator bandwidth.

It was discovered several years ago that for doubly rotated quartz resonators, the slope of the amplitude-frequency effect, as a function of φ angle, changes sign at approximately φ = 27° [5]. Therefore it is expected that resonators manufactured at this angle would not suffer from the undesirable effects described above when driven at higher power levels.

This comes at a price, however, since the stress compensation condition of the SC-cut (φ = 21.95°) is no longer met, and in addition the inflection temperature is increased from ~90°C for the SC cut to ~150°C. Operation

near 150°C is undesirable because the failure rates for semiconductor devices are much higher than for operation near 90°C. LD resonators can easily be manufactured with turn-over temperatures ~90°C, however, because this is further from the inflection temperature, the slope of frequency vs. temperature changes much more rapidly in the vicinity of this temperature than for an SC-cut resonator with the same turn-over temperature [6]. Therefore, oscillators using LD-cut resonators must maintain better temperature control than comparable oscillators using SC-cut resonators.

Nonetheless, the potential for eliminating the undesirable effects of the resonator sensitivity to drive level is worth investigating. To this end, a number of resonators with φ angles in the vicinity of the LD-cut have been manufactured and tested in oscillators. In Figure 5, the amplitude-frequency effect is plotted for several of these resonators, with a typical SC-cut resonator shown for comparison. Although these "LD-cut" resonators do not exhibit zero slope, they clearly exhibit reduced slope compared to SC-cut resonators.

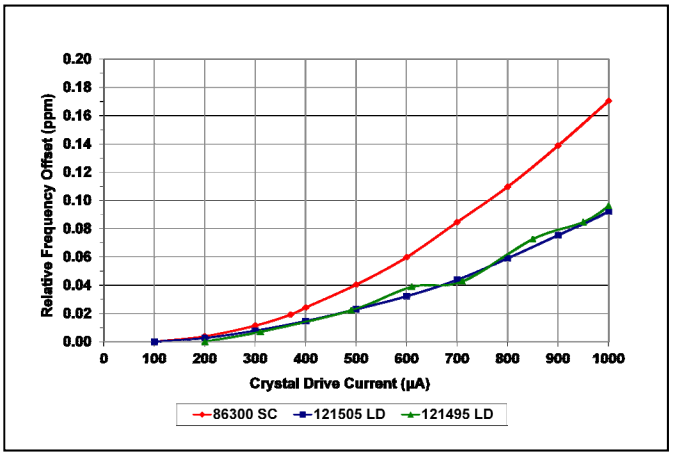

Figure 5. Amplitude-Frequency effect for SC-cut and LD-cut resonators. Slope for LD-cut resonators is significantly less than for SC-cut resonators.

In Figure 6, the phase noise at 1 Hz and 10 kHz offsets are plotted for one of these resonators as a function of resonator drive level. As expected, the noise floor, indicated by the phase noise at 10 kHz offset, improves at higher drive levels. Yet the close in phase noise, indicated by the phase noise at 1 Hz offset, is not appreciably degraded at these higher drive levels. This is the sought after reduction of the amplitude-frequency effect.

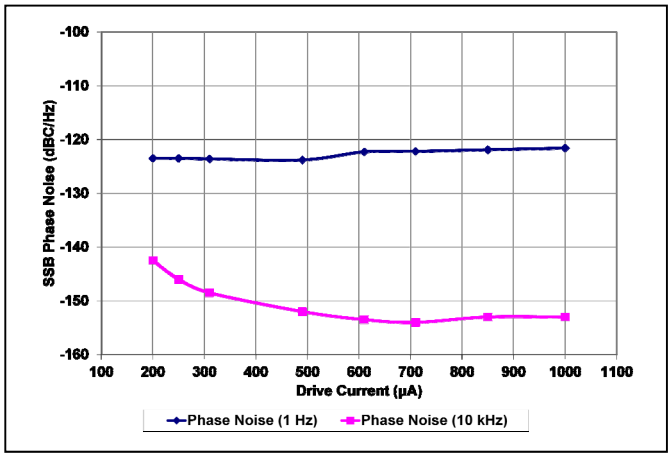

Figure 6. Phase Noise at 1 Hz and 10 kHz offsets as a function of drive current for an LD-cut resonator.

V. SUMMARY

An on-going effort, targeted at satellite applications, to improve frequency stability performance of precision 5 MHz quartz oscillators has been described. This effort has focused on the quartz resonator as the main performance limiting factor. Performance within 3 dB of the theoretical material limit of quartz has been obtained with several SC-cut resonators, where particular attention was paid to the quality of the resonator edges.

Preliminary attempts have also been made to manufacture and test LD-cut resonators. The results of these preliminary tests are promising, but further work is necessary in order to optimize the trade-off between stress compensation, temperature sensitivity, and frequency dependence on drive current.

Abstract— **The Whispering Gallery Mode Maser Oscillator (WHIGMO) uses paramagnetic Fe^{3+} ions in HEMEX sapphire at low temperature, and has been described in many previous publications [1-7]. The fractional frequency instability has been demonstrated to be as low as $\sigma_y(1s<\tau<100s) = 10^{-14}$. This instability is normally measured at the frequency-temperature turnover point of the sapphire where the effects of temperature fluctuations on frequency are nullified to first order [8-9]. Usually the temperature is determined by the relative concentrations of several paramagnetic ions such as Cr^{3+}, Mo^{3+}, and Ti^{3+}. In this paper, we show that Fe^{3+} ions have a strong effect on the turnover point. We compare the behavior of two crystals – "Pinocchio" (concentration of active Fe^{3+} ions = 10ppb) and "Geppetto" (100ppb). We also report the observation of an upper limit for maser operation above 30K. This limit is explained using a Boltzmann distribution for the active ion, and we show that the populations of the energy levels are so close at this temperature that the effect of the pump at 31 GHz used to create the maser at 12 GHz is ineffective.**

I. INTRODUCTION

To build an ultra-stable oscillator in the X-band, it is desirable to use crystals with low loss and high *Q*-factor. The best material for this purpose is HEMEX grade sapphire, which demonstrates *Q*-factors of order 10^9 when cooled to 4.2 K. The resonant frequency of the Whispering Gallery mode of interest is fixed when operated at a particular temperature, the 'turnover point', where temperature dependent frequency fluctuations are cancelled to first order. Many publications describe the application of this self-compensation technique. [8-17], and all show that the turnover temperature is dependent on the presence and relative concentrations of paramagnetic ions such as Cr^{3+} with an Electron Spin Resonance (ESR) at 11.4 GHz, Mo^{3+} (100 GHz) and Ti^{3+} (1 THz). The ions are substitutionally included in the crystal lattice and for purest sapphire result from the crystal growing process and occur unintentionally. We show in this paper how we can control the temperature annulment point of the Fe^{3+}-WHIGMO by manipulating the amount of ions involved in the maser process.

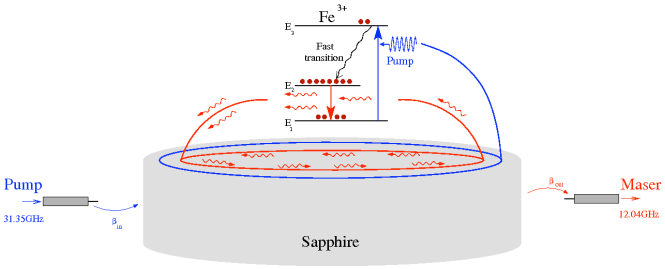

Figure 1. Principle of operation: We apply a signal at 31.35 GHz, coinciding with a WG mode, to pump the ions from the lowest energy level |1/2> to the third |5/2>. The ions then (non-radiatively) relax to the second energy level |3/2>. A population inversion is obtained between the two lowest energy levels, and stimulated emission can be obtained at 12.04GHz, which is enhanced by another WG mode coincident in frequency.

II. MASER DESCRIPTION

The maser scheme is based on the three energy levels of the Fe^{3+} ions at zero applied DC magnetic field in a WG sapphire resonator (Figure 1). The concentration of ions used to create the effect is about 10-100ppb, whereas the total concentration is on the order of 1ppm. The bandwidth of the

karim.benmessai@uwa.edu.au

ESR is $\Delta\nu_{Fe^{3+}} \approx 100$MHz, where the WG mode width is only $\Delta\nu_{WG} \approx 10$Hz at 4.2K.

The maser signal frequency ν_{op} is fixed at the frequency ν_{WG} of the WG mode involved in the process. It's well known that the frequency ν_{WG} is strongly sensitive to temperature variations and needs to be precisely controlled. In this kind of resonator, ν_{WG} possesses a temperature turnover point above 4.2 K. The frequency variations can be described by [8]:

$$\frac{\nu_{WG} - \nu_0}{\nu_0} = AT^4 + C(\mathrm{T}) \qquad (1)$$

where ν_0 is the mode frequency at 0 K without ions, and AT^4 is the thermal sensitivity due to the sapphire dilation ($A \approx 10^{-12}\mathrm{K}^{-4}$ for our modes). The other term $C(\mathrm{T})$ is thermal sensitivity due to the paramagnetic ions and is defined by (2):

$$C(\mathrm{T}) = \frac{1}{2}\sum_i \eta_i(\nu)\chi_0 \frac{\left(2\pi\tau_2^{(i)}\right)^2 \nu_i(\nu_i - \nu)}{1 + \left(2\pi\tau_2^{(i)}\right)^2 (\nu_i - \nu)^2} \qquad (2)$$

where η is the magnetic filling factor of the mode describing its magnetic field distribution compared to paramagnetic ions in the crystal, and χ_0 is the DC magnetic susceptibility of the ion.

III. Measurements

To characterize the maser signal we amplify it first (30dB) and then compare it to a signal from a synthesizer referenced to a hydrogen maser. The beat note is then amplified and band pass filtered before being counted (Figure 2). The accuracy of the temperature control at resonator cavity is about 2 mK.

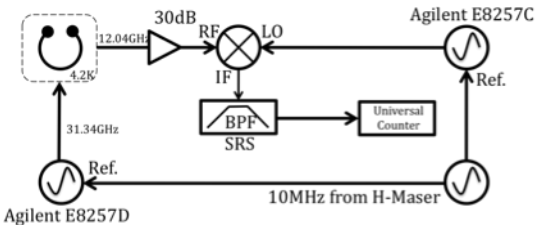

Figure 2. Experimental setup: The crystal is a cylindrical HEMEX sapphire, 30mm height and 50mm diameter, placed in a cylindrical cavity and cooled to 4.2K using a cryocooler .

A. "Pinocchio" behaviour

The maser signal characterized in this section is oscillating at the $WGH_{17,0,0}$ mode frequency of 12.038 GHz, and can be excited using a pump signal corresponding to any of several WG modes around 31.3 GHz. The frequency of the WG mode which enhances the maser signal is measured with a network analyzer and shows a turn over temperature T_{inv} around 7.8 K, with no dependence on the input power level applied to the crystal.

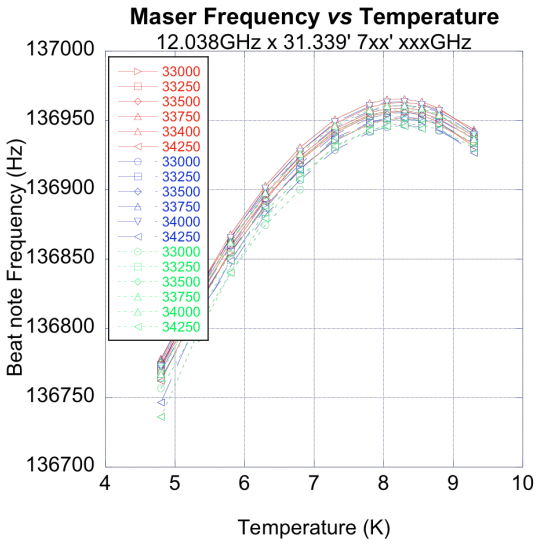

Figure 3. Evolution of the maser frequency (for "Pinocchio") at 12.037 GHz with temperature for different pump power levels. The turnover temperature stays constant around 8.3K The red curves are for a pum power at 17dBm, the blue at 16dBm and the green at 15dBm.

We vary the frequency of the pump signal used in the process, and observe the evolution of the maser frequency with temperature. For each pump we change its frequency in steps of 250 Hz and at varying power levels. As Figure 3 shows, T_{inv} is completely independent of the input power level, and the value of the pump frequency T_{inv} stays sensitively around 8.3K.

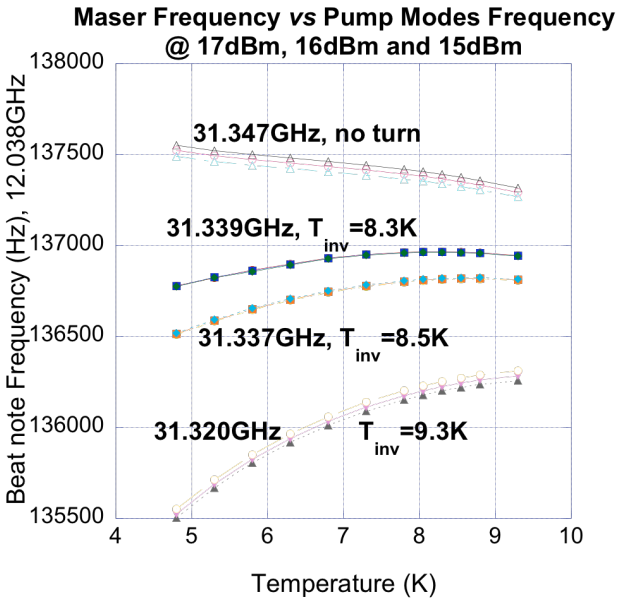

Figure 4. Evolution of the maser signal frequency with temperature for different pumps at 31.3xxGHz and different input power levels

Despite the fact that T_{inv} is independent of the input power and frequency of the pump signal (for a particular choice of pump mode), its value does change when a different pump WG mode is selected, as shown in Figure 3. The turnover point is inversely proportional to the pump frequency in the range 31.320–31.339 GHz. No turnover point is observed at higher frequencies. Note that for each pump mode, T_{inv} stays independent of power. The turnover point can be calculated for each pump by a simple second order polynomial equation.

B. "Geppetto" behaviour

For the second crystal, the maser operation is different. The concentration of the active ion is higher, resulting in a higher maser output power of –40dBm, compared to –56dBm for *Pinnochio*. In addition, maser signals are observed not only at the $WGH_{17,0,0}$ frequency, but also at different modes at frequencies within the ESR bandwidth[6]. Like *Pinnochio*, all the pump modes for which a maser signal can be excited in *Geppetto* have a temperature turnover point independent of the applied power.

Characterizing the turnover point for this crystal reveals more complex effects than *Pinocchio*. Figure 5 shows the signal at 12.037 GHz oscillating for a pump applied at 31.349 GHz. It represents the maser frequency dependence for pump frequencies in the range 31.349,782,015 – 31.349,782,715 GHz in steps of 100 Hz. Here, the maser frequency shows a strong dependence on the pump tuning. We note that when the frequency is in the range 31.349,782,115 – 31.349,782,315 GHz, there are three T_{inv} – one near 6 K, the second around 8 K and the third at approximately 10.5 K. For the range 31.349,782,415 – 31.349,782,715 GHz, there is only one T_{inv} around 8 K and the system behaves in the same classical fashion as the first crystal.

The behaviour of another maser signal oscillating simultaneously at 12.014 GHz when pumped at 31.310 GHz is shown in Figure 6. We again observe a strong dependence of T_{inv} on the pump frequency. When the pump frequency is swept in the range 31.310,667,885 – 31.310,678,485 GHz, we see T_{inv} moving from 9K to 8.7K and subsequently disappearing. The maser frequency also shows that more than one T_{inv} exists depending on the frequency tuning of the pump. For example, at 31.310,677,985 GHz the maser has two turnover points (T_{inv1} = 9 K, T_{inv2} = 11 K), at 31.310,678,185 GHz it has three (T_{inv1} = 8.7 K, T_{inv2} = 10.1 K and T_{inv3} = 11 K), and at 31.310,678,285 GHz there is no T_{inv} observed at all.

The temperature turnover point depends on the distribution of the ions and the population difference between their energy levels. When we measure T_{inv} for the $WGH_{17,0,0}$ mode using a network analyzer, no change is seen due to the small population difference at this frequency (5% of the total active population). However, when the maser is operating, i.e. being pumped, the configuration of the ions is completely different: population inversion exists between the |1/2> and |3/2> levels, and saturation is seen at 31 GHz where the population of the states |1/2> and |5/2> are equal. The population inversion rate is determined by the choice of pump mode near 31 GHz. For each pump, we can have strong or weak maser signal depending on its coupling and spatial field distribution in the crystal. Strong coupling allows an optimum exchange of energy with the ions, and field distributions occupying more volume in the crystal increase the interactions with different classes of ions. Considering the inhomogeneous broadening of the line at 31 GHz in addition to these factors, we can understand why T_{inv} is different from one pump to another. The Fe^{3+} spins act as individual packets selected by the pump WG mode corresponding to the applied pump signal. The pump signal selects a different quantity of ions depending on their ESR frequency.

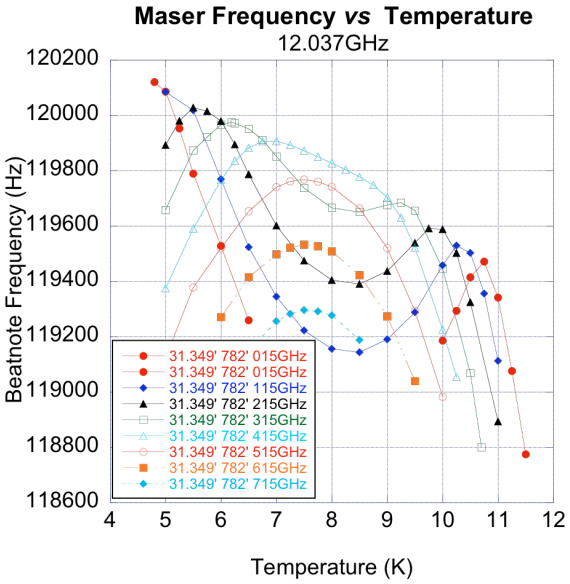

Figure 5. Evolution of the maser signal frequency at 12.037GHz with temperature for different value of the same pump at 31.349GHz

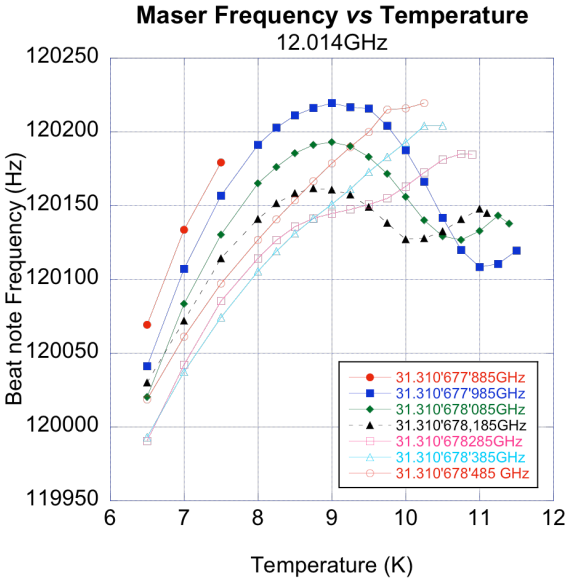

Figure 6. Evolution of the maser signal frequency at 12.014GHz with temperature for different value of the same pump at 31.310GHz

For *Geppetto* the case is more complex because T_{inv} is not only different from one pump to another for the same maser

signal, but is different for the same pump mode when the frequency is tuned. The maser frequency shows more than one temperature turnover point for some pump frequencies, and no inversion for others.

The characterization of the maser frequency with temperature was performed at a fixed pump frequency. However, the pump WG mode is temperature dependent as well as the WG modes near 12.04 GHz. To optimize the maser operation, it is necessary to tune the pump frequency for each operating temperature. This optimum frequency corresponds to maxima or minima of the maser frequency depending on the T_{inv} being measured. Figure 7 shows how the maser frequency varies with temperature for different pumps modes.

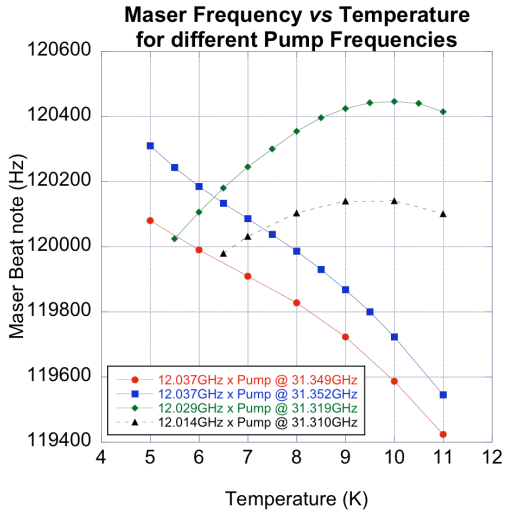

Figure 7. Evolution of the maser signal frequency with temperature for different pumps.

The signal at 12.14 GHz has a turnover point at 10K, the one at 12.029 GHz is at 10.3K, and the one at 12.037 GHz shows no turnover temperature at all. The measurements were performed at different power levels, which were found to have no effect on the turnover temperature.

IV. Maser Temperaure Operation Limit

In order to characterize the upper temperature limit for maser operation, we adjust the pump frequency for each measurement as per the last section. The dependence of the maser frequency is shown in Figure 8. The 12.037 GHz maser signal oscillates until 28 K when pumped at 31.349 GHz, and 30K when pumped at 31.352 GHz. The power of the maser signal is observed to decrease as the temperature is raised. This is due to the fact that, at thermal equilibrium, the populations of the Fe^{3+} energy levels follow a Boltzmann distribution. At higher temperatures, the difference in population between levels is reduced, resulting in less efficient masing.

At high temperature (20-30K) the number of ions pumped at 31.3 GHz is lower than at 4.2 K, leading to a smaller population inversion ratio. This directly affects the maser power and causes it to drop as temperature rises. In addition, the absorption at 31.3 GHz is a result of a mixing between the |1/2> and |5/2> ion states and occurs with very small probability [18-20]. The population difference at 31 GHz is high enough to create the maser signal with this probability at low temperatures (<30K), but not at high temperatures (>30K).

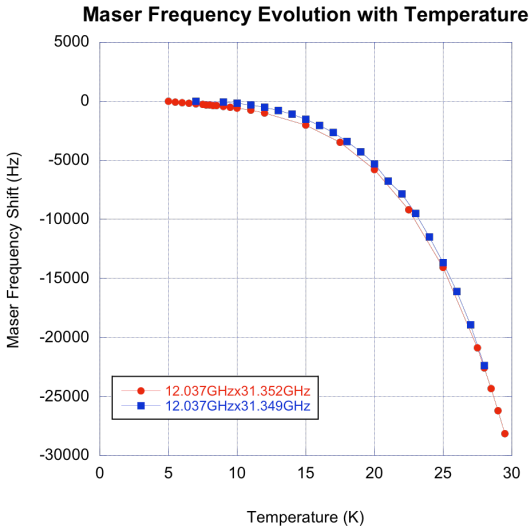

Figure 8. Evolution of the maser signal frequency with temperature for different pumps. The pump frequency is adjusted for each temperature in sort of having an extrema on the maser frequency.

At higher temperatures still, characterization of the WG modes around 12.04 GHz showed absorption effects up to 140 K. This strength of the absorption decreases when we increase the temperature. However no maser operation has been observed at these temperatures.

Conclusion

We have demonstrated how Fe^{3+} ions in a sapphire maser influence the frequency-temperature turnover point of the maser signal. We compared the behavior of two crystals, one with a low ionic concentration and the other with a high concentration. The first crystal showed classical behavior where T_{inv} is independent of the pump power and frequency, but was different between pump modes due to different packets of ions being accessed for each pump. The ions that create the maser are affecting a change in the intrinsic mode T_{inv}. The crystal with higher Fe^{3+} concentration showed a more complex behavior where T_{inv} was different not only from one pump mode to another, but showed many turnover points for some choices of pump, and in some cases none at all.

Abstract— On-board atomic clocks represent the key technology for the success of any satellite navigation system mission and their development has been continuously supported by ESA. The PHM (Passive Hydrogen Maser) has been selected as master clock of the Galileo Navigation Payload and the almost three years of continuous observation on board of GIOVE-B satellite have confirmed the outstanding performance in terms of frequency stability and negligible drift [1]. The results coming from ground life testing have given important feedbacks on the PHM technology capability to comply with the required 12 years of lifetime. The above was the starting point for the development of a Miniaturized PHM (mPHM) carried out in the frame of the ESA European GNSS Evolutions Programme. The main target was to preserve the excellent PHM frequency stability performance with reduction of the overall mass and instrument sensitivity to the environmental conditions (in particular to temperature). This paper presents an overview of the main results achieved by the design, manufacturing and testing of a MPHM elegant breadboard (EBB); the 30% of mass reduction already achieved on the Physic Package gives the concrete possibility to have a complete instrument with a mass of 12Kg.

I. INTRODUCTION

The PHM is the best performing on-board clock ever produced for the navigation market. However the constraints associated to its state of the art performances in terms of mass and power consumption, represent a critical point to be investigated and possibly reduced in order to meet the requirements for the next generation navigation systems. Over the last year, various innovative techniques and technologies, especially for the Physic Package (65% of the PHM mass), have been identified for significant improvement of mass, volume and power consumption without affecting electrical performance, in particular frequency stability. In the frame of the ESA European GNSS Evolution Programme, several modifications have been introduced, with benefits in terms of mass and volume. In addition to Physic Package miniaturization, also a considerable dc power saving has been achieved, considering that almost the 40% of the PHM power consumption is presently used for heating and thermal regulation of some critical parts (H2 pressure, microwave cavity assembly, RF sensitive sub-modules). In parallel some activities have been focused for correction and improvement of some performance of the PHM present design. The excellent frequency stability demanded to the passive hydrogen maser makes it very sensitive to environmental parameters, first of them temperature, which leads to very severe operating constraints. The reduction of such sensitivity would reduce also the constraints, leading to the simplification of the navigation payload thermal design.

II. PHYSIC PACKAGE MINIATURISATION DESCRIPTION

The actual design, as developed in the frame of Galileo Programme, was the starting point of the activities (Figure 1). The overall Physic Package (PP) performs the function of a very narrow-band microwave amplifier and frequency discriminator, featuring an extremely stable central frequency. Main items composing the PP are the Microwave Cavity and Shield Assembly (MCSA), that includes the storage bulb, the microwave cavity, its magnetic shielding and the thermal control devices. A low vacuum enclosure is built over the MCSA to simulate actual in space thermal exchange conditions. Other fundamental items are the Hydrogen Beam Assembly, that includes the hydrogen purifier, the dissociator bulb, the beam collimator and the state selector. The hydrogen supply is assumed by the HSA (Hydrogen Storage Assembly), that is composed by a solid-state hydrogen storage vessel, with relevant pressure and temperature devices. The high vacuum is assured by the ion pump and the getters.

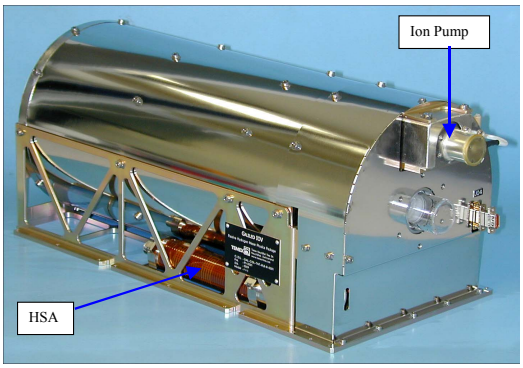

Figure 1. Galileo PHM Physic Package

The goal of the PHM improvement for the next Galileo generation was to reduce the mass by 30%, without affecting its frequency stability performance. As the core of the Physics Package, the microwave cavity is the key component for the mass, size and the electrical performance of the whole PP. The magnetron cavity structure has been maintained in order to preserve a correct distribution of the electric field. However several modifications have been simulated in order to achieve the best compromise between size reduction and quality factor.

The final solution has allowed a volume reduction of the cavity close to 30%; all structures enclosed the cavity such as magnetic shields, low vacuum chamber and mounting structure have been reduced by a similar ratio.

Other area of improvements have been explored and different solutions adopted. They can be resumed as following:

- Removal of the third thermal regulated stage
- Improvement of the magnetic field homogeneity
- Hydrogen tank thermal control simplification
- Getter high vacuum chamber redesign

The initial goal of 30% of mass reduction has been finally achieved (Figure 2), without affecting the storage bulb dimensions and hydrogen flux. This was, since the beginning, the necessary condition in order to minimize the risk of signal to noise ratio reduction. Of course degradation of the atomic gain quality factor was expected, as effect of the microwave cavity losses increasing. This has not been considered a limitation factor to achieve the frequency stability requirements, considering the margin existing in the PHM Physic Package and improvements planned on the RF receiver.

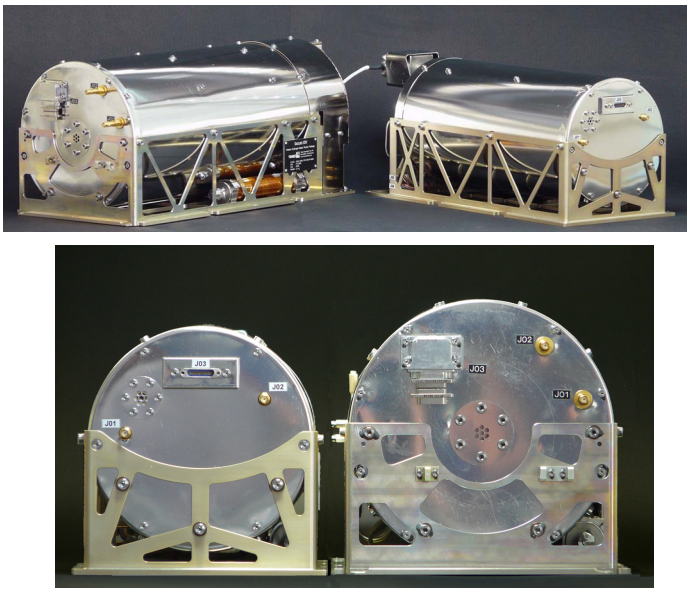

Figure 2. mPP vs PP comparison

III. ELECTRONIC PACKAGE

The LNA and Interrogation sub-module of the EP have been recognized as those with significant margin for improvement from an electrical standpoint and therefore to be submitted to an optimization activity, in the frame of the development phase. No mass reduction has been foreseen for the Elegant Bread Board (EBB) phase, since the electronic package gives a minor contribution to total mass. In addition it was preferred to proceed step by step, without modifying the electrical and mechanical interfaces with the PP.

Major objectives of the RF interrogation chain modification have been the following:

- Improvement of the phase modulation symmetry
- Reduction of the modulator thermal sensitivity
- Reduction of the phase noise contribution due to the multiplication chain (flicker PM in particular)

The first objective was related to the possibility to reduce the instrument atomic gain variation sensitivity. A parallel study has been carried out by KyTime in order to provide an assessment of this aspect. The outcomes have been translated into requirement specifications, which have been fully achieved with the adoption of a new design of the phase modulator.
Result of the redesign is a reduction of a factor 10 of instrument frequency sensitivity to the atomic gain variation.

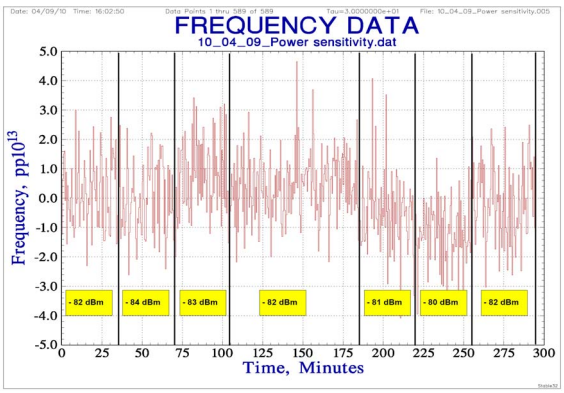

Figure 3. Frequency sensitivity to interrogation power with the new phase modulator

Figure 3 shows the results of a test giving the indirect verification of the sensitivity. The test consists in changing the power level of the interrogation signal, which simulates a variation of the atomic gain. The typical PHM sensitivity value is around $2*10^{-13}$/dB, now reduced to few parts per 10^{-14}.

The remaining two objectives (thermal sensitivity, phase noise) have been achieved reaching the reduction of a factor of 10 of the modulator thermal sensitivity ($<1*10^{-14}$/°C without temperature compensation) and improvement of more than 10 dB on the added phase noise.

Activity has been also devoted to the receiver noise figure (NF) improvement. Moreover matching technique has been adopted to have a tunable coupling between microwave cavity and RF receiver. The final result is the availability of an additional degree of freedom in order to obtain the best compromise between reduction of the white frequency noise (due to receiver NF) and minimization of the cavity pulling due to receiver load variation.

Finally a general review of the Electronics Package structure has been carried out for mass reduction and optimization/adaptation of the Hydrogen Dissociator Oscillator (HDO) housing to the new Mini PP interface. Tailoring of the current thermal control circuits to the new thermal interface requirements of the miniaturized physics package has been implemented as well.

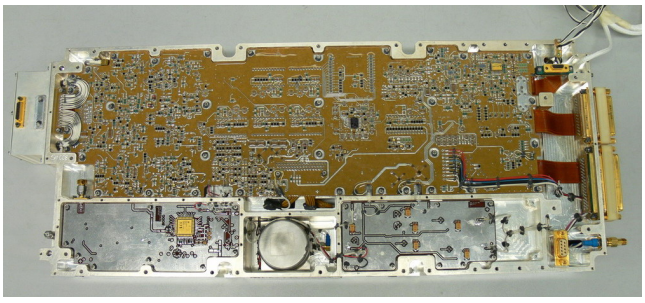

Figure 4. Main Electronic Module

IV. MPHM EBB INTEGRATION RESULTS

Both the Electronic Package (EP) and the Physic Package (PP) have been independently verified using reference PP and reference EP. This development philosophy has given sufficient degree of confidence that no issues were present before integration. The Programme objectives have been carefully verified by test.

A. REDUCTION OF TEMPERATURE SENSITIVITY

The EBB-MPHM thermal sensitivity has been verified in vacuum conditions applying several temperature transitions between +15°C and -5°C. Very low sensitivity to temperature variation has been observed, giving confirmation of the promising results obtained at EP and PP level. A detail of the instrument actual temperature sensitivity is provided in Figure 6.

The measured temperature coefficient is well below $1*10^{-14}$/°C, which is enough to comply with the Galileo Allan Deviation (ADEV) requirement, even considering a 20°C peak to peak temperature variation (refer to Figure 7).

Figure 5. Thermal Vacuum chamber

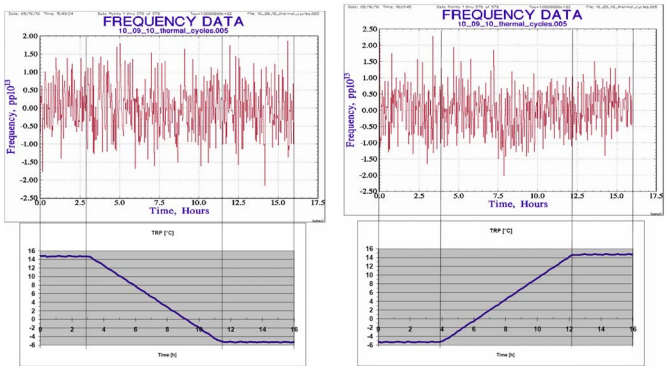

Figure 6. EBB-MPHM output frequency vs basplate temperature transition

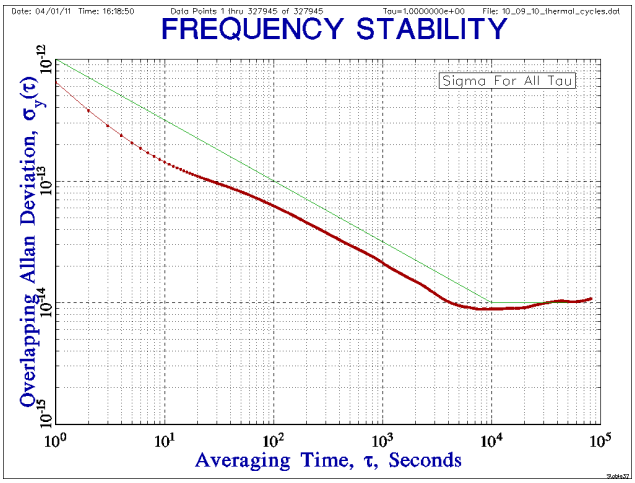

Figure 7. ADEV using frequency data during thermal cycle. In green the GALILEO requirement

B. FREQUENCY STABILITY PERFORMANCES

Measurements of frequency stability has been performed with a total duration of almost 1 month. The measured frequency drift is lower than $2*10^{-15}$/day. This value is perfectly in line with the typical PHM frequency drift [2] [3]. The measured frequency stability is reported in figure 8

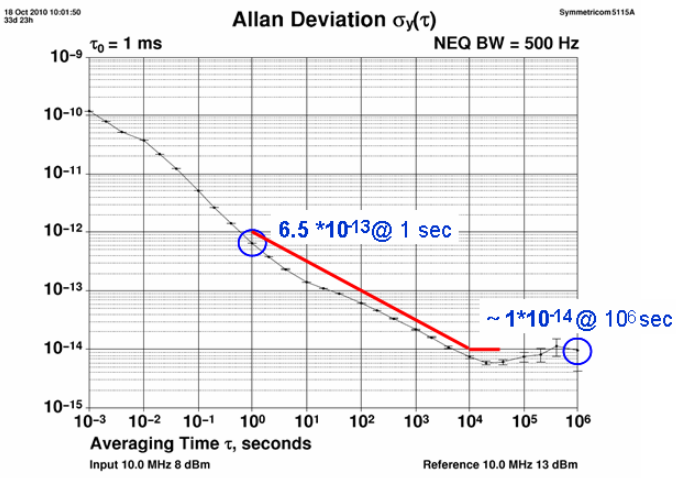

Figure 8. ADEV over 28 days of measurement. In red the GALILEO requirement.

It is worth noticing that the above measurement has been obtained after a few days of stabilization time and at the first attempt. The reduction of the added phase noise in the RF interrogation chain is noticeable from the good ADEV value achieved also at short term (i.e. $6.5*10^{-13}$ @ 1 sec). The long term measurement has given the opportunity to evaluate, from the EBB mPHM telemetry, the cavity drift. As expected the redesign of the microwave cavity and C-field coil has reduced the microwave cavity drift [2] by one order of magnitude with respect to the PHM typical cavity drift for the same observation time.

C. MASS AND POWER CONSUMPTION

The initial mass breakdown of the PHM is reported in the following table.

TABLE I. PHM MASS BREACKDOWN

Item	Mass (Kg)	Percentage
Electronic Package	6.2	33.33%
Physic Package	12.4	66.67%
Total	18.6	100%

The mass reduction achieved at PP level has reduced the relevant mass of 30%. The EBB mPHM resulting mass breakdown is detailed hereafter.

TABLE II. EBB MPHM MASS BREACKDOWN

Item	Mass (Kg)	Percentage
Electronic Package	6.2	43.42%
Physic Package	8.08	56.58%
Total	14.28	100%

The next step will be the reduction of the Electronic Package mass in order to achieve the target at instrument level of 12 Kg.

Power saving with respect to the PHM declared consumption has been obtained and further area of improvements have been identified.
10W power saving along the operating temperature range is expected starting from the actual measurements on the EBB mPHM.
The following table summarizes the expected improvements of the mPHM with respect to the PHM. Most of the parameters have been already verified on the EBB, providing a good degree of confidence on their feasibility.

TABLE III. PHM VS MPHM SUMMARY TABLE. IN GREEN THE IMPROVED PARAMETERS

	PHM	mPHM	Remark
Parameter			
Mass (Kg)	18.6	**12**	with mEP
Power Consumption (W)	64	**54**	@ 10°C
ADEV (sec)			
1	$1.8*10^{-12}$	**$6.5*10^{-13}$**	Measured on EBB
10	$3.2*10^{-13}$	**$1.4*10^{-13}$**	Measured on EBB
100	$7*10^{-14}$	**$6.3*10^{-14}$**	Measured on EBB
1000	$2.2*10^{-14}$	$2.2*10^{-14}$	
10000	$7*10^{-15}$	$7*10^{-15}$	
50000	$< 1*10^{-14}$	$<1*10^{-14}$	
Frequency drift (/day)	$< 1*10^{-14}$	$<1*10^{-14}$	
Temperature coefficient (/°C)	$2*10^{-14}$	**$1*10^{-15}$**	Measured on EBB

V. CONCLUSIONS

The outputs from the EBB Phase provide good confidence that a lighter PHM, with same frequency stability performances, but reduced constraints from integrator point of view, will be available in the close future.

It is worth noticing that the Mini-PHM shall be considered an evolution of the present PHM, because no new technology is developed, preferring an optimization or refining of existing solutions. This is basically the reason that makes the mPHM one of the most interesting clocks for future Space application, where outstanding frequency stability requirements are demanded in combination with stringent reliability figure.

***Abstract*— HORACE is a compact cold caesium (Cs) atom clock using isotropic light cooling technique directly inside the spherical microwave cavity. It has been designed for onboard and space applications. Ultimate stability as low as 2.2 10^{-13} $\tau^{-1/2}$ had been demonstrated, limited by atomic shot noise and quantum projection noise. Influence of Dick effect has been studied and a compact and simple frequency synthesizer using off the shelf quartz has been realized and characterized. As atoms remain in the cavity during Ramsey sequence, long term stability evaluation focused on cavity pulling effect. This proceeding presents both the microwave synthesizer development and cavity pulling study using a tricky technique to tune the microwave cavity.**

I. INTRODUCTION

HORACE is a compact cold atom clock designed at SYRTE for onboard and space applications. In this clock all the interactions between atoms and light or RF magnetic field are performed inside the microwave cavity. Technical details about the setup can be found in Figure 1 and in [1].

The clock sequence is divided into four successive steps:

- Cooling of up to 2 10^8 atoms using the isotropic light technique.
- Preparation of the atomic sample in a pure hyperfine state.
- Ramsey interrogation performed while atoms are falling down inside the cavity.
- Optical detection of atomic population with a signal to noise ratio (SNR) up to 1000.

With this sequence, the clock cycle duration is about 85 ms. Comparison between atomic transition frequency and clock signal generated by microwave synthesizer is then performed every 85 ms. During time between two consecutive comparisons, the frequency fluctuations of the local oscillator (LO) induce a noise on the clock signal frequency, called Dick effect [2].

During all the interrogation time, the atoms remain still inside the microwave cavity. This difference with usual fountain clock justifies a detailled study of cavity pulling identified as one of the main systematics on HORACE clock.

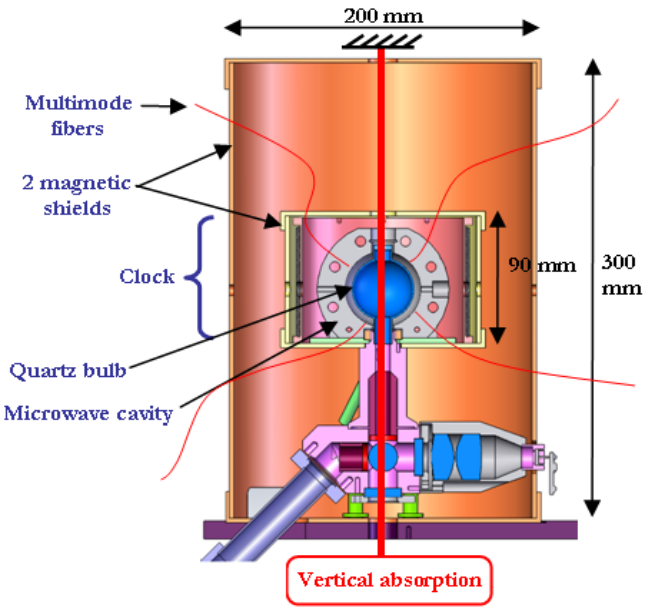

Figure 1: Cut-scheme of the experiment with the vacuum chamber surrounded by the cavity and the 2 magnetic shields. Inner walls of the cavity are optically polished to act as an integrating sphere. This cooling zone is fed by 6 multimode fibres. Detection of atomic populations is made with a retro-reflected vertical beam. The time of flight zone above the cavity is used for atomic temperature diagnostic.

II. NEW MICROWAVE SYNTHESIZER

In previous measurements presented in [1], the interrogation microwave signal was based on a 100 MHz very low noise signal generated from a Cryogenic Sapphire Oscillator (CSO) [3]. This CSO is 1 m^3 size and for obvious reasons is not adapted for onboard and space applications. In order to have a stand alone working of the clock, we need to use a portable LO. In addition, this new LO should not induce noticeable degradation of the short term stability of the clock. Therefore a new microwave synthesizer has been developed based on a suitable LO, designed to minimize the impact of Dick effect.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

In order to determine the characteristics of the new LO, some simulations have been performed, which estimate the impact of Dick effect on the short term stability directly from noise frequency spectrum of a LO. Assumptions made for these simulations are a cycle rate of 10 to 15 Hz and an interrogation time of 35ms, corresponding to typical values where interrogation time is limited by free fall of atoms in the cavity.

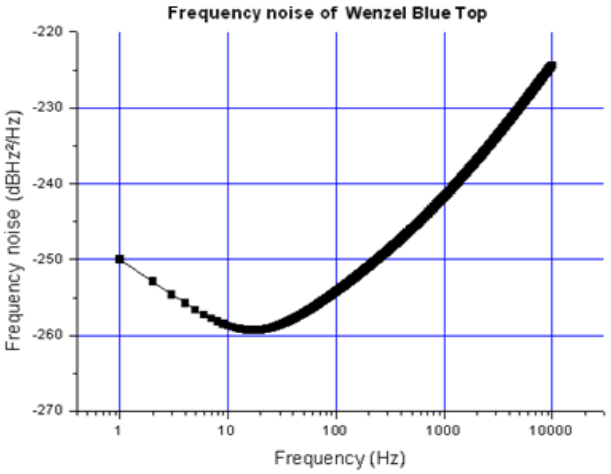

Figure 2: Frequency noise characteristics of the Wenzel Blue Top quartz. It presents a minimum around 15Hz, corresponding to the HORACE cycle rate.

With the objective to reduce impact of Dick effect above 2 10^{-13}, simulations lead to the selection of Wenzel Blue Top quartz. Its specifications are presented on Fig. 2 and show a frequency noise minimum around the clock cycle frequency. Considering the sequence parameters of HORACE and the characteristics of the Blue Top quartz, the expected contribution of the Dick effect is about 10^{-13}, which leads to a slight degradation of the short-term stability from 2.2 10^{-13} to the level of 2.4 10^{-13}.

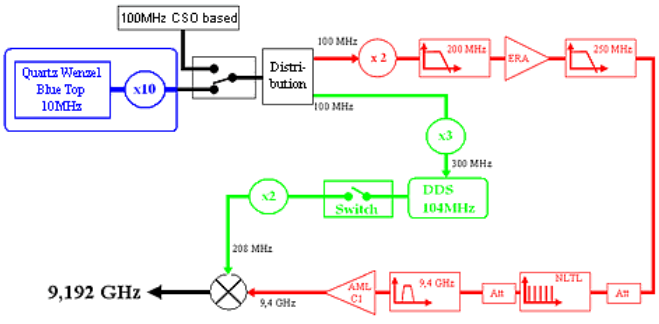

Figure 3: Scheme of the structure of the new synthesis. In red is the generation of the 9.4 GHz signal with a NLTL. In green is the RF signal produced by a DDS. To facilitate the characterization, the synthesis can be fed either by the Blue Top quartz, either by the reference based on CSO.

A new microwave synthesizer based on the Blue Top quartz has been build to generate the 9.192 GHz interrogation signal. The architecture of this synthesizer is shown on Fig. 3. The 10MHz signal generated by the Blue Top quartz is multiplied by ten to generate a 100 MHz reference signal. This signal feeds a NonLinear Transmission Line (NLTL), which the output RF frequency comb is filtered to keep the 94th harmonic. To obtain the clock signal, the 9.4 GHz signal is mixed with a 2x 104 MHz signal coming from a DDS synchronized with the 100 MHz reference signal.

The advantage of this new synthesizer is a simplicity that also characterises the whole clock:

- No secondary oscillator is used (like DRO or YIG). The output signal is generated from a NLTL [4].
- Instead of using a microwave switch, the RF component of the signal is toggled on/off to produce the 9.192 GHz signal.

Despite the use of RF filters in every stage, the output signal is polluted by spurious frequencies. Hopefully, the microwave cavity acts as a very narrow band filter that reduces by a factor of 40dB the parasite frequencies, as shown on Fig. 4.

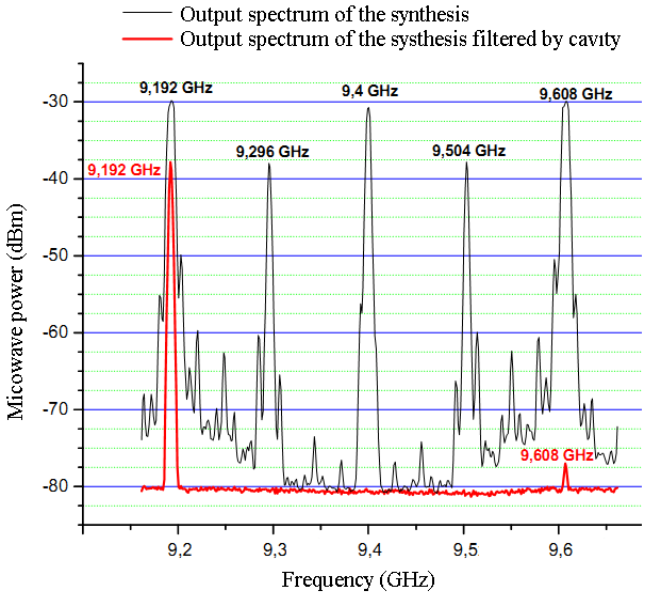

Figure 4: Filtering effect by the microwave cavity. The black line is the spectrum of the output signal of the new synthesis. The red line is the spectrum of the signal transmitted by the cavity.

The main objective of this new synthesizer is to reproduce the characteristics of the LO at 9.192 GHz. In other terms, the phase noise contribution of the synthesis must be negligible compared to the one of the Blue Top quartz, estimated at 9.192 GHz. The measurement has been performed using a similar synthesis, both fed by the same reference signal. Then the same measurement has been done using the Blue Top quartz as LO for the new synthesis, and the CSO signal for the other synthesis. The results are shown on Fig. 5.

To validate the new microwave synthesizer, short-term stability of HORACE clock has been measured using the CSO then the microwave synthesizer. Unfortunately, when these measurements have been performed, the signal to noise ratio was degraded due to extra instrumental noises, and the short-term stability with the CSO was of 3.3 10^{-13}. With the microwave synthesizer based on Blue Top quartz the short term stability increased to 3.7 10^{-13}, leading to a Dick effect induced by the synthesizer of 1.7 10^{-13}.

Although there is an extra noise compared to the expected 10^{-13} level Dick effect, this measurement validates the performances of this new microwave synthesizer as LO for an onboard HORACE clock.

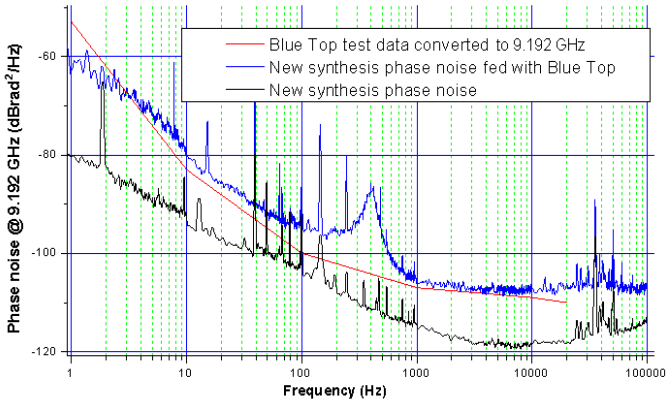

Figure 5: Phase noise of the new synthesis. The black line is the phase noise measurement of the new synthesis. The red line is the phase noise data of the Blue Top converted to 9,192 GHz. The blue line is the phase noise measurement of the new synthesis fed by the Blue Top against a similar synthesis fed by SYRTE reference signal. The excess of noise around 400 Hz is due to the comparison with CSO reference signal [5].

III. LONG TERM STABILITY: CAVITY PULLING

Contrary to the case of atomic fountain, in the case of HORACE the atoms remains still into the cavity during Ramsey interrogation, therefore the cavity pulling effect becomes the predominant systematic. As a first approximation model of cavity pulling in HORACE clock, we start from the one developed for atom fountain [6]:

$$\Delta\nu_{cav,pull} \propto \frac{\tau}{T}\frac{\mu_0\mu_B^2 N_{int} Q_{cav}}{2\pi\hbar V_{mode}} \times \left[\frac{2(\omega_{at}^2/Q)(\omega_{at}^2-\omega_c^2)}{(\omega_c^2-\omega_{at}^2)^2+(\omega_{at}\omega_c/Q)^2}\right] \quad (1)$$

In Eq. 1, the frequency shift depends on 3 parameters: the cold atoms number into the cavity (N_{int}) participating to the microwave interrogation, the ratio between the duration of each microwave pulse (τ) and the effective interrogation time (T), and the difference between resonant frequency of the cavity (ω_c) and the atomic frequency (ω_{at}).

In order to estimate the influence of the 3 parameters, some instrumental improvements have been done on the setup. First, electrical environment has been clean up. Then magnetic and thermal controls of the microwave cavity have been implemented to enhance the reliability of the experiment. With these upgrades, the long-term stability of HORACE clock has reached the 3 10^{-15} level within 2 10^4 seconds of integration.

We present an ingenious method to easily change the detuning of the microwave cavity. Instead of modifying the temperature of the cavity, as it used to be done in atomic fountains, we introduce some dielectric directly inside the microwave cavity. As shown on Fig. 1, there is a small air space between the quartz bulb and the inner walls of the cavity. Two small apertures allow the insertion of small rods: first one in copper to increase the frequency, second one in Pyrex to decrease it. In order to validate the method, the quality factor of the cavity and the transmitted RF power must remain the same. As presented on Fig. 6, the safe region allows a detuning of the cavity frequency of ± 600 kHz.

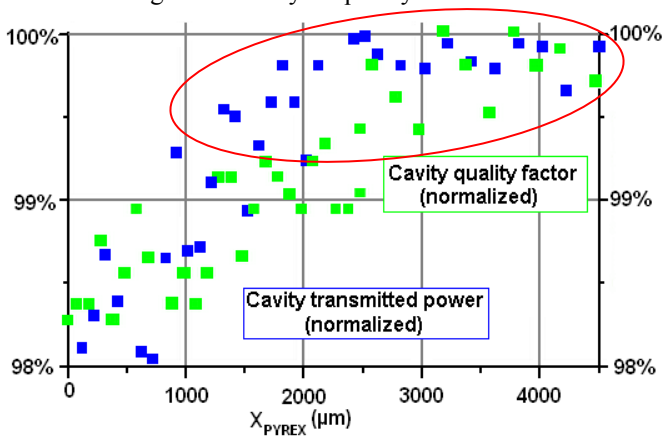

Figure 6: Variation of the normalized quality factor of the cavity (green squares) and of the normalized transmitted power by the cavity (blue squares), with the position of Pyrex cylinder. The same goes for the copper cylinder. The O position of the cylinder corresponds to the maximum of insertion into the cavity. The degradation of each factor does not excess 1%, for a position higher than 1500µm (corresponding to a 600 kHz tune). The useful zone is circled in red.

By fixing 2 of the 3 different parameters with a relative stability of 1% at one day for the cold atoms number, and uncertainty of 10 mK for the temperature of the cavity, we verified the influence of 2 of the 3 parameters:

- the τ/T dependency, with a slope of 1,9 10^{-12} which confirm the interest in using a Ramsey interrogation, instead of a Rabi interrogation, to minimize the amplitude of the effect (Fig. 7).

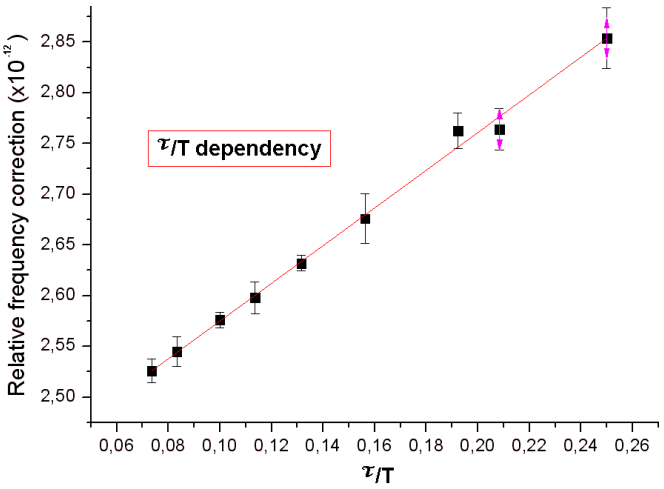

Figure 7: Linear dependency of the cavity pulling with the ration between the duration of a between the duration of each microwave pulse and the effective interrogation time.

- the cavity detuning dependency, with a maximum amplitude at $\nu_c = \nu_{at} \pm \Gamma/2$ with Γ as the line width of the resonant frequency of the cavity (Fig. 8).

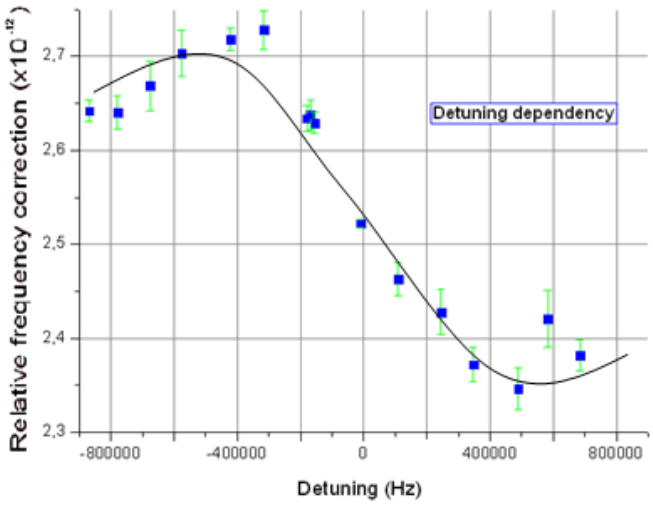

Figure 8: Relative clock frequency shift as a function of the cavity detuning, with τ = 2.5ms and T = 29ms.

Concerning the dependency with N_{int}, it appears that the effect decreases first with N_{int}, then increase again at low N_{int}. This can be related to one of the main issue in the experiment, concerning the lack of knowledge about the shape and the evolution of the cloud of cold atoms, and then the density of cold atoms and its evolution. The model used for the depedency need to be reviewed to adapt to the particularity of the clock.

IV. CONCLUSIONS AND PERSPECTIVES

With an expected contribution of Dick effect at 1 10^{-13} and a measured contribution at 1.7 10^{-13}, further investigations need to be done to understand this difference.

Concerning cold atoms density and its evolution, investigations are under progress, in order to refine the model of cavity pulling and to estimate the last main systematic measure: the shift due to cold collisions.

ACKNOWLEDGMENT

The authors would like to thank the French space agency (CNES) and Thales Electron Devices (TED) for supporting this work and for providing research studentship respectively. N. Rossetto would like to thanks R. Lambert and F. Chapelet for their essential help on the building and characterization of the synthesizer.

***Abstract*—We demonstrate a 10 GHz photonic oscillator based on optical frequency division of a high-stability optical reference with a modelocked fs laser. Characterization with a second independent photonic oscillator reveals a close-to-carrier phase noise that is < 100 dBc/Hz, reducing to a shot noise floor of -156 dBc/Hz at a 1MHz offset.**

I. Introduction

A photonic approach to microwave generation that uses high quality factor ($Q \sim 10^{11}$) optical cavities and optical frequency division can enable high-stability and low timing-jitter signals without requiring cryogenic temperatures [1-3]. Stabilization of the light from a continuous wave (CW) laser to a high-finesse, passive optical cavity can yield a fractional frequency instability of $\Delta f/f \leq 1\times10^{-15}$ for short averaging times [4, 5]. Ideally, transfer of this stability to the microwave domain with a modelocked fs laser preserves the frequency stability of the reference while reducing the optical phase noise by the division factor squared. Using this technique, we demonstrate a 10 GHz microwave signal with a fractional frequency instability $< 1\times10^{-15}$ and with a phase noise that is < 100 dBc/Hz at a 1 Hz offset. The integrated timing jitter of the phase noise spectrum from 1 Hz to 1 MHz is < 1 fs.

II. Generation of 10 GHz Micorwave Signals Via Optical Frequency Division

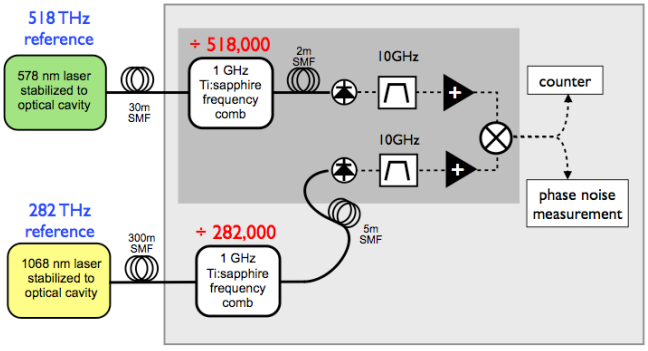

Figure 1. Generation and characterization of 10 GHz signals via optical frequency division. SMF denotes single mode fiber.

We generate 10 GHz microwave signals via photodetection and of the tenth harmonic of the repetition rate, f_r, of a 1 GHz Kerr-lens modelocked Ti:Sapphire laser [6] that is phase-locked to an high-Q optical reference [4, 5]. Stabilization of an optical frequency comb divider (OFCD) to an optical reference transfers the stability of that reference to a timing stability in the OFCD laser pulse train. Photodetection of this pulse train produces photocurrent that yields a microwave spectrum of harmonics of f_r up to the photodetector (PD) cut-off bandwidth. A spectrally pure 10 GHz microwave signal is extracted via electronic filtering and amplification of the photocurrent signal. As seen in Figure 1, a second similar but fully independent photonic oscillator is used to characterize the frequency stability and phase noise of the generated 10 GHz microwave signals. Details of the measurement methods can be found in [1].

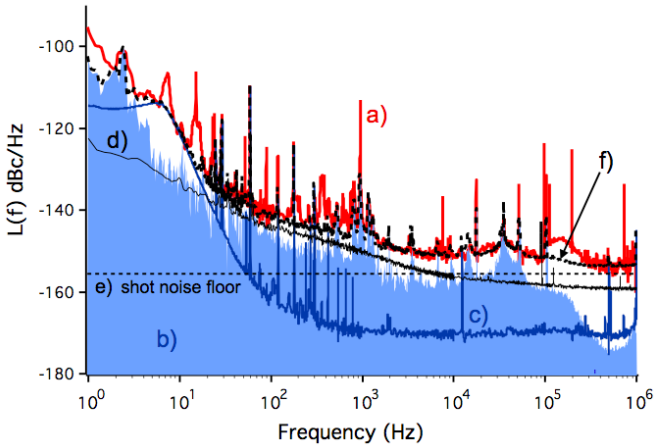

Figure 2. Single sideband phase noise on a 10 GHz carrier contributed by two oscillators. a) red solid trace – phase noise resulting from the comparison of two independent photonic oscillators. b) blue filled trace - phase noise contribution, scaled to 10 GHz, of the optical references, and the optical frequency comb dividers. c) blue solid trace – phase noise of the digital phase noise measurement system. d) black solid trace – phase noise contributed by the electronic amplifiers. e) Shot noise floor from two photonics oscillators. f) black dashed line – sum of the noise contributions from b), c), d) and e)

Figure 2 shows the phase noise on a 10 GHz carrier that is generated via comparison of two photonic oscillators. Also shown is the optical phase noise, scaled to 10 GHz, which is contributed by the optical references and the residual noise of

the OFCDs. Fig 2b represents the microwave phase noise that would be possible ignoring the noise that is contributed by the measurement electronics and photodetection of the laser repetition rate. Figure 2c is the calculated noise that results from contributions of the electronic amplifiers, the phase noise measurement system, the shot noise floor, the optical references and the residual noise of the OFCD. The good agreement between the calculated and the measured phase noise demonstrates that we have properly identified the current limitations to the purity in the 10 GHz microwave signal.

In conclusion, we have produced 10 GHz microwaves with sub-femtosecond timing jitter. The demonstrated phase noise produced is comparable to, or better than those achieved with cryogenic dielectric oscillators [7-9]. Future work will aim at reducing the phase noise contributions of the electronics and photodetection. At frequencies > 10 kHz photodetector nonlinearities result in a saturation of the photocurrent at -8 dBm for 12 mW of incident optical power [10]. In the future, the shot noise limited floor can be decreased with more optical power provided the high-speed photodetector remains linear. Additionally saturation effects in the PD can be mitigated by repetition rate filtering with a Fabry-Perot cavity [Kirchner]. A still lower noise floor would require photodetectors with increased power handling or an alternative hybrid approach with a dielectric sapphire oscillator locked to our photonic oscillator.

The fundamental limits to the achievable phase noise of our photonic approach are given by thermally-excited noise in the glass spacer, mirror substrates and optical coatings of the FP reference cavity [Numata], as well as the photodetector shot noise mentioned above. The lowest reported thermal noise for a FP reference cavity corresponds to approximately L(f) = -117 dBc/Hz at 1 Hz offset when converted to a 10 GHz carrier.

Email: ahajjam@du.edu

***Abstract*— This paper reports on high frequency micromechanical resonant silicon microbalances capable of detection and concentration measurement of volatile organic compounds in gas phase. In this work, regular gasoline has been used as the source of organic compounds in gas phase and 1813 photoresist has been used as the absorbent coating on the resonator surfaces. A new technique for formation of thicker polymer coatings on resonator surfaces has been utilized allowing frequency shifts as high as 2200ppm to be achieved for the resonators upon exposure to gasoline vapor. This is equivalent to an effective thickness of ~40nm for the absorbed organic compounds. Measured response time constants are around 40 seconds. Faster and more sensitive responses are expected to be achievable by maximization of the absorbing surface area using porous resonator structure coatings.**

I. INTRODUCTION

Sensors capable of detection of organic compounds in gas phase could have several applications in oil and gas industry among others. Examples of such applications include rapid estimation of oil content of oil sand samples and early detection of hazardous leaks. Such sensors can help save plenty of time and resources during oil exploration by avoiding the costly and time consuming process of using off-site laboratory analysis. Sensors for detecting volatile organic compounds using surface acoustic wave (SAW) resonators and quartz crystal microbalances (QCM) have previously been demonstrated [1-4]. The detection mechanism in such sensors is based on a frequency shift caused by the added mass from the absorbed molecules.

MEMS resonators, as smaller versions of such resonant devices, are interesting candidates for development of more sensitive and highly integrated chemical and biological sensors. Arrays of such sensors can be batch fabricated at high quantities at a very low cost. As a result, a variety of microscale electromechanical resonators have been considered for sensory applications lately [5,6].

MEMS resonators mostly make use of electrostatic (capacitive) [7] or piezoelectric [8,9] electromechanical transduction with both methods having their respective advantages and disadvantages. Electrostatic excitation suffers from relatively small actuation forces available from electrostatic actuators and the need for very thin transduction gaps complicating fabrication of such devices. Furthermore, narrow transduction gaps are also very vulnerable to contaminants in environmental sensing applications.

Another popular type of MEMS resonators are the piezo-electrically actuated resonators which have better robustness in comparison to electrostatic resonators but piezoelectric transduction requires integration of piezoelectric thin films and metallic electrodes with the micromechanical elements which makes the fabrication somewhat challenging. Such devices usually have lower quality factors in comparison to capacitive devices.

Thermally actuated resonators are the third group of MEMS resonators [10-12]. In addition to having a very simple fabrication process, they are very suitable for sensory applications. Their monolithic structures have shown excellent robustness when in direct contact with the surrounding environment Frequencies up to 60MHz have been demonstrated for thermally actuated micromechanical resonators [13] and much higher frequencies can be achieved by shrinking the resonator dimensions [14]. Power consumption is usually a concern for thermally actuated devices but it has been shown that if the devices are small enough, power consumption can be in the sub-milliwatt range [14]. In addition, power consumption makes such devices active components capable of self sustained oscillation without the need for additional electronic circuitry [15].

II. RESONATOR FABRICATION

The standard single mask SOI process was used for fabrication of the thermal-piezoresistive resonators used in this work [15]. This process starts by growing a thin (~200 nm) layer of silicon dioxide on the substrate. The silicon dioxide layer is patterned to define the resonator structures. The silicon structures are then carved into the SOI device layer by deep reactive ion etching (DRIE) of silicon all the way down to the buried oxide layer (BOX). Finally, the underlying buried oxide is removed in hydrofluoric acid (HF). At the same time the remaining oxide mask on top of the structures is also etched away. The whole procedure is shown in steps a to c of Figure 1. The result is suspended single crystalline silicon

This work was supported by National Science Foundation (NSF) under grants MRI-RAPID #1061489 and MRI #0923518.

resonant structures with integrated thermal actuator/piezoresistive sensors.

In a previous work, polymer coatings were formed by dipping the resonator sample in a highly diluted polymer solution in acetone leading to very thin polymer coatings [16]. The resonators were spun and hard baked in order to get rid of the excess solvent (step d of Figure 1). Even though the results in [16] showed that the coated resonators were responding to organic vapors, the sensitivity was not very promising and a maximum frequency shift of only 200 ppm was obtained for a highly saturated gas sample. The reason for such low frequency shift was suspected to be the small polymer thickness on the surface of the devices. Much higher sensitivities are expected to be achievable for thicker polymer coatings.

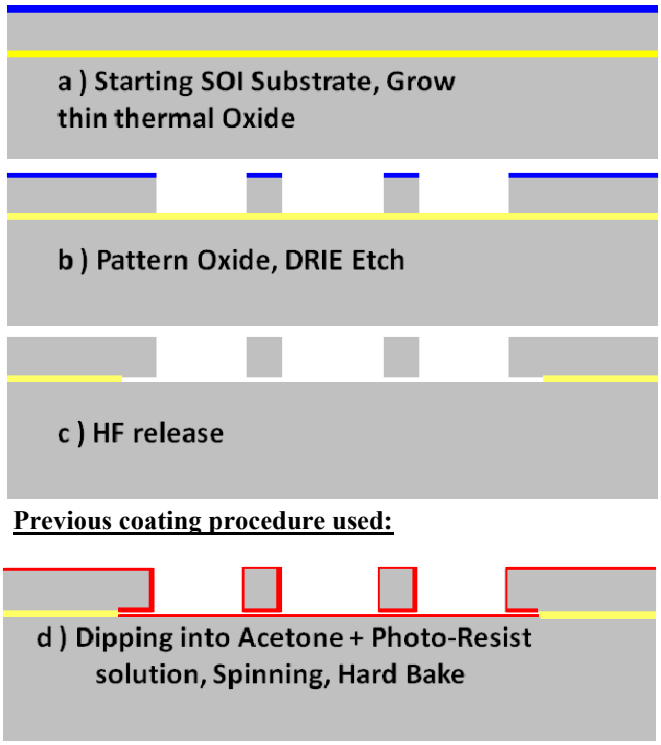

Figure 1. a-c) Thermally actuated resonator fabrication process flow and d) polymer coating.

Using higher concentration polymer solutions in this technique to achieve higher polymer thickness generally results in excessive polymer residues in the gap between the resonators and the SOI handle layer leaving the devices non-operational as can be seen in the SEM picture in Figure 2.To overcome this problem, a new procedure was utilized in this work for polymer coating of the devices (Fig. 3). Steps a and b which are not shown in Fig. 3 are identical to the fabrication process shown in Figure 1. However, in this approach the polymer solution (a much higher concentration solution) is added and spin coated before the devices are undercut. Undercut is done in hydrofluoric acid after coating with polymer (steps c and d of the fabrication process shown in Figure 3. Therefore, using this approach there will be no polymer residue underneath the device structures.

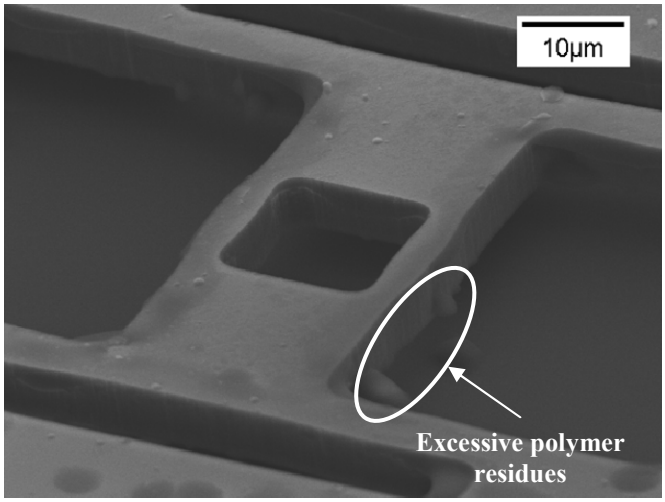

Figure 2 SEM view of a device in which high polymer thickness has resulted in excessive polymer residues in the gap between the resonators and the SOI handle layer which has left the devices non-operational.

SEM view of a 24MHz I-shaped bulk acoustic resonator polymer coated using the abovementioned technique is also shown in Fig. 3. This resonator has been fabricated on a SOI substrate with both device layer and BOX thickness of 5µm.

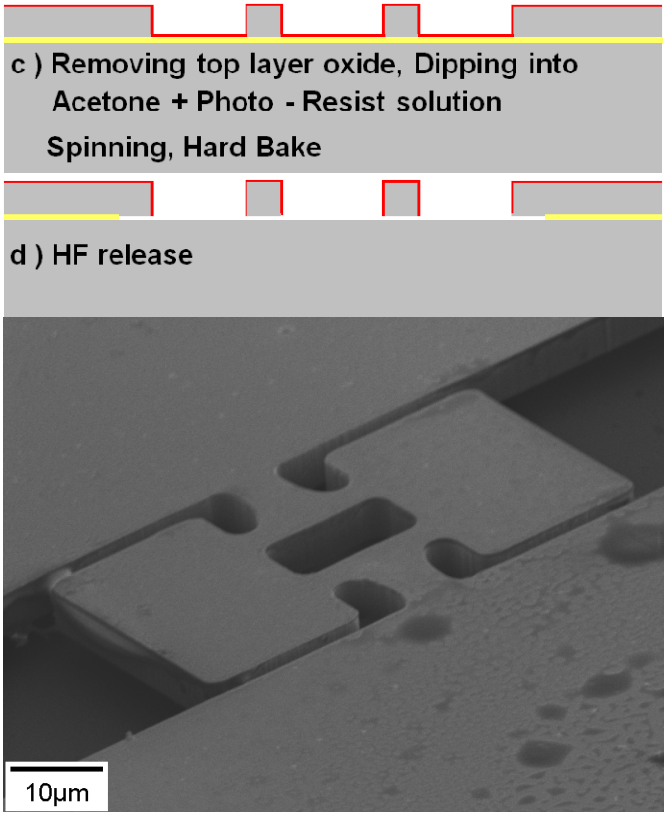

Figure 3. New procedure for coating of the thermally actuated resonators in which the polymer is added before the devices are undercut and undercut is done in hydrofluoric acid after coating with polymer. Also, an SEM picture of a 24MHz IBAR resonator used in this work along with its electrical connections is shown.

III. Resonator Description

Figure 4a shows the schematic view of the resonant structures used in this work referred to as dog bone or I-shaped resonators. They can cover a wide range of frequencies from a few MHz to tens of MHz. Such devices are very suitable for thermal actuation and their operating principle has thoroughly been explained in [13]. The resonators were operated in a one-port configuration with the thin actuator beams of the structures acting simultaneously as both thermal actuators and piezoresistive sensors. Actuation occurs by passing a fluctuating electrical current through the actuator beams in the middle of the structure.

Figure 4b shows the in-plane extensional resonant mode of an I-shaped resonator. In this mode the masses on the two ends of the beams vibrate back and forth in opposite directions. At resonance, the resistance of the actuator beams is modulated by the resulting alternating mechanical stress due to the piezoresistive effect. This results in a detectable small signal motional current in the device.

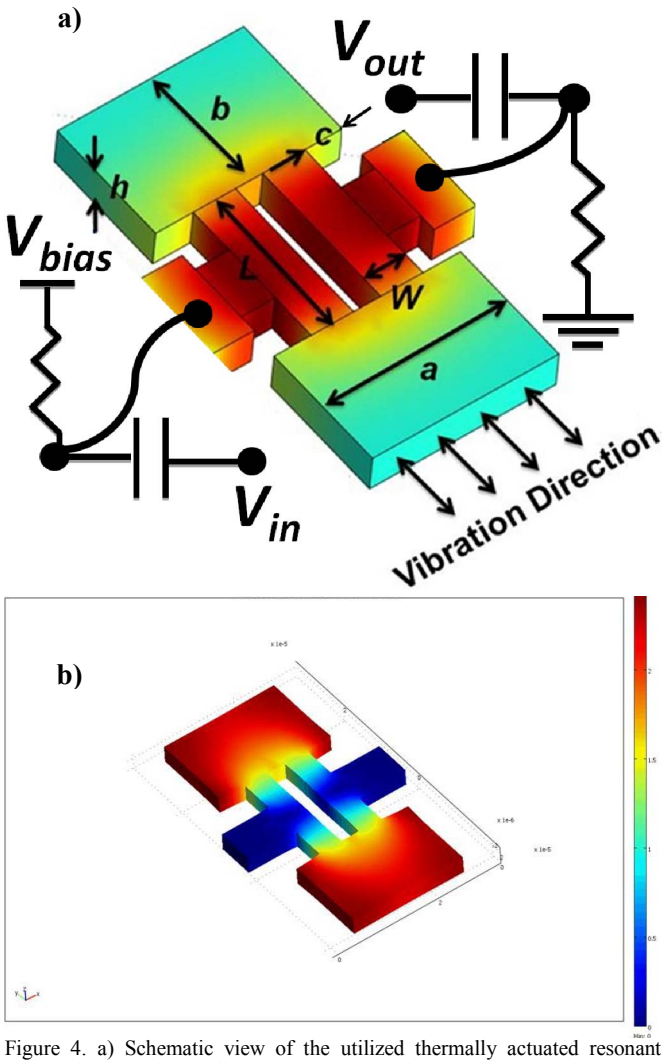

Figure 4. a) Schematic view of the utilized thermally actuated resonant sensor showing the qualitative distribution of AC temperature fluctuation amplitude (red being the maximum and blue the minimum). The electrical connections required for one-port operation of the resonator are also shown; b) COMSOL eigen frequency analysis results showing the fundamental in-plane resonance mode shape for an I-shaped structure.

IV. Measurement Setup And Results

Figure 5 shows the camera picture of the setup used in order to characterize the resonator sensory response as well as its schematic diagram. In this setup, nitrogen bubbled through a gasoline container is directed towards the resonator under test.

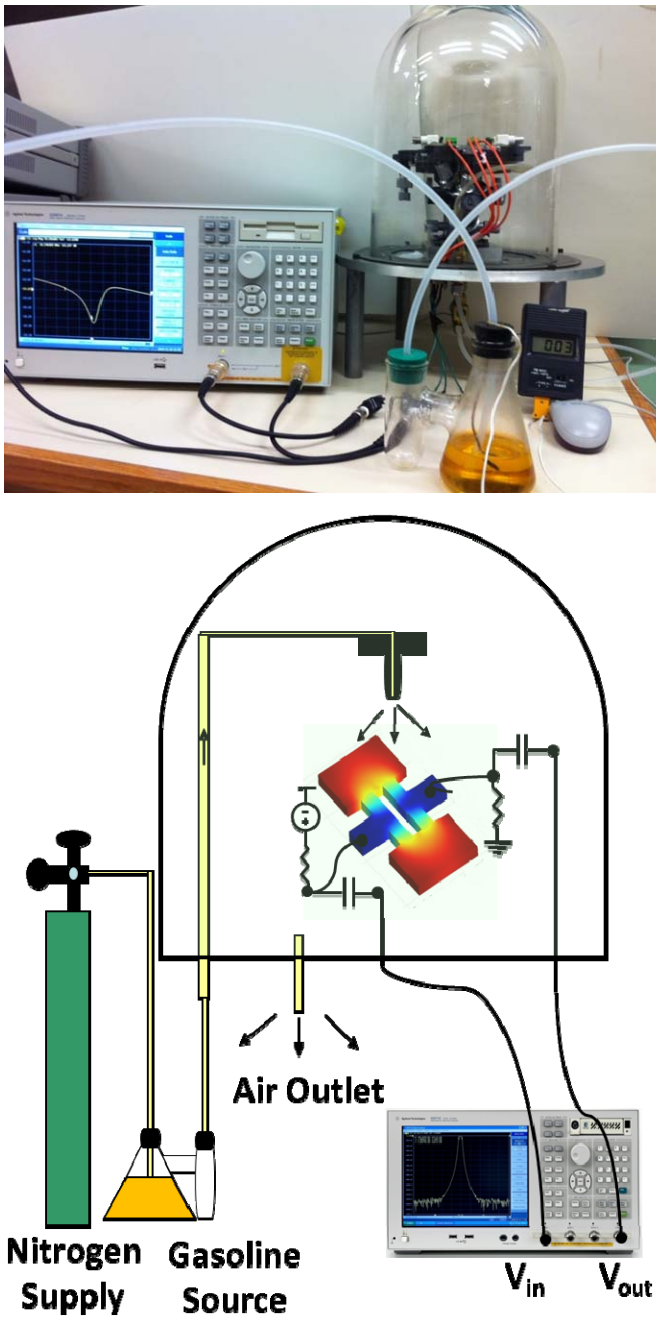

Figure 5. Schematic diagram and camera picture of the test setup used to characterize the resonator sensory behavior in which nitrogen, bubbled through a gasoline container, is directed towards the resonator under test.

Having a flow of the gas sample passing over the resonator surfaces maximizes the contact between potential molecules of interest in the gas sample and the resonator surface, hence, maximizing the absorption probability.

Figure 6 shows the change in the measured frequency versus time for the resonator shown in Fig. 3 upon exposure to nitrogen flow rich with gasoline vapor at room temperature. As can be seen, upon exposure, the resonance frequency reduces over time with a time constant of ~40sec. Restoration of the resonant frequency to its initial value happens very quickly as soon as the source is removed. It can be seen that more than 10 times freq shift (in ppm) is achieved in comparison to ~200ppm frequency shift obtained using the previous coating procedure [16].

The mass sensitivity of the resonators can be theoretically calculated as follows:

$$f = \frac{1}{2\pi}\sqrt{\frac{k}{m}} \Rightarrow \frac{\partial f}{\partial m} = -\frac{f}{2m} \qquad (1)$$

where k, m, and f are the effective stiffness, effective mass and resonant frequency of the resonator respectively. Knowing the dimensions and therefore the mass of the resonators, the mass of the deposited organic molecules (∂m) was estimated from the measured frequency shifts to be ~35pg. Assuming an approximate density of 720 kg/m^3 for the organic compound, the volume and consequently the effective thickness of the absorbed organic compounds (assuming a uniform distribution over all resonator surfaces) was calculated. The observed maximum frequency shift of 2200ppm (0.22%) is equivalent to an absorbed organic layer of ~40nm thick.

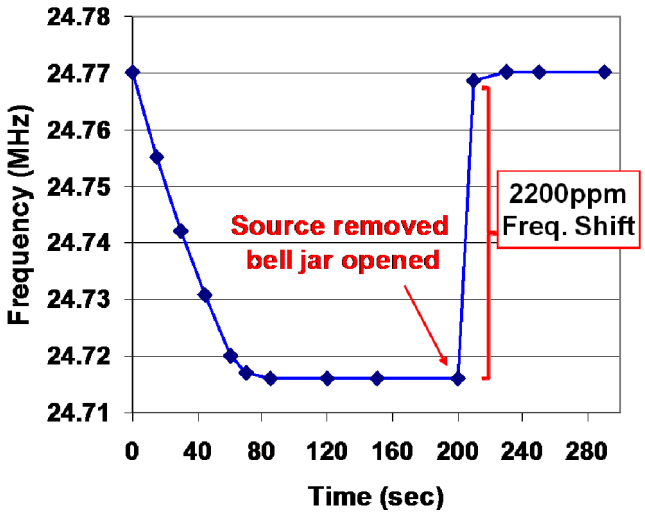

Figure 6. Change in the measured resonance frequency for the 24MHz IBAR resonator of Fig. 4 as a function of the cumulative exposure time showing an overall frequency shift of ~54KHz (2200 ppm). The source was removed after 200 sec. The return to a frequency very close to the initial frequency is almost instantaneous.

The vapor pressure which is an indication of a liquid's evaporation rate increases exponentially with temperature according to the Clausius–Clapeyron relation. In order to see how the sensor responds to different gas concentrations its frequency shift was measured while varying the temperature of the gasoline source. Fig. 7 shows the resonator frequency shift as a function of the temperature of the gasoline sample. As expected, at lower temperatures the lower organic vapor pressure leads to smaller frequency shifts. The shift increases exponentially with temperature (as the vapor pressure increases exponentially with temperature). At about 5ºC, the sensor response starts to saturate and stays constant for temperatures above ~15 ºC .

Gasoline is a mixture of different hydrocarbons with Toluene being one of the main ones. Therefore, in order to approximate the concentration of the detected gasoline vapor, our calculations are based on the saturated vapor pressure of Toluene. Based on the vapor pressure taken from [17], assuming a temperature of -10C°, the minimum gasoline concentration detected corresponds to ~4000 ppm whereas; the minimum LOD measurable would be ~5.5ppm.

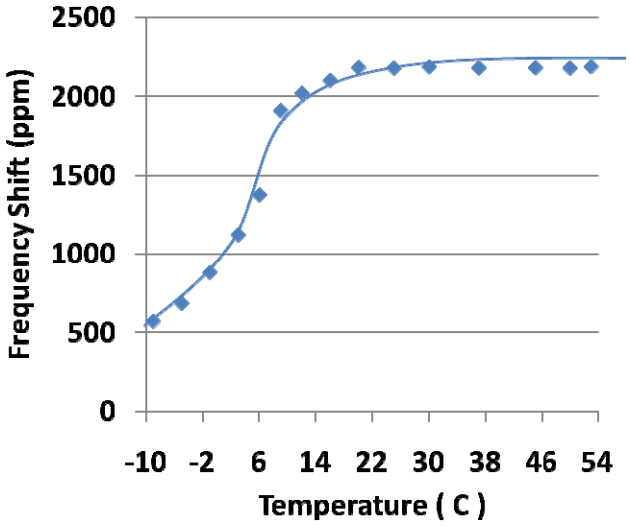

Figure 7. The resonator frequency shift as a function of the temperature of the gasoline. The frequency shift increases with temperature as the organic vapor pressure increases. The increase is exponential at lower temperatures, until the sensor reaches saturation.

V. CONCLUSION

A thermally actuated high frequency in-plane silicon resonator was successfully used for estimation of concentration of gasoline vapor in gas samples. Such a device has a monolithic crystalline silicon structures which makes it very robust towards contaminants and can be fabricated using a very simple CMOS compatible process. The observed maximum frequency shift of 54kHz (2200ppm) is approximately 10 times the frequency shift measured using the previous resonator coating procedure. This measured frequency shift corresponds to a thickness of 40nm deposited organic compound on the surface of resonator. Minimum LOD was estimated to be ~5.5 ppm. Future work includes further design optimization of the resonators and narrowing down their thickness to achieve higher mass sensitivities. Using more suitable absorbent polymer coatings and maximization of the absorbing surface area using porous resonator structure coatings could significantly improve the sensitivity.

Receptor-Coated Porous Silicon Resonators for Enhanced Sensitivity of Vapor Detection

Yongha Hwang, Sungmin Kim, and Rob N. Candler
Electrical Engineering Department
University of California, Los Angeles
Los Angeles, USA
Email: hwangyongha@ucla.edu

***Abstract*—We present microscale silicon resonators with nanoscale pores for increased surface area, which are capable of providing enhanced sensitivity in vapor sensors. Increased mechanical stability and detection performance are also achieved by keeping parts of the resonating device nonporous and adding a receptor coating. We demonstrate improvements up to 165% and 654% in resonator sensitivity to isopropyl alcohol (IPA) for partially-porous silicon resonators and receptor-coated partially-porous silicon resonators, respectively, as compared to nonporous silicon resonators.**

I. INTRODUCTION

MEMS/NEMS resonators are commonly used as chemical or biological sensors, as surface-bound analytes change the mechanical stress and total mass of the resonator, leading to measureable shifts in resonant frequency. The sensitivity to adsorbates can be enhanced by scaling devices down to the nanoscale. Ultrasmall NEMS resonators have demonstrated resolution on the order of attograms or less [1-2]. These extremely sensitive resonant sensors, however, have additional challenges, such as fabrication process and signal detection [3-4].

Rather than fabricating nanoscale devices, our approach uses widely available microscale fabrication techniques to achieve porous structures with nanoscale features, for the possibility of microscale devices with nanoscale sensitivity. By building resonators that have a porous silicon surface, we take advantage of the increased area for molecular binding and improve the sensitivity of the resonators to the vapor concentration of interest. In addition, while achieving high sensitivity by shrinking resonators to the nanoscale results in the decrease of sensing area, the microscale sensors with nanoscale porous of this work can simultaneously achieve high sensitivity and a large capture cross section. This enables the porous resonators to detect low concentrations of analytes without the sample preconcentration that may be required for nanoscale resonators.

We previously demonstrated initial results for silicon resonators that were fully porous [5]. This work focuses on silicon resonators with targeted regions of porosity and functionalization, combining the advantages of increased surface area of porous silicon with the structural strength of nonporous silicon.

II. FABRICATION OF RECEPTOR-COATED POROUS SILICON RESONATORS

The nonporous silicon resonator consists of whole polycrystalline silicon. Regions of the nonporous resonators can be converted to porous by electroless metal-assisted etching. We designed a fully-porous silicon resonator and a partially-porous silicon resonator in order to compare their performance. While both the center paddle and torsional beams of the fully-porous structures consist of porous-etched silicon, only the center paddle is porous-etched, and the torsional beams remain nonporous-etched silicon for the partially porous device as shown in Fig. 1(h). This is done in order to maintain the stiffness of the torsional beams and improve yield during the release process.

We have fabricated each type of resonator using surface micromachining process as shown in Fig.1. Porous and nonporous silicon resonators were fabricated on the same wafer in order to quantify the enhancement in sensitivity. The resonators were fabricated on 4-inch (100) silicon wafers as the substrates, followed by depositions of 5.5-μm-thick silicon dioxide serving as a sacrificial layer and 470-nm-thick polycrystalline silicon by LPCVD. After the resonator structures were defined by photolithography and deep reactive ion etched, a standard photoresist (AZ 5214) was patterned to serve as a mask for selective porous etching. The surface was made porous using an electroless metal-assisted etching technique, which involves randomly depositing gold clusters as chemical catalysts [6]. A cathode reaction happens with hydrogen peroxide on the top surfaces of gold clusters, and an anode reaction happens with silicon and hydrofluoric acid on the bottom surfaces. These reactions supply hole injection into silicon and etch silicon molecules underneath gold clusters. By changing the fabrication conditions, such as thickness of gold clusters and etch time of porous silicon, porosification

This work was supported by the BRIGE program of the National Science Foundation under award # 0926228 and the Center on Functional Engineered Nano Architectonics (FENA).

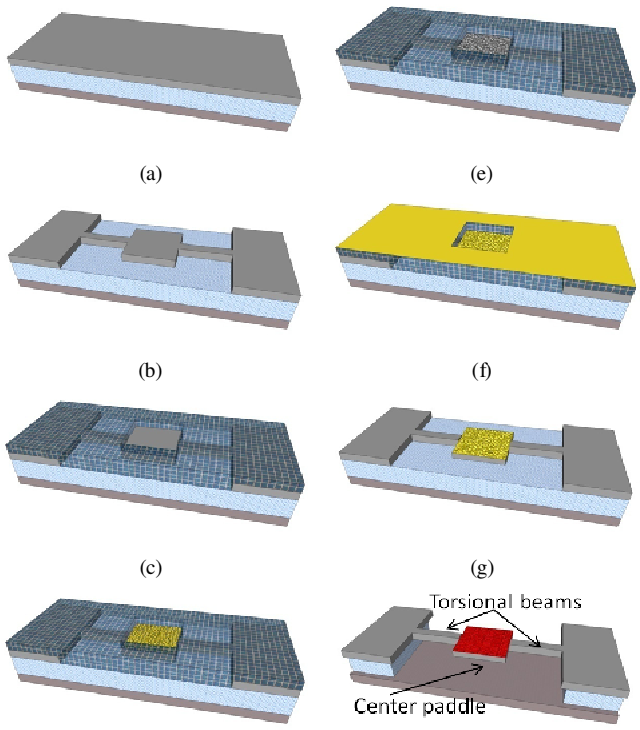

Fig. 1. Fabrication process for partially-porous silicon resonators. (a) Deposition of SiO_2 and polycrystalline silicon by LPCVD. (b) Photolithography and polycrystalline silicon etching by DRIE for defining body of the resonator. (c) Photolithography for opening of selective porous region. (d) Random gold cluster coating. can be controlled. The remaining gold clusters were subsequently removed. After this, 25 nm-thick chromium and gold films were deposited for adhesion of the receptor coating. The electroless metal-assisted porous etching steps were omitted for the nonporous silicon resonators and the second photolithography for partial opening of the center paddle was omitted for fully-porous silicon resonators. Followed by liftoff of metal layers and sacrificial layer etch, the samples were coated with receptor solution. 4-mercaptobenzoic acid was used as a receptor material since it interacts with alcohol through hydrogen bonds [7].

Fig. 2 shows the change in roughness due to the porous etching process; this allows the porous silicon resonators to have a larger surface area than the non-porous resonators. According to the AFM root-mean-square surface roughness measurements, the surface area of the nonporous silicon and the porous silicon are 28.5 μm^2 and 158 μm^2, respectively, for a scan range of 5 µm ×5 µm. Depending on the porous etch time, the silicon surface becomes rough, and the total thickness gets reduced, as shown in Fig. 3.

III. RESULTS AND DISCUSSION

The frequency spectra of the resonant vapor sensors were measured by an optical beam deflection setup that consists of a laser Doppler vibrometer (LDV) system (Polytec OFV-5000), a custom-built vacuum chamber, and a network

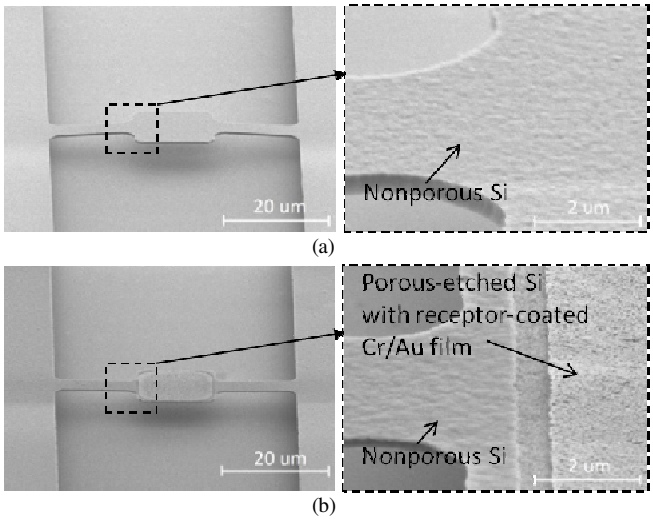

Fig. 2. SEM images of (a) the nonporous silicon resonator and (b) the partially-porous silicon resonator with the receptor coating.

analyzer (HP 8753D) as shown in Fig. 4. To induce mechanical vibration, the resonator sample was mounted on an external piezoelectric actuator (Thorlabs AE0203D08F) controlled by the stimulus signal from the network analyzer. Measurements were performed in a vacuum chamber in order to avoid energy losses by air damping. A stainless-steel reservoir that was filled with isopropyl alcohol (IPA) was connected to the vacuum chamber via a metering valve to control the vapor concentration. Resonator vibration was detected by reflection of the laser. The reflected beams were converted to an electrical signal by the LDV controller, and the network analyzer recorded the resonant frequency of the resonator mass sensor. Silicon resonators can detect IPA vapor since IPA adsorb to silicon surface via oxygen atoms [8].

The first two modes of oscillation for the resonator are a translational mode, corresponding to motion of a center paddle normal to a substrate, and a torsional mode, corresponding to rotation of the center paddle around axis of the torsional beams. The LDV system measures the difference of motion at

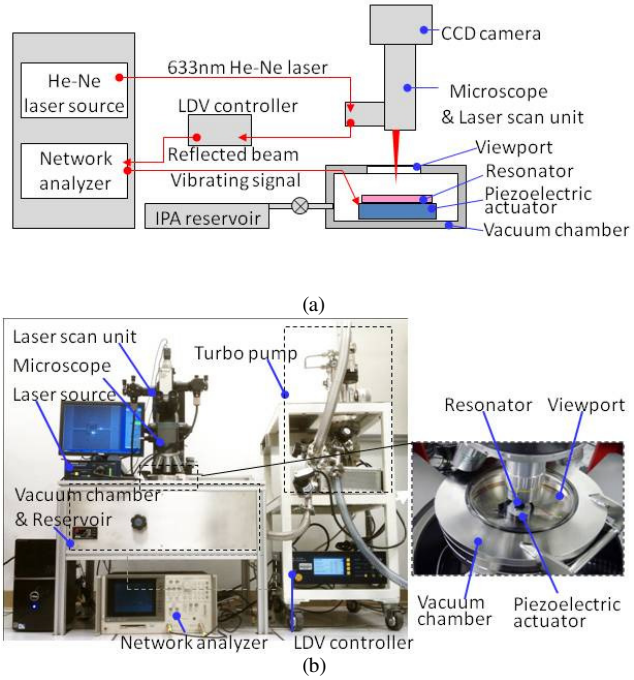

Fig. 4. (a) Schematic diagram. (b) Photos of the experimental setup for mechanical actuation and readout using a laser Doppler Vibrometer.

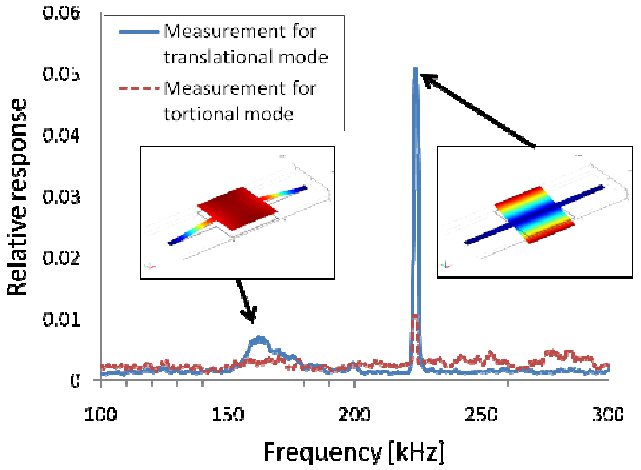

Fig. 5. A comparison of relative displacements of the translational mode and the torsional mode of the nonporous silicon resonator. The insets show schematics of the translational mode (left) and the torsional mode (right).

different two positions. One reflected beam for reference is positioned on the nonmoving pad structure, and the other is on the center of the paddle or edge to see the translational mode or torsional mode. As shown in Fig. 5, experimental results show the torsional mode has greater peaks than the translational mode. It is because torsional mode minimizes environmental damping, as the resonator undergoes less volume change [9]. In addition, torsional mode is known to be relatively insensitive to mechanical nonlinear effects due to the increase in drive amplitude [10].

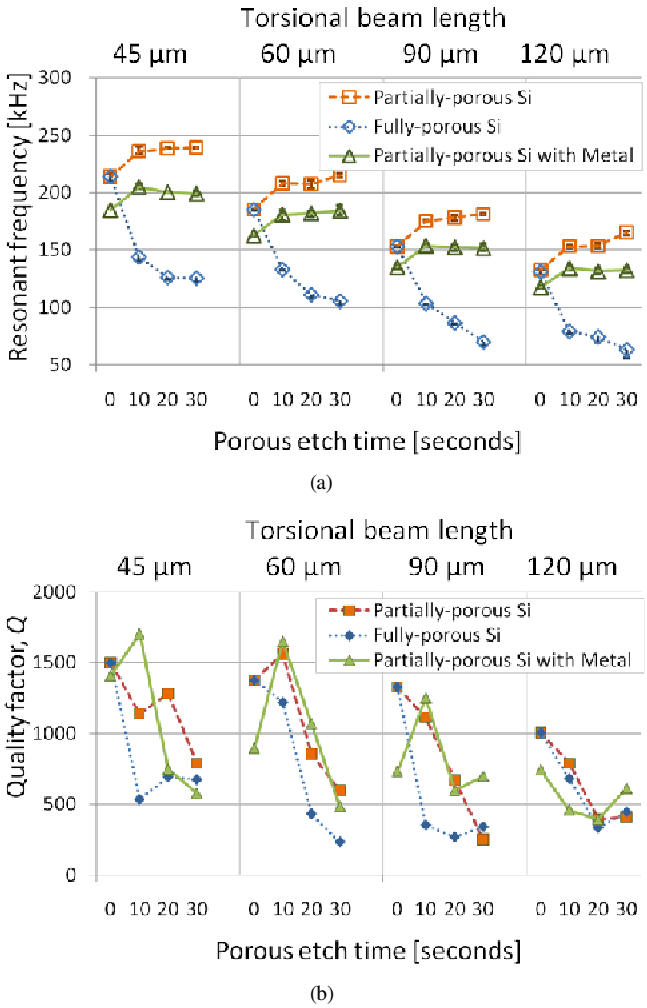

Fig. 6. Measured (a) resonant frequencies and (b) quality factors for different etch times and torsional beam lengths. The values of zero–second-etched condition indicate the case of nonporous silicon resonators.

Fig. 6 shows the dependence of resonant frequency and quality factor on the etch time for porosification (0-30 seconds) for resonators with different lengths of torsional beams (45-120 µm). As porous etch times increase, the resonant frequencies of fully-porous and partially-porous silicon structures have opposite tendencies because the partial porous structures primarily have a decrease in mass, whereas the fully-porous structures also have a large decrease in stiffness due to the porous beams. Partially-porous silicon structures with metal and receptor coating have the same trends with uncoated partially-porous silicon structures except having a frequency offset due to additional coating of metal and receptor. The quality factor decreases due to the increase in surface to volume ratio of resonators due to further porous etch. Also, the quality factors of these devices are lower than desired at ~1000. Enhancement of quality factors of these devices is an area of ongoing research.

Fig. 7 illustrates the different responses of each type of structure by the relative resonant frequency shift from different IPA concentration. The resonator sensitivities are calculated from the slopes of the normalized frequency shifts.

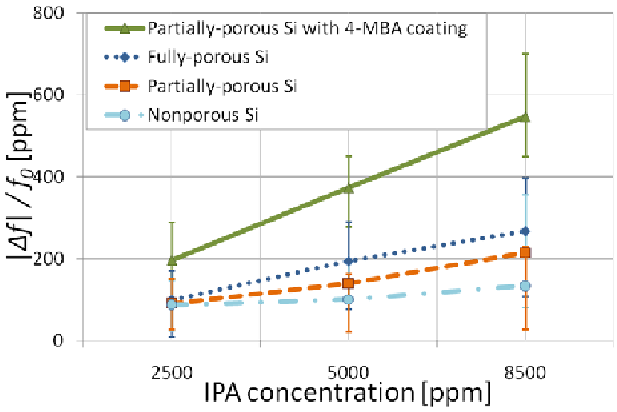

Fig. 7. A comparison of relative frequency shifts vs. gas concentration. The error bars indicate the standard deviation in the data, which comprised five measurements at five minute intervals for each concentration.

The sensitivities of partially-porous, fully-porous, and receptor coated partially-porous structure are improved to 261%, 165%, and 654%, respectively. The partially-porous structures have a slightly smaller improvement in sensitivity when compared to the fully-porous structure because the fully-porous structures have higher surface area. Another reason is the initial mass of the partially-porous silicon resonator is greater than the fully-porous resonator, which is relevant because sensitivity is dependent upon fractional mass change of adsorbed gas molecules.

Relative resolution is inversely proportional to the product of sensitivity and quality factor [11-12]. We demonstrate that the resolution was reduced to 44% of nonporous silicon structure in the case of the partially-porous silicon structure, and 26% for the receptor-coated partially-porous silicon structure. In addition, torsional beams of the fully-porous silicon structure which are already weakened by porosification limit further porosification for larger surface area, whereas porous paddle of the partially-porous silicon structure can be porous-etched more deeply in order to further enhance the sensitivity.

We have demonstrated enhanced chemical vapor sensitivity using partially porous functionalized silicon resonators by using a microscale device with nanoscale features. By keeping critical parts of the resonator non-porous, the mechanical stability of these resonators is improved over their fully porous counterparts. The combination of porous surface and functionalization for resonant sensing can be extended to many other adsorption-based sensing applications.

ACKNOWLEDGMENT

The authors gratefully thank Prof. C. J. Kim and C. Y. Lee for helping us to process the porous silicon etching. We would also like to thank Tom Lee of the Nanoelectronics Research Facility at UCLA for assistance in fabrication of the test chamber. Device fabrication was performed in the Nanoelectronics Research Facility (NRF) at UCLA.

***Abstract*-An analytical approach is taken to investigate SH wave propagating in layered piezomagnetic/ piezoelectric structure where a thin piezomagnetic film with a mass layer bonded to a semi-infinite piezoelectric substrate. The dispersion relations are obtained and the effect of the thickness and the density of the mass layer on the properties of the SH waves are figured and presented.**

I. INTRODUCTION

It is well known that the composites made of piezoelectric/piezomagnetic materials exhibit magneto-electric effect that is not present in single-fields. Consequently, the coupling nature of piezoelectric phase and piezomagnetic phase has led to wide applications in adaptive material systems, and they are extensively used as sensors and actuators, acoustic devices, and transducers, etc. The development of micro-acoustic sensors provide the need for further investigations of the SH wave propagating in layered piezomagnetic/piezoelectric structure with a mass layer.

Soh and Liu [1] obtained the existence of the interfacial SH waves in transversely isotropic piezoelectric/ piezomagnetic structure, gave the conditions that the materials should be satisfied when the SH waves exist. Du et al. [2] introduced the SH waves propagating in a circular cylindrical layered piezoelectric structure with initial stress. Wang [3]and Liu [4] discussed a horizontal shear surface wave in magneto-electro-elastic materials at the same time.

In this paper, the effect of the thickness and the density of the mass layer on the properties of the SH waves propagating in layered piezomagnetic/piezoelectric structure is investigated analytically.

II. PROBLEM FORMULATION

Consider a layered piezomagnetic/piezoelectric structure where a thin piezomagnetic film with a mass layer bonded to a semi-infinite piezoelectric substrate. The piezomagnetic and piezoelectric materials are polarized along the z-axis direction. We here only consider the so-called anti-plane wave propagation problem. The displacement components, the electric potential and the magnetic potential are assumed as

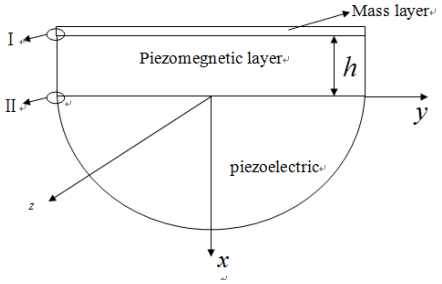

Fig.1 A layered magneto-electric structure

$$u(x,y)=0,\ \ v(x,y)=0,\ \ w=w(x,y,t),$$
$$\varphi=\varphi(x,y,t),\ \ \psi=\psi(x,y,t), \tag{1}$$

where u,v,w are the displacement components in x,y,z direction, respectively; ϕ is electric potential, and φ is magnetic potential.

For linearly magneto-electric materials, the equilibrium equations of elasticity without body forces and the Gauss's law of magneto-electrostatics without free charge are given as follows

$$\sigma_{ji,j}=\rho\ddot{u}_i,\ \ D_{i,i}=0,\ \ B_{i,i}=0,\ \ (i,j=1,2,3), \tag{2}$$

where σ_{ij},D_i,B_i are the stress, electric displacement and magnetic induction components, respectively. ρ is the mass density. The subscript comma denotes a partial derivative with respect to the coordinates, and a superimposed dot represents the derivative with respect to the time.

For an anisotropic and linearly magneto-electro-elastic solid, the coupled constitutive relation can be written as

$$\begin{aligned}\sigma_i &= c_{ik}\gamma_k - e_{ki}E_k - f_{ki}H_k,\\ D_i &= eik\gamma_k + \varepsilon_{ik}E_k + g_{ik}H_k,\\ B_i &= f_{ik}\gamma_k + g_{ik}E_k + \mu_{ik}H_k,\end{aligned} \tag{3}$$

where γ_i, E_i and H_i are the strain, electric field, and magnetic field components, respectively; c_{ij}, ε_{ij} and μ_{ij} are the elastic, dielectric, and magnetic permeability coefficients, respectively; e_{ij}, f_{ij} and g_{ij} are the piezoelectric, piezomagnetic, and magneto-electric coefficients, respectively. For a linearly transversely isotropic magneto-electric-elastic medium with the poling direction along the *z*-axis, the coupling wave equations can be obtained as

$$c_{44}^{*}\nabla^2 w = \rho\frac{\partial^2 w}{\partial t^2},\ \nabla^2\xi = 0,\ \nabla^2\zeta = 0, \tag{4}$$

where

$$c_{44}^{*} = c_{44} + \frac{e_{15}}{\mu_{11}\varepsilon_{11} - g_{11}^2}(\mu_{11}e_{15} - g_{11}f_{15}) + \frac{f_{15}}{g_{11}^2 - \varepsilon_{11}\mu_{11}}(g_{11}e_{15} - \varepsilon_{11}f_{15}),$$

and $\xi = e_{15}w - \varepsilon_{11}\varphi - g_{11}\psi,\ \zeta = f_{15}w - g_{11}\varphi - \mu_{11}\psi.$

$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$ is the two-dimensional Laplacian operator in the Cartesian coordinates. The electric potential and magnetic potential can be written as

$$\begin{aligned}\varphi &= \frac{1}{\mu_{11}\varepsilon_{11} - g_{11}^2}\left[\left(\mu_{11}e_{15} - g_{11}f_{15}\right)w - \mu_{11}\xi + g_{11}\zeta\right],\\ \psi &= \frac{1}{g_{11}^2 - \varepsilon_{11}\mu_{11}}\left[\left(g_{11}e_{15} - \varepsilon_{11}f_{15}\right)w - g_{11}\xi + \varepsilon_{11}\zeta\right].\end{aligned} \tag{5}$$

The displacement, electric potential, and magnetic potential in the substrate tend to zero far from the layer along the positive *x*-direction

$$x \to +\infty,\ w_m = 0,\ \varphi_m = 0,\ \psi_m = 0, \tag{6}$$

The continuity conditions at the interface between the thin piezomagnetic layer and the piezoelectric substrate are written as

$$\begin{aligned}&w(0,y) = w^{(m)}(0,y),\ \tau_{zx}(0,y) = \tau_{zx}^{(m)}(0,y),\\ &\varphi(0,y) = \varphi^{(m)}(0,y),\ D_x(0,y) = D^{(m)}(0,y),\\ &\psi(0,y) = \psi^{(m)}(0,y),\ B_x(0,y) = B^{(m)}(0,y),\end{aligned} \tag{7}$$

where the superscript m indicates the quantities in the substrate. There are two typical cases being considered in this study, namely, the magneto electrically open and the shorted surface conditions. The magneto-electrically open conditions are written as

$$\tau_{zx}(-h,y) = \rho' h'\ddot{w},\ D_x(-h,y) = 0,\ B_x(-h,y) = 0. \tag{8}$$

The magneto electrically shorted conditions are given as

$$\tau_{zx}(-h,y) = \rho' h'\ddot{w},\ \varphi(-h,y) = 0,\ \psi(-h,y) = 0, \tag{9}$$

where ρ', h' are the density and the thickness of the mass layer, respectively.

III. SOLUTION OF THE EQUATIONS

A. Solutions in the piezomagnetic layer

We consider the following solution of (4)

$$\begin{aligned}w(x,y,t) &= w(x)\exp[ik(y-ct)],\\ \xi(x,y,t) &= \xi(x)\exp[ik(y-ct)],\\ \zeta(x,y,t) &= \zeta(x)\exp[ik(y-ct)],\end{aligned} \tag{10}$$

where $k = 2\pi/\lambda$ is the wave number, $i = \sqrt{-1}$, c is phase velocity. Substituting (10) into (4), we can obtain

$$\begin{aligned}&w''(x) + k^2b^2w(x) = 0,\\ &\xi''(x) - k^2\xi(x) = 0,\\ &\zeta''(x) - k^2\zeta(x) = 0,\end{aligned} \tag{11}$$

where $b^2 = \rho c^2/c_{44}^{*} - 1 > 0$. The solutions are

$$\begin{aligned}w(x) &= Ae^{-ikbx} + Be^{ikbx},\\ \xi(x) &= Ce^{-kx} + De^{kx},\\ \zeta(x) &= Ee^{-kx} + Fe^{kx}.\end{aligned} \tag{12}$$

So for the piezomagnetic layer, we can summarize

$$\begin{aligned}&w(x,y,t) = [A\cos(kbx) + B\sin(kbx)]\cos(ky - \omega t),\\ &\varphi(x,y,t) = \frac{1}{\mu_{11}\varepsilon_{11} - g_{11}^2}\begin{Bmatrix}(\mu_{11}e_{15} - g_{11}f_{15})[A\cos(kbx) + B\sin(kbx)]\\ -\mu_{11}(Ce^{-kx} + De^{kx}) + g_{11}(Ee^{-kx} + Fe^{kx})\end{Bmatrix}\cos(ky - \omega t),\\ &\psi(x,y,t) = \frac{1}{g_{11}^2 - \varepsilon_{11}\mu_{11}}\begin{Bmatrix}(g_{11}e_{15} - \varepsilon_{11}f_{15})[A\cos(kbx) + B\sin(kbx)]\\ -g_{11}(Ce^{-kx} + De^{kx}) + \varepsilon_{11}(Ee^{-kx} + Fe^{kx})\end{Bmatrix}\cos(ky - \omega t),\\ &D_x(x,y,t) = k(-Ce^{-kx} + De^{kx})\cos(ky - \omega t),\\ &B_x(x,y,t) = k(-Ee^{-kx} + Fe^{kx})\cos(ky - \omega t),\end{aligned} \tag{13}$$

where A, B, C, D, E, F are unknowns to be determined.

B. Solutions in the piezoelectric substrate

The displacement, electric potential and magnetic potential are given as

$$\begin{aligned}w^{(m)}(x,y,t) &= A_1e^{-kb^m x}\exp[ik(y-ct)],\\ \xi^{(m)}(x,y,t) &= C_1e^{-kx}\exp[ik(y-ct)],\\ \zeta^{(m)}(x,y,t) &= E_1e^{-kx}\exp[ik(y-ct)],\end{aligned} \tag{14}$$

where $b^{m2} = 1 - \rho^m c^2/c_{44}^{m^8} > 0$, A_1, C_1, E_1 are unknown constants. So for the piezoelectric substrate, we can summarize

$$w^{(m)}(x,y,t) = A_1e^{-kb^m x}\cos(ky - \omega t),$$

$$\phi^{(m)}(x,y,t) = \frac{1}{\mu_{11}^m\varepsilon_{11}^m - g_{11}^{m2}}\begin{bmatrix}A_1(\mu_{11}^m e_{15}^m - g_{11}^m f_{15}^m)e^{-kb^m x}\\ -C_1\mu_{11}^m e^{-kx} + E_1 g_{11}^m e^{-kx}\end{bmatrix}\cos(ky - \omega t),$$

$$\psi^{(m)}(x,y,t)=\frac{1}{g_{11}^{m2}-\varepsilon_{11}^{m}\mu_{11}^{m}}\begin{bmatrix}(g_{11}^{m}e_{15}^{m}-\varepsilon_{11}^{m}f_{15}^{m})A_1e^{-kb^m x}\\ -g_{11}^{m}C_1e^{-kx}+\varepsilon_{11}^{m}E_1e^{-kx}\end{bmatrix}\cos(ky-\omega t),$$

$$D_x^{(m)}(x,y,t)=-C_1ke^{-kx}\cos(ky-\omega t),$$

$$B_x^{(m)}(x,y,t)=-E_1ke^{-kx}\cos(ky-\omega t). \tag{15}$$

IV. SOLUTION OF THE PROBLEM

From (7) we can obtain

$$\begin{aligned}
&A-A_1=0,\\
&Bm_1b-Cm_2+Dm_2-Em_3+Fm_3\\
&+A_1b^m m_1^m+C_1m_2^m+E_1m_3^m=0,\\
&A(\mu_{11}e_{15}-g_{11}f_{15})(\mu_{11}^m\varepsilon_{11}^m-g_{11}^{m2})-C\mu_{11}(\mu_{11}^m\varepsilon_{11}^m-g_{11}^{m2})\\
&-D\mu_{11}(\mu_{11}^m\varepsilon_{11}^m-g_{11}^{m2})+Eg_{11}(\mu_{11}^m\varepsilon_{11}^m-g_{11}^{m2})+\\
&Fg_{11}(\mu_{11}^m\varepsilon_{11}^m-g_{11}^{m2})-A_1(\mu_{11}\varepsilon_{11}-g_{11}^2)(\mu_{11}^m e_{15}^m-g_{11}^m f_{15}^m)\\
&+C_1\mu_{11}^m(\mu_{11}\varepsilon_{11}-g_{11}^2)+E_1g_{11}^m(\mu_{11}\varepsilon_{11}-g_{11}^2)=0,\\
&-C+D+C_1=0,\\
&A(g_{11}e_{15}-\varepsilon_{11}f_{15})(g_{11}^{m2}-\varepsilon_{11}^m\mu_{11}^m)-Cg_{11}(g_{11}^{m2}-\varepsilon_{11}^m\mu_{11}^m)\\
&-Dg_{11}(g_{11}^{m2}-\varepsilon_{11}^m\mu_{11}^m)+E\varepsilon_{11}(g_{11}^{m2}-\varepsilon_{11}^m\mu_{11}^m)\\
&+F\varepsilon_{11}(g_{11}^{m2}-\varepsilon_{11}^m\mu_{11}^m)-A_1(g_{11}^m e_{15}^m-\varepsilon_{11}^m f_{15}^m)(g_{11}^2-\varepsilon_{11}\mu_{11})\\
&+C_1g_{11}^m(g_{11}^2-\varepsilon_{11}\mu_{11})-E_1\varepsilon_{11}^m(g_{11}^2-\varepsilon_{11}\mu_{11})=0,\\
&-E+F+E_1=0,
\end{aligned} \tag{16}$$

1) The magneto-electrically shorted conditions:

$$\begin{aligned}
&(\mu_{11}e_{15}-g_{11}f_{15})[A\cos(kbh)-B\sin(kbh)]\\
&-\mu_{11}(Ce^{kh}+De^{-kh})+g_{11}(Ee^{kh}+Fe^{-kh})=0,\\
&(g_{11}e_{15}-\varepsilon_{11}f_{15})[A\cos(kbh)-B\sin(kbh)]\\
&-g_{11}(Ce^{kh}+De^{-kh})+\varepsilon_{11}(Ee^{kh}+Fe^{-kh})=0,\\
&m_1[Ab\sin(kbh)+Bb\cos(kbh)]+m_2(-Ce^{kh}+De^{-kh})\\
&+m_3(-Ee^{kh}+Fe^{-kh})=\rho' h'kc^2[-A\cos(kbh)+B\sin(kbh)].
\end{aligned} \tag{17}$$

In order to obtain the nontrivial solutions of the above-mentioned unknown constants A,B,C,D,E,F,A_1,C_1,E_1, the determinant of the coefficient matrix of liner algebraic equations (16), (17) have to be equal to zero.

2) The magneto-electrically opened conditions:

$$\begin{aligned}
&k(-Ce^{kh}+De^{-kh})=0,\\
&k(-Ee^{kh}+Fe^{-kh})=0,\\
&m_1[Ab\sin(kbh)+Bb\cos(kbh)]+m_2(-Ce^{kh}+De^{-kh})\\
&+m_3(-Ee^{kh}+Fe^{-kh})=\rho' h'kc^2[-A\cos(kbh)+B\sin(kbh)],
\end{aligned} \tag{18}$$

In order to obtain the nontrivial solutions of the above-mentioned unknown constants A,B,C,D,E,F,A_1,C_1,E_1, the determinant of the coefficient matrix of liner algebraic equations (16), (18) have to be equal to zero.

V. NUMERICAL RESULTS AND DISCUSSION

We assume that the thickness of the piezomagnetic layer is 0.1mm in calculation. It is supposed that the unknown constant $A=10^{-9}m$ to make the displacement results understood easily.

Figs.2-5 are presented here in order to illustrate the effect of the thickness of the mass layer on the phase velocity and the displacements. We assume the density of the mass layer is $3.6\times10^3 kg/m^3$. We can find that both velocity and the displacements decrease with increase of thickness of the layer.

Figs.6-9 are presented here in order to illustrate the effect of the density of the mass layer on the velocity and the displacements. We assume the thickness of the mass layer is $h'=0.0002mm$. The results show that the velocity and the displacements also decrease with increase of the density of the layer.

VI. CONCLUSIONS

An analytical approach is taken to investigate SH wave propagating in layered piezomagnetic/ piezoelectric structure where a thin piezomagnetic film with a mass layer bonded to a semi-infinite piezoelectric substrate. The results show that the thickness and the density of the mass layer have significant effect on the phase velocity of SH waves and the distribution of the displacements. The results show that the phase velocity and displacements decrease with the increase of the thickness and the density of the mass layer for both electrically opens and shorted cases.

***Abstract*— We transfer the frequency of an ultra-stable laser over a 470-km optical link comprising 400 km of public telecommunication fiber network, simultaneously carrying data traffic. A dense wavelength division multiplexing scheme is used. The ultrastable signal is inserted in and extracted from the communication network using bidirectional optical add-drop multiplexers. The link passes through two important nodes of the telecommunication network and an amplification stage. The phase noise on the optical link is compensated with the usual round-trip technique. The 470-km multiplexed link shows an Allan deviation of 5×10^{-15} at one second and 1.3×10^{-18} after 1 hour. This work paves the way to a wide dissemination of ultra stable optical clock signals between distant laboratories via the Internet network.**

I. Introduction

The transfer of ultra-stable frequency signal between distant laboratories is required by many applications in time and frequency metrology, fundamental physics, particle accelerators and astrophysics [1-8]. Stable radio and microwave frequencies transmission over an optical link has already been demonstrated [2-5,9-12]. Frequency transfer using the optical phase of an ultra-stable laser over a dedicated fiber link was reported on distances up to about 200 km by several groups [13-19]. The present challenge is to extend this technique of frequency dissemination on longer distances in order to connect laboratories of different countries.

For this purpose, we have recently developed a novel dissemination approach over non-dedicated fibers [20, 21]. We take advantage of the existing Internet fiber network, already connecting every laboratories via the National Research Networks. The ultra-stable frequency signal is propagating simultaneously with the Internet traffic in the same fiber using one dedicated wavelength in a dense wavelength division multiplexing (DWDM) approach.

With Internet fibers, we have a very limited control on the fiber network and the attenuation and noise is likely to be higher than with dedicated fibers, which can limit the transfer to a few hundreds of km. For longer distances, we have foreseen the segmentation of the link into several cascaded sections. In that case, a repeater station should be used between the different segments of the link. This multiple sub-link approach allows for an increased correction bandwidth and robustness regarding attenuation.

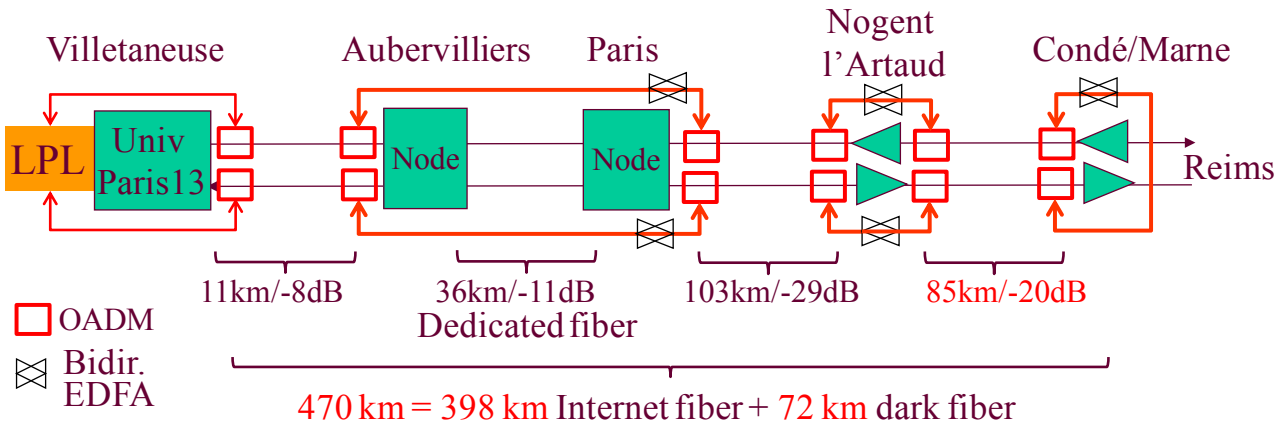

Figure 1. Scheme of the 470 km multiplexed optical link

II. MULTIPLEXED OPTICAL LINK

We have demonstrated a first implementation of a 470-km multiplexed optical link using the French National Telecommunication network for Technology, Education and Research (RENATER).

The overall scheme of the 470 km-long optical link (LPL-Condé sur Marne-LPL) is depicted in Fig. 1. Concerning the ultrastable signal transmission, round-trip propagation of the optical signal is required over the same fiber for noise compensation. For that purpose we use bidirectional off-the-shelf optical add-drop multiplexers (OADM). Such three-port component can insert or extract the 1542.14 nm wavelength from the other wavelengths, with isolation better than 25 dB for an adjacent channel (100 GHz) and better than 40 dB for other channels. Twelve OADMs are used along the link to insert and extract the ultrastable signal.

This link starts and ends at LPL laboratory, at Université Paris 13, in the north surroundings of Paris. It is composed of three different fiber spans. The first span is composed by two 11 km-long fibers connecting the information service and technology center of Université Paris 13 to a Data Centre Facility located in Aubervilliers (Interxion1). The digital stream between Université Paris 13 and Aubervilliers is encoded over an optical carrier on the channel #34 (1550.12 nm) of the International Telecommunication Union grid (ITU) whereas the ultrastable signal is carried by the channel #44, at 1542.14 nm. The second span is composed of two 36 km-long dedicated dark fibers which connect the two Data Centre Facilities of Interxion 1 and TeleHouse 2, downtown Paris. The third span is composed of two 188 km longhaul intercity fibers simultaneously carrying internet data traffic. In this part the digital data signal are transferred over two channels #42 and #43, only 0.8 nm and 1.6 nm away from the ultrastable signal. Moreover, this span includes two amplification stages for the data transfer, at Nogent l'Artaud. We have installed two OADMs linked with a bidirectional amplifier to bypass this amplification stage, enabling a selective bidirectional amplification of the ultrastable signal. At Condé sur Marne the reference signal arriving from one fiber is sent into the other 235 km-long fiber back to Université Paris 13. Figure 2 depicted the OADMs and amplifiers modules installed at Condé sur Marne.

Figure 2. OADMs and bidirectional amplifiers inside the shelter of Condé sur Marne

Total attenuation along the link is more than 136 dB due to the large number of connectors and the OADMs. In order to overcome the round-trip link losses, we used five bidirectional Erbium-doped fiber amplifiers.

III. EXPERIMENTAL RESULTS

The optical phase noise power spectral density of the 470-km optical link is shown in Fig. 3, without and with compensation. The phase noise reduction is around 40 dB at 1 Hz.

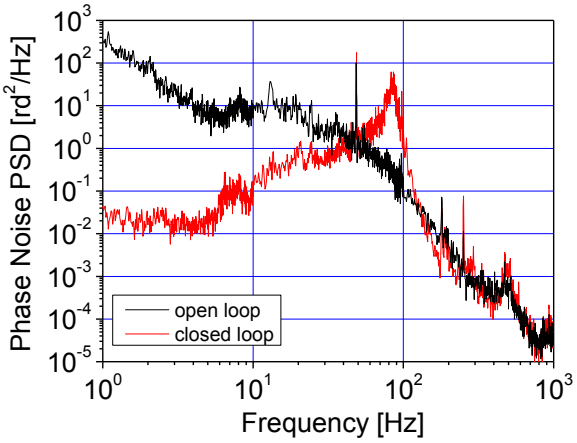

Figure 3. Phase noise power spectral density of the free running (black line) and compensated 470-km link (red line)

Fig. 4 shows the fractional frequency stability (Allan deviation) of the 470 km link for about 15 hours of continuous operation, measured with a Π-type frequency counter. The free-running fiber frequency noise (black circles) is measured simultaneously using the compensation signal applied to the AOM. For a measurement bandwidth of 10Hz, the Allan deviation is 5×10^{-15} at 1 s averaging time and scales down as $1/\tau$ from 1 s to 8000 s reaching 7×10^{-19}. With the full bandwidth the Allan deviation is 5 times larger.

IV. CONCLUSION

We demonstrate the ultra stable transfer of an optical frequency over 470 km of installed optical fibers. This ultrastable optical link uses an optical telecommunication network simultaneously carrying Internet data and goes through one amplification stage and two Data Center Facilities using multiplexers and bidirectional erbium-doped fiber amplifiers. We have obtained link instability of 5×10^{-15} at 1 s

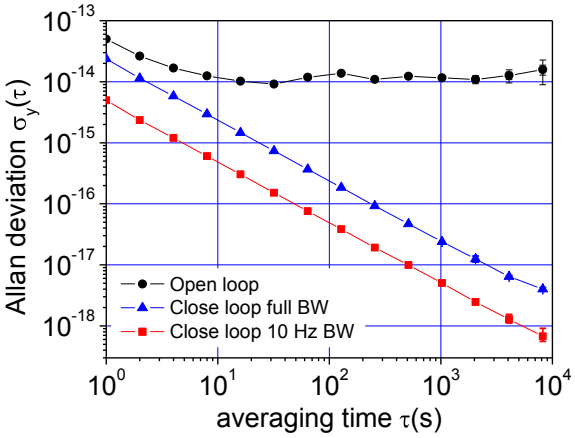

Figure 4. End-to-end fractional frequency instability of the 470-km free running optical link (black circles), and compensated link measured without (blue triangles) and with a 10 Hz filter (red squares)

which scales down to around 1.3×10^{-18} after 1 hour, in a measurement bandwidth of 10 Hz. These results are promising and represent an intermediate step for the future development of continental-scale frequency transfer.

Abstract— **Several communication systems of today rely on the real time accessibility of accurate time and frequency measures and there is an increasing demand for the development of new and redundant methods for the distribution of these measures. The classical two-way method is able to compensate for the inevitable variations in the time and frequency propagation delay. The two-way method is used for time transfer in free space, electrical or optical domain, but has the disadvantage of often using two different paths for transmitting back and forward. The paths may be of equal length and have equal propagation delay, but nevertheless there is often a remaining asymmetry in the propagation paths. The inevitable asymmetry between the paths in the time transfer delay must be detected and compensated for, if an accuracy better than µs-level is needed for transmission distance exceeding a few km. Furthermore, if the number of users is high, there will be a complex and large network of two-way time signal transmissions. Therefore, a solution using one-way broadcasting would be more desirable, and would be possible if the variations in transmission time could be estimated from the received data at the far (user) end. The one-way method uses only one path of transmission and is possible to implement in existing Wavelength Division Multiplexing-networks.**

Proof of concept and results of this one-way time transfer technique based on transmission of a repetitive signal, modulated on two lasers at different wavelengths 8 nm apart and transmitted through an optical fiber, has been presented previously. These data showed a strong correlation between a change in transfer time at one wavelength, and the transfer time difference for the signals at the two wavelengths.

In this paper, the setup and the measurement results have been improved and new data is collected which shows improvement in the reliability and quality of this technique. The stability is improved through component analysis and minimizing error sources. The distance is improved from 38km to 160km.

I. INTRODUCTION

The development of new communication systems and evolution of existing ones has increased the need for precise time and frequency transfer. These transfers often exceed baselines of 100km and GPS is the common technical solution. The main benefit with GPS is that it is easy to install, but it is a single point of failure. Time and frequency transfer utilizing optical fiber is a good alternative to GPS since there in many countries already are existing networks and it does not rely on transmission over radio waves in open air. Several transfer methods using optical fibers has been developed or are under development **[1-4]**, using dedicated fibers or already existing fiber networks. Performance is often the limiting aspect in the choice of transfer method, where the long term stability relies on an accurate estimate of the variations of transfer delay. A common way for high performance transfer is the two-way method, which is an excellent method when the user has easy access to the whole system and when both transmission paths are equal. For the best results both directions in the transfer should operate in the same transmission line to be able to cancel out transmission path delays.

The method can be implemented very efficiently when

978-1-61284-110-6/11/$26.00 ©2011 IEEE

operating on existing data traffic **[5-6]**, however when data format or other limitations require that the time and frequency transfer must operate on dedicated communication channels, the techniques' administration scales with the number of users and becomes capacity consuming.

This paper presents a technique for one-way time transfer utilizing dual wavelengths and the difference in group velocity to estimate the delay variation of the timing signal in one of the wavelength channels. The first proof-of-concept was previously presented **[7-8]**, using modulated lasers at 1310nm and 1550nm and **[9]** wavelengths at 1535 and 1553nm. Those results showed that it is possible to perform a one-way time and frequency transfer with two wavelengths and by evaluate these two against each other, create a correction signal for compensation for influences along the transmission path.

To enable long distance baselines, the optical signal must be possible to amplify. It is also desirable to cover both wavelengths inside the optical C-band (1530 – 1560nm) and for the purposes of using the existing fiber network operate within one band, i.e 8nm.

This evaluation is therefore performed with two wavelengths 8nm apart and the presented result show that it is possible to perform a one way time and frequency transfer if two wavelengths within the same transmission band are used. By evaluation of these two against each other, is it possible to create a correction signal for compensation of transmission time variations using a 160km fiber including Erbium doped fiber amplifiers (EDFAs).

II. BACKGROUND

The occurrence of asymmetry in many two-way transfers is due to many components such as ageing, connector connections and different length in the transfer paths and equipment in and between the nodes. With this classic transfer method as reference point, this paper will discuss a different method based on a single path.

Standardization of single way time transfer is done in the IRIG-B system, and there are commercial fiber based frequency transfer systems available. Neither of these does however take variations in transfer time into account, mainly because they are supposed to work over short distances and not with high time transfer accuracy.

When the distance increase and a large amount of the transmission media is outdoors the temperature will vary along the path as well as the propagation properties of the material. Even fiber below ground is known to experience temperature variations of 20°C over the year **[10]**, and if some sections of the fiber distance are installed along the power grid through air-lines, the propagation delay variation will be even worse, as the variations will follow the air temperature. However, if that is the case, not only the transfer time changes, but also the dispersion, which can be measured at the receiving end of the fiber, and the correlation between these two parameters can be used. The measurement technique for fiber dispersion is well known **[11]** and the variation with respect to temperature have been studied previously **[10, 12].** Nevertheless, the correlation to the time transfer delay has not yet been fully investigated or utilized for time transfer until the first presentations of this work **[7]**.

In a fully operational solution, the time from the Master clock can be distributed to a network of Slave clocks, with a precision better than what would be the case if a single signal was transmitted.

For the one-way time transfer illustrated in Figure 1, there is a time varying part associated with ΔT_A as also is included in Equation (1). Even though the average transfer time can be taken into account through a calibration, the time varying part will pose as an uncertainty unless it continuously is measured and compensated for.

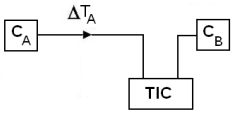

Figure 1. The figure is a sketch of a one-way time transfer between clock A (C_A) and clock B (C_B).

$$C_A\text{-}C_B=TIC\text{-}\Delta T_A(t) \quad (1)$$

A proposed method to solve for $\Delta T_A(t)$ is by transmitting two wavelengths in the same fiber and detect the propagation delay differences between these **[13-16]**. The difference is then applied as a correction term for the delay variations in $\Delta T_A(t)$ **[7-9]**. Development of this one-way transfer method with enhanced stability has resulted in transfer quality well comparable with well established two-way methods.

Furthermore it is operating within the C-band of commercial Dense Wavelength Division Multiplexing-networks (DWDM-network) for distances >100km. The reason for using the C-band is that the commonly used Erbium Doped Fiber Amplifier (EDFA) has a flat gain spectrum between 1530nm and 1560nm. Previously presented experiments **[7-9]**used two wavelengths more than 18nm apart, while this evaluation operates 8nm apart. The used wavelengths corresponds to ITU channel 21 (1558.983nm/192.3THz) and 41 (1550.918nm/193.3THz) in a DWDM system.

III. THEORY

The theory for single way dual wavelength optical fiber time and frequency transfer is based on the transit time τ for propagation of a single mode in a fiber **[17]** expressed as the group velocity for a certain distance L and the wavelength λ.

$$\tau = \frac{L}{c}\left(n - \lambda \frac{dn}{d\lambda} \right) \quad (2)$$

Where n is the refractive index and c is the speed of light in vacuum. The transfer time τ, sometimes known as the group delay time in a fiber, is thus dependent on the refractive index and the wavelength. This means that two different

wavelengths will propagate at different velocity in the same fiber. A standard single mode fiber is temperature dependent, to an extent shown in previous studies **[10]**, and the most important factor to include in the calculations. By calculating the derivative of the transfer time with respect to temperature, both wavelength and refractive index will be taken into account **[9]**. Polarization mode dispersion is omitted since it is small compared to chromatic dispersion over the wavelength span. The variation in transfer time as a function of temperature can thus be calculated **[9]** and that expression shows how the refractive indices of the two wavelengths are influenced by temperature, and based on this the variations in the time transfer delay can be calculated. The time transfer technique uses the property that the variations are different, but correlated, which also is supported by experimental results.

The difference in transfer time through the fiber is dependent on the variation of length, L, and the variation in refractive index, n. Both these effects will affect the chromatic dispersion of the fiber, but through different properties.

The refractive index of the fiber can be described by the Sellmeier equation **[18, 19]**

From the Sellmeier equation and empirical data for fused Silica (SiO2) **[19]** the material dispersion can be calculated with the notation that it may be slightly offset in communication fibers where the silica is doped with small amount of other substances. Nevertheless the overall behavior is comparable. It is possible to estimate the amount of time transfer delay variations with respect to temperature. Assuming a fiber where material dispersion is dominant (as is the case in standard single mode fiber), at a length of 20 km and measurement at 1530 nm and 1560 nm **[9].** The slope of such calculated dispersion is -0.0016 ps/(nm·km·°C), which is comparable to previously reported results -0.0025 ps/nm/km/°C for non-zero dispersion shifted fiber (NZDSF) and -0.0038 ps/nm/km/°C for large core fiber**[10]**.

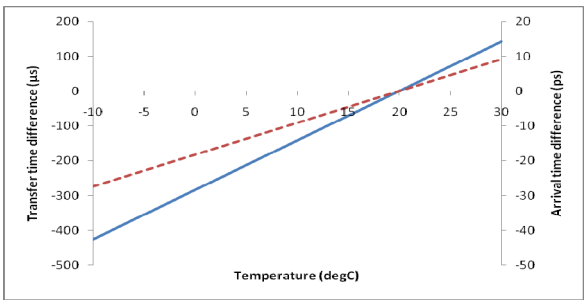

Figure 2. Temperature dependence of transfer time (solid blue, left axis) and arrival time difference (dashed red, right axis)

The solid curve (left axis) shows the calculated time transfer delay for a signal at 1530 nm, and the dashed curve shows the arrival time difference for two signals at 1530 nm and 1560 nm. Both curves are normalized with respect to the value at 20°C, and it is apparent that the time transfer delay within a single, 20 km long fiber varies with almost 0.5 ms when affected by 40°C temperature difference. This variation can be detected and compensated for, using transmission at two wavelengths and a measurement system that can measure time variations on picoseconds level with sufficient precision.

This evaluation assumes that the cabling or mounting will stretch the fiber at increasing temperature, however leaving the volume intact. The variations in dimensions of the glass are assumed to be negligible. If the core of the fiber is modeled as a glass cylinder, of length L and diameter d, a geometrical approach gives that the variation in temperature will change the length with $\Delta L(T\text{-}T_0)$ and the diameter with $\Delta d(T\text{-}T_0)$, such that

$$\frac{\Delta d(T-T_0)}{d} = -\frac{\Delta L(T-T_0)}{2L} \tag{3}$$

where T is the temperature and T_0 is the reference temperature.

This change in diameter will change the dispersion according to the variation in waveguide dispersion **[20, 21]**:

$$D_W(\lambda) = -\frac{n_2\Delta}{c\lambda} V \frac{d^2(Vb)}{dV^2} \tag{4}$$

where n_2 is the refractive index of the cladding and Δ is the relative difference of refractive index in the core and in the cladding. V and b are the normalized frequency and the normalized propagation constant, respectively, and can be found through:

$$V = ka\sqrt{n_1^2 - n_2^2} \cong kan\sqrt{2\Delta} \tag{5}$$

$$b = \frac{(\beta/k)^2 - n^2}{n_1^2 - n_2^2} \tag{6}$$

where k is the free-space propagation constant, β is the propagation constant and $a = d/2$ is the fiber core radius. From these equations, it is apparent that fibers with notable waveguide dispersion, e.g. dispersion shifted fibers, dispersion compensating fibers, etc, will have different response to a change in diameter d, than standard fibers where material dispersion is dominant. However, this response must be evaluated for each fiber design, since the term $V(d^2(Vb)/dV^2)$ is between 0 and 1.2 with a maximum at V≈1.2. These equations show nevertheless that the system of detecting a variation in transfer time through a fiber with substantial waveguide dispersion is possible, but must be optimized for the actual fiber parameters.

IV. EXPERIMENTAL AND REFERENCE SETUP

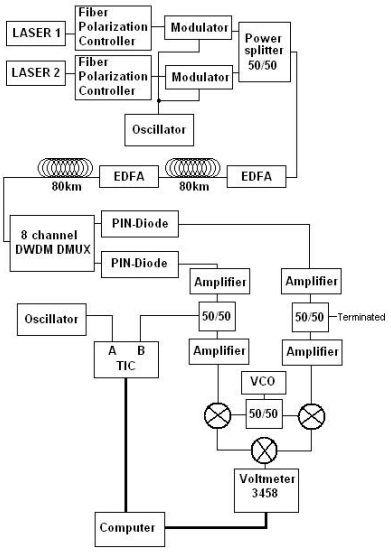

Figure 3. Experimental setup. The PIN-diode includes an electrical trans-impedance amplifier. Amplifiers are electrical amplifiers, 3458 a digital voltmeter and TIC is a time-interval counter

A combination of the experimental setup and the equipment for the verification of the proposed time and frequency transfer technique is shown in figure 3. Two CW lasers at wavelength 1551 nm and 1559 nm are after polarization controllers modulated in separate Mach-Zehnder modulators by a 10MHz reference oscillator, after which the modulated light waves are launched into the SMF through a 50/50 power combiner. The reference oscillator is frequency stabilized by an Auxiliary Output Generator (AOG) connected to a Hydrogen-maser as the Master clock. For this evaluation is the oscillator also used as reference to the measurement equipment, connected as an external oscillator to the Time Interval Counter (TIC), in order to evaluate the one-way technique. The total sum of the two spools of fiber that is in use was measured with an OTDR (optical time-domain reflectometer) to be 2x80km. Added to this length is 188m of transfer fiber between the lab and the outdoor fiber spools. The fiber path starts and ends in the laboratory for evaluation. The use of several fiber spools instead of one creates a similar case to a commercial link, which will be assembled of multiple fibers spliced by connectors, and there is no possibility to know the ageing of all optical fiber along this.

At the receiving end the two wavelengths are separated in an 8-channel Dense Wavelength-Division Multiplexing Demultiplexer (DWDM DMUX), and detected in two 10 Gb/s p-i-n receivers. The signals are amplified and connected to the Radio frequency (RF) ports of two double balanced mixers. One of the signals passes a power splitter that is connected to the reference TIC, which measures the total transfer time as reference. The output of the TIC is interpreted as the precision of an uncompensated single way time and frequency transmission.

By measuring the voltage changes from a third mixer connected to the other two mixers is a correction signal achieved and can be used for a real-time delay control of the uncompensated signal. Most of the equipment is housed in a laboratory with controlled environment, except the spools of SMF28 which is placed outdoors inside a box for emulation of an actual environmental condition.

The 8-channel DWDM DMUX has a built in optical filter function that is used for separation of the two wavelengths. Measurement equipment detects the two 10MHz sine waves after propagation through the fiber link, amplifies and compares with a reference signal, as shown schematically in Figure 4.

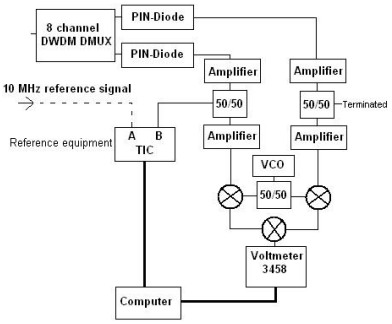

Figure 4. Schematics of the receiver and reference signal placed in the laboratory. The reference signal is compared to the information received from the transmitted wavelenghts

The output signals from the mixer connected to the voltmeter are calculated in Equation (8) and low pass filtered, which results in Equation (9).

$$\omega = \omega_1 = \omega_2 \tag{7}$$

$$M_v = \frac{A_1 A_2 A_L^2}{8}\left(\begin{array}{l}\cos\left(\left(\alpha_1 - \alpha_2\right)(t)\right) + \\ \cos\left(\left(2\left(\omega + \omega_L + \alpha_L\right) + \alpha_1 + \alpha_2\right)(t)\right)\end{array}\right). \tag{8}$$

Low pass filtering

$$M_v = \frac{A_1 A_2 A_L^2}{8}\left(\cos\left(\alpha_1(t) - \alpha_2(t)\right)\right). \tag{9}$$

This means that the measured result from the voltmeter must be corrected for according to Equation (9).

V. RESULTS

A major goal for this experiment was to resemble a fiber optical telecommunication network with a distance longer than 100km and these goals were fulfilled in the experimental setup. The experimental system consisted of a transmission side with lasers tunable within the optical C-band that was connected to fiber polarization controller and later on modulated with 10MHz. The transmission path consisted of a

preamplifier that is a EDFA followed by 80km of standard single mode fiber SMF28, then another EDFA followed by 80km SMF28. On the receiver side an 8-channel DWDM DMUX was used for separation of the two propagated wavelengths after which p-i-n-diodes were used for conversion to electrical domain. The transmitted wavelenghts are only 8nm apart to be able to fit within a single band in the proposed fiber optical university network of Sweden. After conversion to the electrical domain the improved mixer solution is used for extraction of delay difference in propagation, and time interval measurements are made as reference comparisons and verification. Transmitter and reciver are placed in laboratory enviroment as well as the EDFAs while the 160km of transmission fibers were placed outdoors in a container for enviromental impact. The temperature is also logged using an outdoor temperature sensor.

The results are extracted from a dataset of 10 days in the end of March and beginning of April 2011 and are displayed in figures 5 and 6. Time interval measurements in these figures are corrected for jumps as the output range is 0-100 ns, while the mixer solution is set to have a initial calibration at the start to be able to calculate the fiber path parameters that would not be possible to measure in a system spread over a large distance. This calibration is presumed necessary for every individual system. The mixer solution is in this experiment also set to have an initial startup period of 4 hours of which are spend to create a running average, aimed to reduce the noise. Furthermore, the mixer solution is scaled to be able to be evaluated versus the TIC measurements and a graph displaying these data is shown in Figure 5.

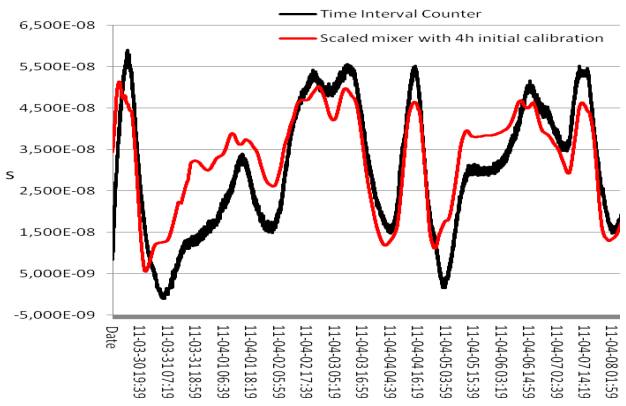

Figure 5. Data from the outputs of the mixer (red curve) and the time interval data represented by the reference TIC (black) is plotted from data during ten days of measurement

A similar behavior between the mixer solution and the reference TIC is read out from figure 5. The graphs in figure 6 include the curves in figure 5 which are plotted against the outside temperature. All three curves confirm a similar behavior. The mixer solution is scaled by a factor of 3 µs/V and has a offset of 15 ns. The standard deviation between the TIC graph and the Mixer graph is 8.45 ns.

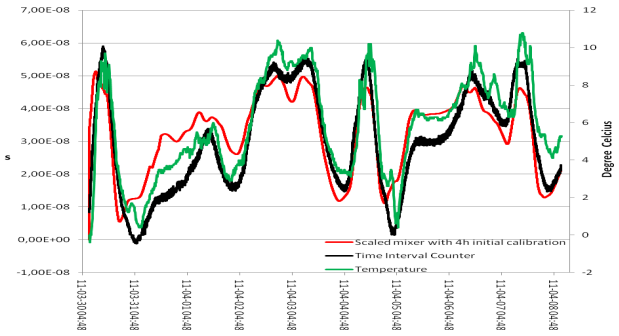

Figure 6. Data from the outputs of the mixer (red curve) and the time interval data represented by the reference TIC (black) is plotted togheter with the outside temperture

To be able to compare the to solutions properly, the original raw data without applicated smoothing should be plotted, and that is displayed in figure 7.

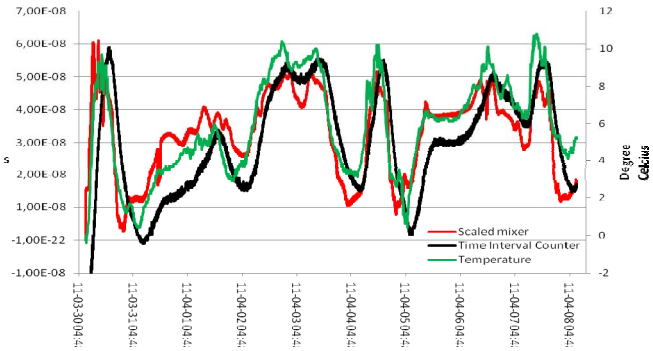

Figure 7. Rawdata from the outputs of the mixer (red curve) and the time interval data represented by the reference TIC (black) is plotted togheter with the outside temperture

By comparing TIC and Mixer data with the outside temperature there are evidence that the TIC add some delay and internal smoothing of the data. Further investigations of these equipment related issues have to be performed.

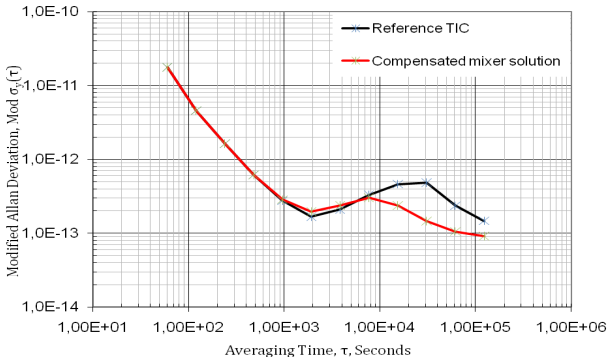

Figure 8. The stability of the reference TIC (black curve) and the scaled compensated mixer solution (red curve)

The stability of the TIC-data and the newly improved scaled compensated mixer solution are plotted as the Modified Allan Variance in figure 8. In the previous experimental setup **[9]** the whole system was affected by white phase noise in the short term and a bump between 500s to almost 4000s was assumed to be noise added from the mixers, amplifiers, long coaxial cables and the voltmeter, but also due to the simple correction algorithm.

A large effort has been made into reducing these noise sources and the result can be seen in figure 8 where the whole bump has disappeared. According to the figure the two systems are comparable up to the vicinity of 5500 seconds. At longer time scales it seems as the mixer systems with compensation is more stable.

VI. CONCLUSION

It is experimentally verified that it is possible to perform a one-way time and frequency transfer of optical single mode fiber with continuous estimate of delay variations. The technique is based on transmission over two wavelengths, separated by 8nm and both residing in the C-band of optical communication. By evaluating the phase difference between these time transfer delay of two signals, a correction can be applied to compensate for the unwanted delay variations along the transmission path.

This experiment has shown proof of concept for long baselines measurement, i.e. distances larger than 100km. Future work includes development of a physical real-time correction component at the end of the link that incorporates the steering signal based on the measured difference between the arriving signals at the two wavelengths. Also there is still some work to be done in reducing the noise in the receiver as well as creating a startup algorithm and a calibration algorithm for the mixer solution. Unlike previous experiments **[7-9]**, many components in the system are replaced e.g, the laser changed to telecom products for DWDM system, and the optical filters and the power splitter at the receiver end are replaced by an 8-channel DWDM DMUX. The transmission fibers are exchanged from 38km to 160km. These changes have resulted in less noise and a more stable system that is possible to incorporate in one band of an active data DWDM-system for evaluation. Nevertheless there are some evaluation of the mixer solution and the TIC that remains.

Abstract— **We will discuss our work on a one-way optical fiber frequency transfer system. The link removes thermally generated delays through sensing the difference in temperature dependent changes in the group index of the fiber for two wavelengths. The system monitors the phase difference between two amplitude-modulated lasers at the edges of the C-band. Using this signal, a temperature controlled spool of fiber compensates for thermally induced phase excursions in the link. We will present preliminary results as well as a discussion of performance limitations.**

I. INTRODUCTION

As atomic clock technology has progressed, great improvements in stability and accuracy have been achieved. Atomic fountain clocks have short-term stabilities in the upper 10^{-14}'s at one second and integrate down to the low 10^{-16}'s in a day [1]. Newer optical clocks are reaching short-term stabilities in the low 10^{-15}'s and averaging down into the 10^{-17}'s in an hour [2]. It is necessary to have a time and frequency transfer method capable of supporting this level of performance.

One of the standard ways of transmitting time and frequency is through two way satellite time and frequency transfer (TWSTFT). While it is practical for transmitting time and frequency over long distance, the performance is not acceptable for some of the newer high quality clocks. Currently, TWSTFT can transmit frequencies with instabilities at the 10^{-15} level and time at the 1ns level after a day of integration [3]. It is clear that to transfer stabilities achieved with modern atomic clocks, both microwave and optical, better transfer methods are needed.

One possibility is time and frequency transfer through fiber optic links. There are many promising aspects for using fiber optic links. First, there is an existing infrastructure that provides a large network for transferring time and frequency. The links are low loss over large distances and are well isolated. The access to a common return path allows for measurement and compensation of phase fluctuations. Finally, there is great potential for scalability in fiber optic networks.

Most methods for transferring time and frequency along fiber links involve establishing a two way link. The timing signal is sent down the link and then returned to the transmitting station. At the transmitting station, the phase variation brought about by fiber noise are measured and corrected for. One approach is to use an amplitude modulated signal. Short-term stabilities of 10^{-15} integrating down into the low 10^{-18}'s have been demonstrated [4]. Another approach involves using the phase of the optical carrier itself. Excellent performance has been achieved with short-term stabilities in the 10^{-16}'s averaging down to the 10^{-19}'s in a day [5]. An in depth overview of fiber transfer techniques can be found in [6].

Here we present results on a different type of fiber optic link. This is a one-way temperature compensated fiber link [7]. A one-way, amplitude modulated signal is transmitted along the fiber along with a proxy for measuring the temperature. The proxy signal is then used to compensate for temperature induced phase fluctuations along the link. This approach differs from the previous methods in that it is a one-way transfer. Bidirectional access to the fiber is not necessary as in the case of two-way links. Also, the ability to build simpler broadcast networks exists with improved scalability.

This one-way transfer method relies on measuring temperature indirectly. We use the phase difference between two separate colors propagating along the fiber to determine temperature. This is due to the temperature dependence of dispersion in fiber. All materials have an index of refraction for light and exhibit dispersion, meaning that the index is wavelength dependent. But in addition to being wavelength dependent, the index is also temperature dependent.

We can model the index of refraction for fiber by using the Sellmeier coefficients for fused silica [8]. In particular we can use temperature dependent coefficients to see the expected temperature dependent features. The temperature dependent index of refraction has the following form

$$n^2(\lambda, T) - 1 = \sum_{i=1}^{3} \frac{S_i(T) \cdot \lambda^2}{\lambda^2 - \lambda_i^2(T)} \qquad (1)$$

where

$$S_i(T) = \sum_{j=0}^{4} S_{ij} \cdot T^j \qquad (2)$$

and

$$\lambda_i(T) = \sum_{j=0}^{4} \lambda_{ij} \cdot T^j. \qquad (3)$$

The S_i coefficients are determined by the strength of resonance features that occur within the fiber at wavelengths λ_i. A thorough description of this model as well as the complete set of values for the different coefficients can be found [8].

Based on this model, we can calculate the time delay for a pulse or any amplitude modulation feature traveling down the fiber at a given wavelength and temperature. If we have two pulses at two different colors traveling down the fiber at a given temperature, they will arrive with a fixed time difference. As the temperature changes, that time difference changes based on the changing index of refraction. This is shown in Figure 1.

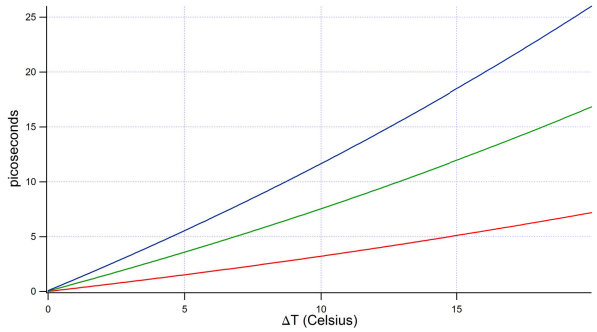

Figure 1. Temperature dependent phase shifts. Calculate results for the changing time delays between two pulses at different colors transmitted on 1km of single mode fiber as the temperature of the fiber changes. Blue corresponds to light at 1530nm and 1565nm. Grey is 1530nm and 1553nm. Red is 1530nm and 1540nm. Increasing wavelength separation gives increasing sensitivity to the temperature dependent phase shift.

From this we see that it is possible to derive a change in temperature in the fiber by measuring the change in time delay between two different color signals. We can use this indirect temperature measurement as a means of compensating for temperature induced phase changes in the fiber. Note that this method only compensates for temperature induced effects. It will not compensate for any mechanically induced phase fluctuations.

II. Experiment

As has been shown, it is possible to use the time delay between pulses at two different colors as a proxy for temperature measurements of a fiber link. Instead of measuring time delays between pulses, the phase change between two amplitude modulated signals were measured. The experimental setup to measure is described in the following and shown in Figure 2.

A master oscillator at 5MHz drives the system on the transmit side. For testing purposes this is just a high quality crystal oscillator. That 5MHz signal is multiplied up to 100MHz. The 100MHz signal feeds a phase locked dielectric resonant oscillator to produce a signal at 6.8GHz. This signal is split and used to modulate two transmit laser modules.

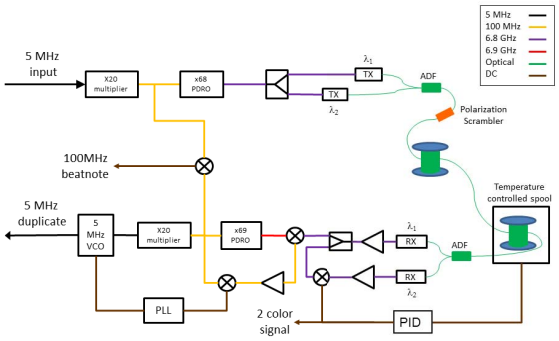

Figure 2. Experimental setup.

The transmit modules are laser diodes with electro-absorptive modulators operating at λ_1 = 1530nm and λ_2 = 1553nm. The two signals are combined onto one fiber using and add/drop filter. The signal then goes through a polarization scrambler. It was experimentally verified that the two color signal has a strong dependence on any birefringence due to residual stress in the fiber. By scrambling the polarization, the signal is averaged over all polarization states and that sensitivity is reduced.

At this point the laser signal travels down the link. For testing purposes, this link is a spool of fiber residing in an environmentally controlled chamber. It was possible to adjust the length of the link from 1m to 30km.

After passing along the link, the signal enters the receive station. The first stage of this station is a temperature controlled spool. The spool consists of 5km of bare single mode fiber wound on an aluminum mandrel. The spool is placed in an insulated box and is temperature controlled using a TEC and commercial temperature controller.

After the temperature controlled spool, the two wavelengths are separated using another add/drop filter and fed to two separate fiber coupled photo receivers. The outputs of each receiver are amplified with a high gain microwave amplifier. The 6.8GHz modulation signal at wavelength λ_1 is split with one half mixed with the entire signal at wavelength λ_2. The change in phase between the two colors' AM signals is the previously described two color signal. The two color signal is amplified and fed to a PI controller. The PI controller determines the set point for the temperature controlled spool to cancel temperature induced fluctuations in the fiber.

The second half of the signal at wavelength λ_1 is used to phase lock a high quality 5MHz quartz crystal to the transmitted signal. The 5MHz signal from the quartz crystal is

multiplied up to 100MHZ and then fed to a phase locked DRO to produce 6.9GHz. The 6.8GHz signal is mixed with the 6.9GHz signal to create a 100MHz signal which is then mixed with the intermediate 100MHz signal in the send station. This error signal is then used to phase lock the crystal to the transmitted signal, completing the clock recovery at the receive station.

In order to test the stability of the transmitted signal, a portion of the 100MHz signal from the transmit station and the send station are mixed together. The resulting beat note is recorded with an analog to digital convert and later analyzed for stability.

III. Results and Conclusions

A first test was to measure the size of the two color signal as a function of temperature change. A 5km spool of fiber was used for the link. The environmental chamber cycled the temperature with 4°C linear ramps every two hours. The PI controller for the compensation spool was turned off, and the temperature set at a fixed value. The two color signal was recorded as was the 100MHz beat note between the transmit and receive stations.

Figure 3 show the results of the measurement. As can be seen, as the temperature changes, there is a change in the relative phase between the transmit and receive stations. For the given link length and temperature difference this is approximately 300ps. Likewise, a phase change in the two color signal is evident, although with a lower magnitude. For the same length and temperature change, the phase change is about 1ps. There is excellent correlation between the 100MHz beat note phase change and the two color signal phase change. The lever arm, or ratio of actual phase change to two color signal phase change, is about a factor of 300. This is an important value in that any noise on the two color signal will get multiplied by the lever arm and written on the actual signal.

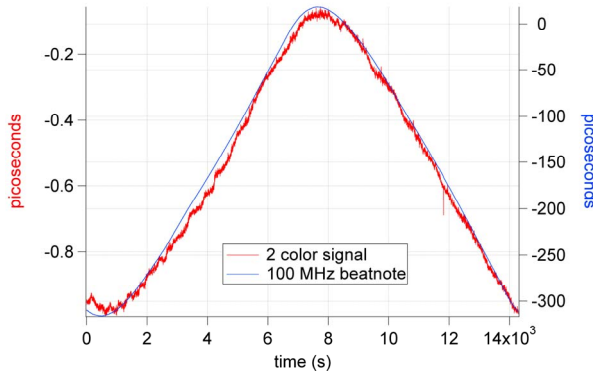

Figure 3. Lever arm measurement. The phase change for the two color signal (red) and the 100MHz beatnote (blue) as a function of changing temperature. The two color signal changes by approximatel 1ps while the 100MHz beatnote changes by over 300ps.

As a note, these results were achieved after ensuring similar fiber throughout the link. The scheme relies on a direct correspondence between temperature and expansion since the actual phase variations are not measured [9]. This means that the coefficient of thermal expansion must be constant for the entire link otherwise different temperature changes give rise to different phase variations. Therefore, bare single mode fiber was used throughout the experiment.

The next test was to use the temperature controlled spool to cancel out the temperature induced phase fluctuations and lock the link. The same 5km spool was used for the link and the same cycling conditions were used in the environmental chamber. The PI controller was turned on and used to adjust the temperature of the compensation spool. The net effect was to drive the two color signal to zero.

The results of locking the link are shown if Figure 4. The link was locked for approximately one day. The two color signal held constant near zero while there are small fluctuations on the 100MHz beat note. For comparison, the link was unlocked, denoted by the black vertical line in Figure 4, and allowed to run for about one day. It is clear that the two color signal as well as the 100MHz signal have much larger phase variations when unlocked.

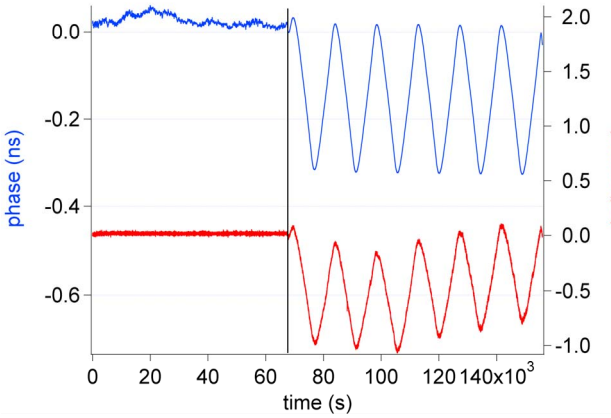

Figure 4. Locked and unlocked link performance. The plot in blue is the 100MHz beatnote signal and the plot in red is the two color signal. The first half of the data set corresponds to the link being locked and compensated. At the black line, the compensation is turned off.

Figure 5 shows the stability of the locked and unlocked links when the environmental chamber is cycling. The Allan deviation is plotted for both situations. First, consider the unlocked case. The stability starts of at 6×10^{-14} at 1 second. It integrates down as $1/\tau$ until about 100 seconds. At that point, the effects of temperature cycling become apparent causing the stability to increase as τ with a peak at half the cycling time of 2 hours.

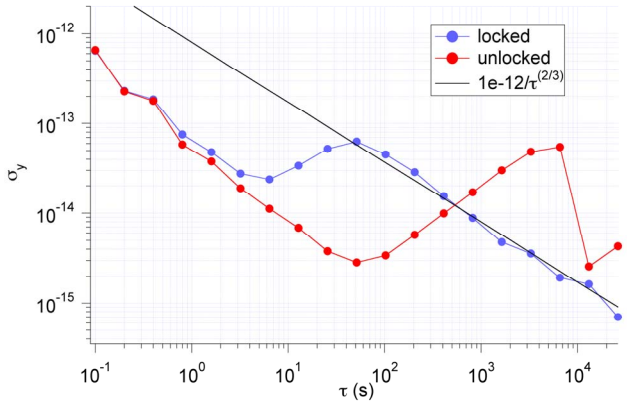

Figure 5. Link Stability. Plotted are the Allan deviations for the locked and unlocked data presented in Figure 4. A reference line of $10^{-12}/\tau^{2/3}$ is plotted as well.

In the case of the locked link, the effects of temperature cycling are removed. Initially, the stability is 6e-14/τ like the unlocked case. At around 10s the stability turns up and eventually latches on to a trend of $1x10^{-12}/\tau^{2/3}$. This comes about because of the temperature control loop and the noise floor of the two color signal. The temperature controlled spool has a time constant on the order of 10 seconds hence the deviation from the unlocked loop around 10 seconds. The stability eventually rolls over to a line defined by the noise floor of the two color signal and the lever arm of the system. For a 10km length of fiber, the noise floor of the two color signal is ~ $3x10^{-15}/\tau^{2/3}$. The measured lever arm is approximately 300; therefore the noise floor is multiplied up by 300 and added to the stability of the loop. That corresponds to ~$9x10^{-13}/\tau^{2/3}$.

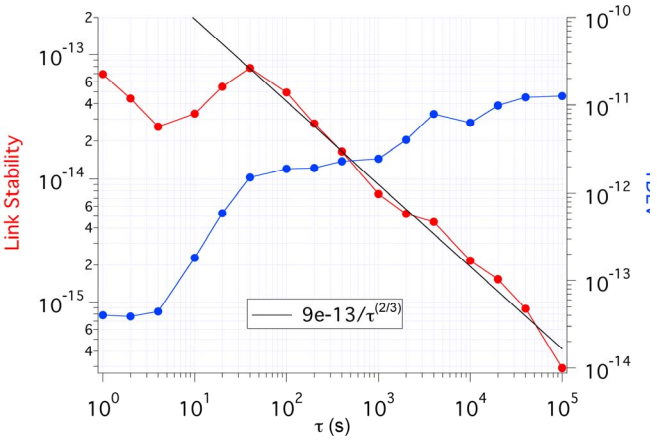

Figure 6. Extended link stability plot. Plotted are the Allan deviation and TDEV for a 5 day continual run of the locked link. . A reference line of $9x10^{-13}/\tau^{2/3}$ is plotted as well.

The results of a longer run with the link locked for 5 days are shown in Figure 6. Throughout, the environmental chamber was changing the temperature as in Figures 3 and 4. From the Allan deviation, we see that the locked link integrates down to the mid 10^{-16}'s in one day with the phase fluctuations suppressed. Also shown is the TDEV for that run. After a day if integration, the TDEV is less than 20ps.

As was pointed out, one of the limiting factors for the performance of the locked link is the noise floor of the two color signal. The limiting stability follows the noise floor times the lever arm. Therefore it is important to know how the noise floor scales with link length. Figure 7 show measurements of the 1 second fractional frequency stability as a function of fiber length. As can be seen, the stability degrades with increasing length and shows that the inherent short term stability increases at $3x10^{-16}$ per kilometer. To ensure that the effect was due to length and not attenuation, the 5km link was remeasured with attenuation equivalent to a 30km link. The results matched the stability of the original 5km link. From this we can infer the performance of longer links. Assuming the same set of transmitting wavelengths, and hence same lever arm, for a 50km link, we should expect the long term stability to behave as $5x10^{-12}$. There is evidence that the polarization scramblers used in the link are not properly optimized. It is possible that improvement of their operation may improve the scale of noise with fiber length.

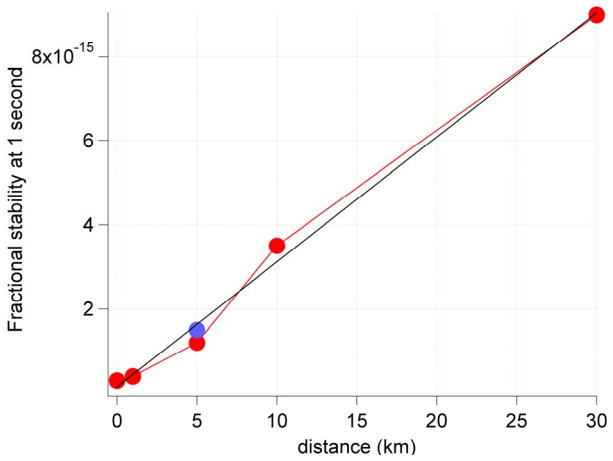

Figure 7. Stability versus length. Plotted is the 1 second stability measurement for the locked link as a function of link length. A fit line corresponding to $1.5x10^{-16} + 3x10^{-16}$/km * distance is plotted as well. The blue data point corresponds to a 5km link with attenuation equivalent to a 30km link.

One means of improving the stability of the link is to decrease the lever arm. This can be done by changing the wavelengths used by the transmit laser modules. A larger wavelength separation gives rise to a larger two color signal and smaller lever arm. Figure 8 shows the possible improvement. By using wavelengths at the edge of the C band (shown in green in the figure), there should be an improvement of roughly a factor of two. By extending even further and using a wavelength in the C band and one at

1300nm (shown in grey in the figure), there is almost an order of magnitude improvement in stability at the cost of no longer being able to use erbium doped amplifiers in the link.

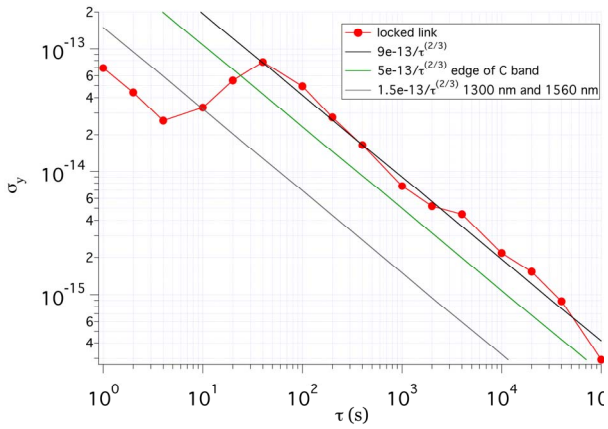

Figure 8. Wavelength improvements. The red curve is the Allan deviation shown in Fig 6. Plotted as well are simulations of changes to the trend line for different wavelength combinations. Black is a fit to the data corresponding to $9\times10^{-13}/\tau^{2/3}$. Green is a simulation for a wavelength combination of 1530nm and 1565nm corresponding to a trend line of $5\times10^{-13}/\tau^{2/3}$. Grey is a simulation for a wavelength combination of 1560nm and 1300nm corresponding to a trend line of $1.5\times10^{-13}/\tau^{2/3}$.

In conclusion, we have demonstrated a one-way temperature compensated fiber optic link. We have shown that by sending two amplitude modulated signals along a fiber optic link, it is possible to recover a record of the thermally induced phase variations and to compensate for them in real time. Some of the length based limitations to performance were discussed as well as possible improvements by appropriate choice of transmit wavelengths. This technology shows promise a viable alternative to two way compensated links when bidirectional access to the fiber is not possible. It also points to easier time transfer through a broadcast protocol as opposed to individual compensated links.

***Abstract*— We have realized a compact, laser-pumped Rb atomic frequency standard in view of next generation space applications. The clock's Physics Package has a volume of 1.1 liters, and includes a frequency-stabilized diode laser and 2 clock resonator packages. The measured clock short-term stability is $5x10^{-13}$ $\tau^{-1/2}$, reaching < $3x10^{-14}$ at τ > 20'000s. The typical clock drift is $2x10^{-13}$/day, on the same level as the drift observed for a modified GALILEO RAFS operated with laser pumping under vacuum.**

I. INTRODUCTION

Rb atomic frequency standards ("Rb clocks") have found a variety of applications as local frequency references, in fields such as telecommunications, science, and satellite navigation systems, thanks to their compact volume and low mass while providing competitive frequency stabilities. Here we report on our development of a laser-pumped Rb clock [1] with improved clock performance, that meets the performance requirements for on-board clocks in advanced satellite navigation systems ($\sigma_y(\tau) < 1x10^{-12}$ at τ=1s and $< 1x10^{-14}$ at 1 day [2]) while maintaining the compact outline of a high-performance Rb clock (≤3 kg mass, ≤3 liters volume) [3]. To achieve this goal, the approach of a cw laser-pumped Rb clock with optimized key technologies (including the buffer-gas cells, laser stabilization, etc.) is chosen [4].

II. CLOCK REALISATION

In order to keep the clock scheme as simple as possible, a continuous-wave interrogation scheme combined with optimization of the key clock technologies was selected. The block scheme of the clock is given in Figure 1. The light emitted by a DFB laser diode is frequency-stabilized to saturated-absorption lines obtained from a small evacuated Rb reference cell [5]. In order to achieve best possible frequency stability from a simple setup, the cell is temperature-stabilized

This work was supported by the European Space Agency ESA (contract no. 19392/05/NL/CP), the Swiss State Secretariat for Education and Research – Space Affairs Division, the Swiss National Science Foundation, and Fondation en faveur d'un Laboratoire en Recherche Horlogère.

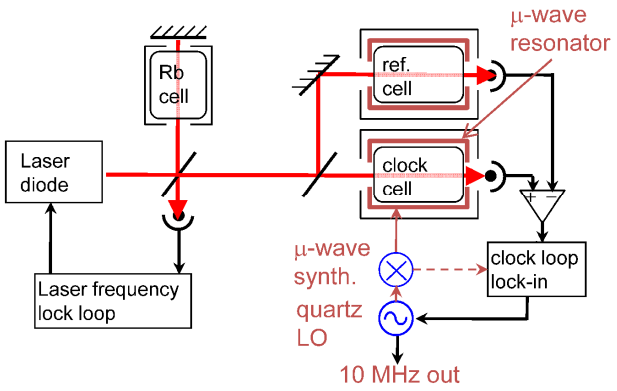

Figure 1. Block scheme of the clock.

and surrounded by two layers of magnetic shields. Laser stabilization is achieved by frequency modulation spectroscopy at a frequency around 50 kHz, resulting in a laser frequency stability of $< 5x10^{-12}$ at all relevant time scales. A more detailed description of the stabilized laser module can be found in [6, 7, 8].

The clock cell contains enriched ^{87}Rb and a buffer-gas mixture and is placed in a small magnetron-type microwave resonator [4]. The resonator and clock cell are temperature-stabilized and surrounded by a 3-layer magnetic shield to form an atomic resonator package, of 4.0cm x 4.4cm x 6.4cm outer dimensions. By injecting low phase-noise microwave radiation into the resonator, a clock signal can be detected on the photodetector placed after the atomic resonator package. The detection noise is dominated by laser-induced noise (including laser AM noise and FM-AM noise conversion), thus a second cell identical to the clock cell is used in a second, identical atomic resonator package into which no microwave radiation is injected, in order to subtract the detection noise from the actual clock signal for improved short-term stability.

The stabilized laser module and the two atomic resonator packages are mounted on a common, temperature-stabilized baseplate and occupy a volume of 1.1 liters. Figure 2 shows

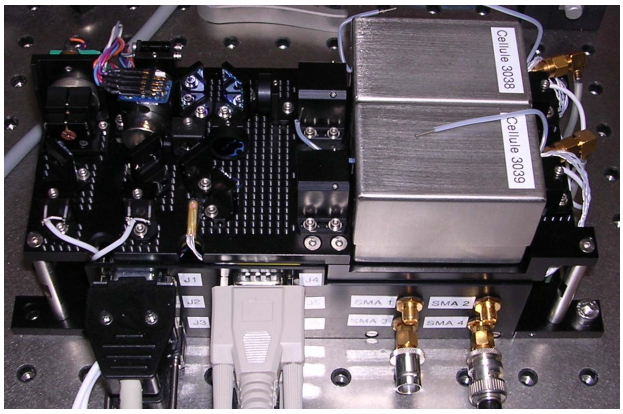

Figure 2. Fully assembled clock package. Overall dimensions are 10cm x 10cm x 24cm, with only 1.1 liter occupied by the core physics package (laser + atomic resonator modules).

the assembled clock, including also proximity electronics in an overall 10cm x 10cm x 24cm volume (2.4 liters) [7].

Under typical operating conditions, the double-resonance clock signal has a linewidth of ≈ 1 kHz and a contrast of 7%, which results in a discriminator slope of 680 pA/Hz (measured at line center in the de-modulated error signal). When using one clock cell only, the shot-noise limit is $3\text{x}10^{-13}\ \tau^{-1/2}$, and the signal-to-noise stability limit is $1.1\text{x}10^{-12}\ \tau^{-1/2}$, mainly due to additional laser noise (including FM-AM conversion in the clock cell).

Because the noise cancellation scheme requires identical clock cells, and in order to investigate on future issues on the production of many clocks, we have investigated on the reproducibility of the clock cell's buffer-gas mixture, which directly affects the cell temperature required to operate at minimized temperature coefficient (inversion temperature, [9]). For this purpose we have produced 4 completely independent batches of cells with nominally identical buffer-gas mixture, distributed over a period of 3 months. Evaluation of the cells' performance in a Rb clock shows that the inversion temperature does not scatter more than ±2°C, which is acceptable for clock operation and production constraints.

III. Clock Performance Results

Figure 3 shows the clock's measured short-term stability.

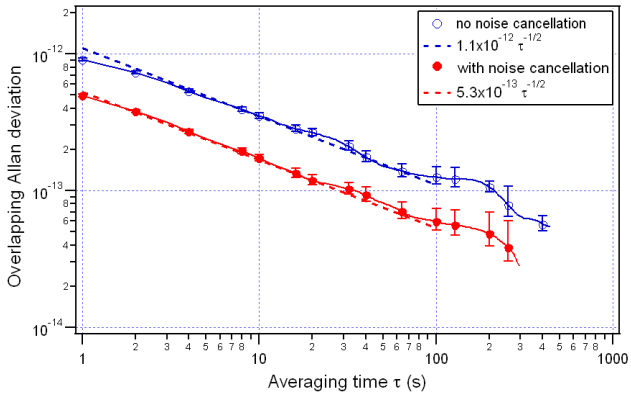

Figure 3. Short-term stability of the clock, measured with and without noise cancellation.

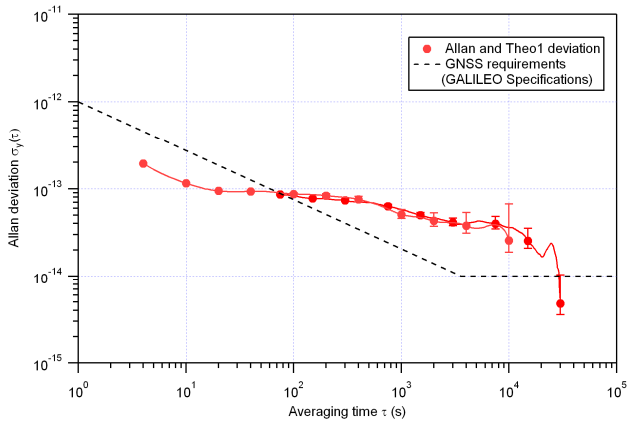

Figure 4. Measured medium-term stability of the clock. Typical frequency drift is around $2\text{x}10^{-13}$/day.

Short-term stabilities of $1.1\text{x}10^{-12}\ \tau^{-1/2}$ and $5.3\text{x}10^{-13}\ \tau^{-1/2}$ are obtained when operating the clock without and with the noise cancellation scheme implemented, respectively, in agreement with the calculated signal-to-noise limits. The latter result is also close to the shot-noise limit of $4.5\text{x}10^{-13}\ \tau^{-1/2}$, slightly increased here due to the implementation of two independent photodetectors when operating with the noise cancellation scheme.

The medium-term stability of the clock is shown in Fig. 4. It reaches $< 3\text{x}10^{-14}$ at $\tau > 2\text{x}10^{4}$s, with a typical drift of $2\text{x}10^{-13}$/day. This stability is mainly limited by temperature variations in our laboratory, acting on the laboratory-style clock electronics and directly on the clock physics (not sufficiently optimized thermal isolation using 2 thermostat stages only operating in standard atmosphere), to be mended in next development stages.

IV. Long-Term Clock Studies

In order to validate and evaluate the operation of a laser-pumped Rb clock under vacuum, we operate a modular Rb clock over extended times in a vacuum chamber held at $< 2\text{x}10^{-6}$ mbar. This laser-pumped Rb clock is composed of a stabilized laser head [5] and a lamp-removed GALILEO RAFS clock [3], as described in [4]. The stability of this clock is $1.6\text{x}10^{-12}\ \tau^{-1/2}$ at $\tau <$ 100s and reaches $2\text{x}10^{-14}$ at 20'000s. Figure 5 shows the clock frequency recorded continuously over 4 months, where the 12-hour mean uncertainty is $2\text{x}10^{-13}$. A stable linear drift of $1.8\text{x}10^{-13}$/day is found, and no frequency jumps linked to unexplained events or changes in the light source intensity (as found in lamp-pumped clocks [10]) are observed over the full measurement time within the 12-hour uncertainty. The only frequency jumps, observed (end of September 2010) are due to maintenance work in the laboratory.

By recording the laser diode's injection current, we can extract the aging of the current on resonance, i.e. of the laser current required for operating at the Rb D2 frequency (at constant laser temperature). A decrease of the current at resonance of –50 µA/month is observed, which corresponds to a + 60 MHz/month change in laser frequency (at constant current and temperature). A similar rate of frequency aging (-80 µA/month) was obtained for laser diodes operating in air

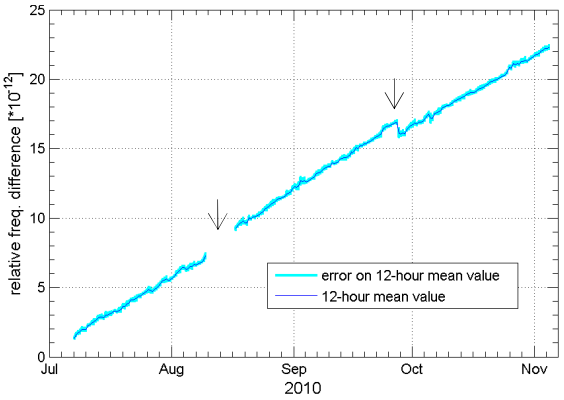

Figure 5. Frequency of the laser-pumped RAFS operated under vacuum, recorded over 4 months continuous operation. The events marked by vertical arrows are due to maintenance and temperature changes made on the laboratory air conditioning system.

in a dedicated test setup over more than 5 months. By linear extrapolation of the data we predict that the laser diodes can be operated at the Rb resonance wavelength for 15 to 20 years, by only slightly adjusting the laser temperature. A detailed study of this laser frequency aging is reported in [11].

V. CONCLUSIONS

We have developed and evaluated a very compact (< 2.5 liters volume) and high-performance laser-pumped Rb clock, that is based on the simplest possible schemes and uses optimized clock technologies. A short-term stability of $5.3 \times 10^{-13}\ \tau^{-1/2}$ is achieved without need for switching of the optical or microwave fields (like used in the pulsed optical pumping approach [8]), which significantly simplifies the clock scheme. Dedicated studies on the long-term behavior of a laser-pumped Rb clock operated under vacuum and on the frequency aging of the implemented laser diodes show that our clock can operate over extended times under vacuum, and that the laser frequency lifetime is compatible with a clock lifetime of at least 15 years. The developed clock is thus an attractive candidate for a number of space applications, including telecommunication, satellite navigation, and science missions.

***Abstract*—In this paper we present a prototype of Rb clock working in pulsed regime with high freq stability performances. In particular, a frequency stability as low as $1.6\times10^{-13}\tau^{-1/2}$ has been measured for integration times up to 10^5 s. In the short term, this represents a record result for a hot-vapor-cell frequency standard.**

I. INTRODUCTION

The pulsed optical pumping (POP) scheme relies on the time separation of the following three phases that generally rule the operation of an atomic clock: laser optical pumping, microwave interrogation with Ramsey scheme, and detection of the clock transition [1]. It is well established that this technique has proven very effective to reduce the transfer of laser noise to the atomic resonance (the so called light-shift), increasing the frequency stability performances with respect to a continuous approach. In the case of the POP maser, in which the clock signal is detected in the microwave domain, we have in fact already reported a frequency stability (Allan deviation) of $1.2\times10^{-12}\,\tau^{-1/2}$ for integration times up to 10^5 s, and the 10^{-15} region has been reached after drift removing [2].

According to the theory we developed [3], the detection of the clock transition in the optical domain can lead to even better results. In fact, because of the higher energy carried by optical photons with respect to microwave photons, a higher signal-to-noise ratio is predicted and so a better short term stability. In addition, there is a secondary advantage: we do not need a high-*Q* cavity because the cavity is used to interrogate the atoms and does not play any role during detection; a lower cavity pulling is expected. The heterodyne detector is not more required and instead we have the photodiode and the transimpedance amplifier. A new physics structure has been then designed and implemented. Moreover, to take full advantage of the POP clock with optical detection, a very low-phase noise synthesis chain has been realized. The pulsed operation is ruled by a pattern generator implemented on a digital board.

Clock measurements have been done using optical pumping on either the Rb D1 or D2 optical lines.

II. PHYSICS PACKAGE

Fig. 1 shows a schematic of the physics package. It has a layer structure, from the innermost component to the outmost the following components can be recognized:

1) Quartz cell;
2) Microwave cavity system (including optical detector: trans-impedance plus photodiode and microwave cable to inject and detect microwave signals, not shown in the figure);
4) C field solenoid;
5) Internal heater;
6) First magnetic shield;
7) External heater;
8) Two external magnetic shields.

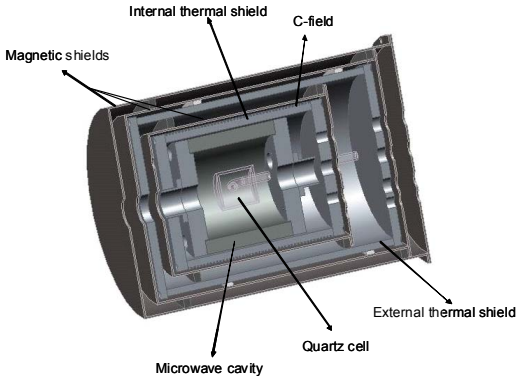

Fig. 1. Schematic of the physics package.

Two different cells have been filled with ^{87}Rb atoms and a mixtures of buffer gases (Ar and N_2 in the pressure ratio 1.6, with a total pressure of 25 Torr) at the LTF facilities. The buffer gas mixture is temperature compensated around 64 °C.

One of the two cells has been placed inside a Mo cavity that has a loaded quality factor lower than 1000. In Fig. 2 it is possible to identify the two cell stems, the microwave cable, the tuning screw and the photodiode.

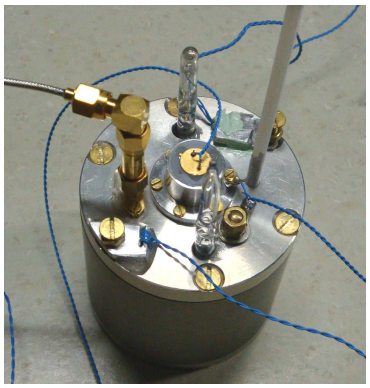

Fig. 2. The cavity system.

The physics structure has been placed in a vacuum chamber in order to isolate it from environmental fluctuations (barometric pressure, humidity, temperature, etc.); the vacuum is provided by rotative and turbo pumps and the vacuum level is below 10^{-6} mbar.

Since the clock frequency is temperature-dependent due to buffer gas collisions, an active control of the physics structure temperature is required. In particular, we implemented two different temperature controls: the innermost controls the cavity temperature and works in AC; the second one works in DC and controls the stem of the cell. Between the stem and the cavity a temperature gradient is maintained to generate a cold point in the structure (the stem) in order to avoid a deposition of Rb inside the walls of the cell that would alter significantly the cavity Q.

As shown in Fig. 3 a temperature stability for the stem and for the rest of the cell inside the cavity below 100 µK up to 100000s is achieved.

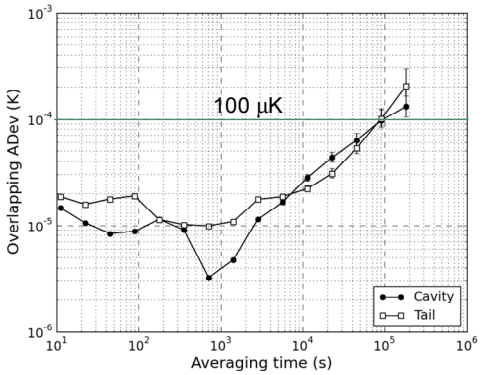

Fig. 3. Allan deviation of the temperature fluctuations of the cell stem (white squared) and of the cell body (black circles).

III. ELECTRONICS

The electronics architecture (see Fig. 4) is very similar to that we developed for the POP maser [3].Here we focus only into the main differences. In the optical detection the laser is not only used to pump the atoms but also to detect the clock resonance; the atomic signal is then processed by a transimpedance amplifier followed by a signal conditioning step to match the input dynamic of the lock-in amplifier. The rest of the electronics has been redesigned in order to support the expected stability.

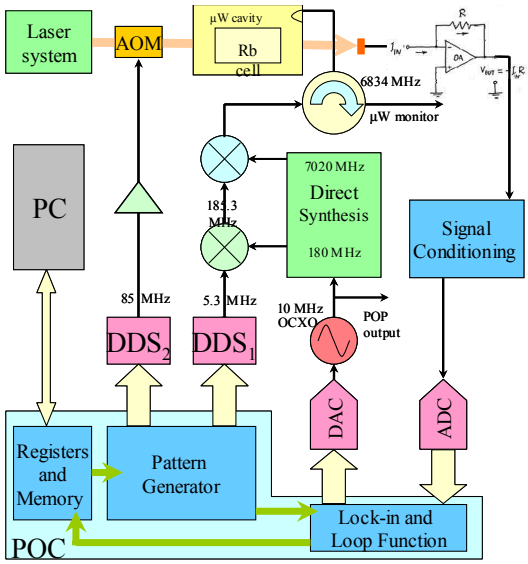

Fig. 4. Scheme of the POP clock from an electronic point of view.

In particular, the synthesis chain (SC) is based on non-linear transmission lines (NLTL) instead of step-recovery diodes (SRD) used in the maser approach. As usual, the SC is a direct multiplication from the 10 MHz of the OCXO to about 7GHz; the first multiplication stages are the most critical one: we have a distribution amplifier to provide the clock output, then a x9 multiplier, followed by a x2 multiplier and finally a PLL that filters the multiplication spurs. The phase noise of the OCXO plus the SC is shown in Fig. 5; it has been obtained by the beat note of two nominally identical devices. The Dick effect turns out $7\text{x}10^{-14}$ at 1s.

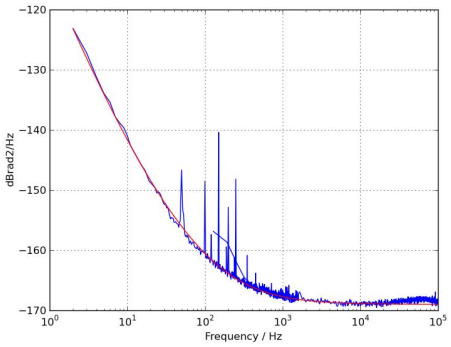

Fig. 5. Phase noise of the SC.

IV. CHARACTERIZATION

The assembled system has been tested using two different optical wavelengths, the Rb D1 line (795nm) and the Rb D2 line (780nm): Optical pumping on the D1 line is achieved with a DFB laser, using a compact and frequency-stabilized laser head build by LTF-UniNe and described in [4].

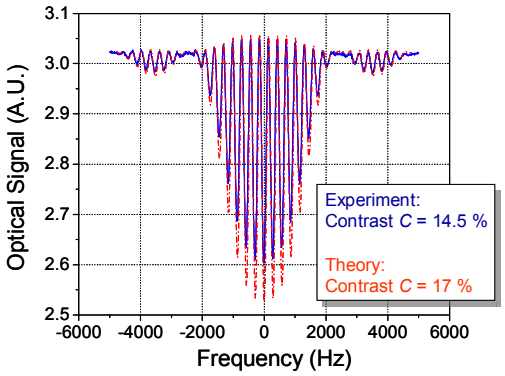

Fig.6. Ramsey fringes with D1 line; pumping time t_p = 3.7 ms; microwave pulse duration t_1= 400 µs; Ramsey time T = 3ms; detection time t_d = 150 µs, laser power during pumping P_L^{pump} = 1.4 mW, P_L^{det} = 300 µW.

Fig. 6 refers to a comparison between experimental (blue line) and theoretical (red line) Ramsey fringes obtained with D1 line. The agreement between the two curves is very good; in particular, the contrast that is one of the key parameter is around 15 %. When the local oscillator is locked on the central fringe of the Ramsey pattern we obtain the frequency stability of Fig. 7. The measured Allan deviation is $4.2 \times 10^{-13} \tau^{-1/2}$ up to average times of 10000 s. the bump around 2000 s is due to the thermal fluctuations not completely understood and solved at the time of the measurement.

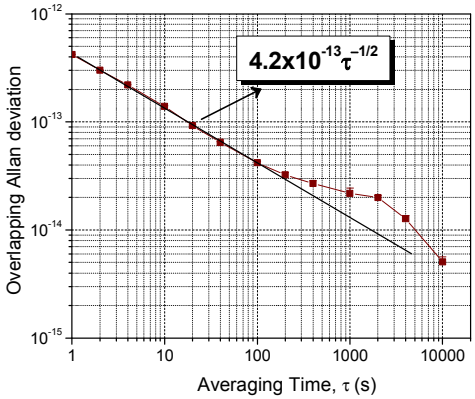

Fig. 7. Allan deviation of the POP clock with optical detection using D1 as pumping light.

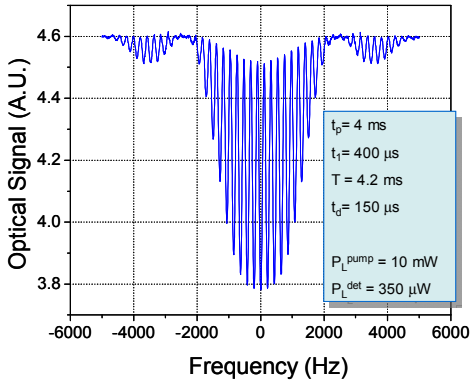
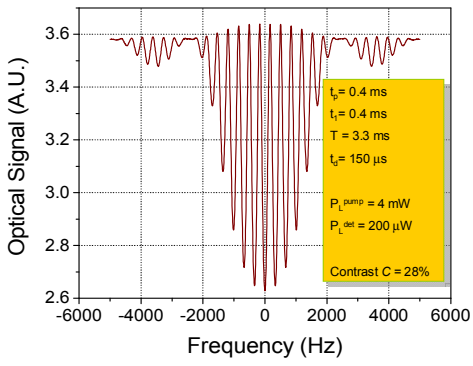
The same characterization measurements have been done using a DFB laser locked to the D2 line. Fig. 8 shows the observed Ramsey fringes for two different temperatures.



(a)



(b)

Fig. 8. Ramsey fringes observed with D2 line; (a) temperature T= 58 °C; (b) T= 68 °C. The timing and the adopted laser powers are indicated in the figures.

In particular, a contrast of the 28 % for the central fringe is achieved. The corresponding frequency stability is reported in the following figure 9 and now we have 1.7×10^{-13} at 1s and

the white frequency region noise goes down and reaches $5x10^{-15}$ at 10000s. This is, in our opinion, due to some residual environmental effects.

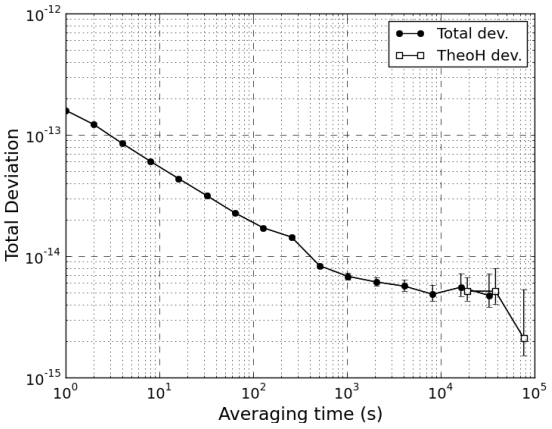


Fig. 9. Allan deviation of the POP clock with optical detection using D2 line as optical pumping.

The drift has not been removed from the data and turns out $-3x10^{-15}$/day.

In conclusion, we have implemented and characterized a Pulsed Optically Pumped frequency standard with optical detection that confirms the significant benefit in the short term stability predicted by the theory. Both the frequency stability and the drift are already fully compliant with the Galileo PHM specifications We might cite the article by Belloni et al. on PHM here, Procs EFTF2010.

The Influence of Laser Polarization Variations on CPT Atomic Clock Signals

Michael Huang and James Camparo

james.c.camparo@aero.org

***Abstract*— The Coherent-Population-Trapping (CPT) vapor-cell atomic clock represents a clear break from previous vapor-cell clock technology. As such it has advantages that may result in significant frequency stability improvements. However, along with the technology's benefits come new effects that may limit the CPT clock's capabilities, and one such effect is laser polarization noise. Here, we present our first results looking at the response of a CPT signal to modulation of a laser's polarization. Our results show that the CPT clock signal undergoes a splitting when the polarization modulation is rapid, suggesting that various Fourier components of a field's stochastic polarization fluctuations will affect the CPT clock signal in qualitatively different ways.**

I. INTRODUCTION

In the CPT clock, the microwave atomic signal is generated in an all optical fashion [1]. Briefly, sidebands are placed on the optical carrier at one-half the frequency of the ground state hyperfine splitting, $\Delta\nu_{hfs}$, (i.e., 6.8 GHz for Rb^{87}), and when the separation between the two sidebands, 2δ, matches the ground state hyperfine splitting both levels are simultaneously coupled to the same excited state. It is a feature of the atom's quantum nature that excitation pathways interfere, and when the two hyperfine states are coupled to the same excited state in this fashion the pathways interfere destructively (i.e., the atom cannot make a real transition to the excited state). If the atoms cannot be excited, there is no absorption of the laser light, and consequently the intensity of light transmitted by the vapor increases. The transmitted light thereby acts as a monitor of the atoms' interaction with a microwave signal (i.e., the laser sideband separation), and this can be used to lock the frequency of a quartz crystal oscillator to the atom's ground state hyperfine splitting.

One obvious advantage to this design is that the microwave cavity of the traditional vapor-cell clock is eliminated. In addition to allowing for "chip-scale" atomic clocks [2], elimination of the microwave cavity removes all microwave power shifts that can give rise to frequency instability [3]. In particular, effects like alkali surface migration on the resonance cell's glass walls [4], which affect the microwave cavity Q, are eliminated. Moreover, fewer components in general translate into greater device reliability. Nevertheless, though the CPT clock has real advantages over the conventional laser-pumped atomic clock [5], its novel nature suggests that it may be subject to new processes that play little, if any, role in the conventional laser-pumped clock. One of these processes concerns the effect of laser polarization fluctuations on the CPT clock signal [6], which the present work was initiated to investigate.

II. THE PROBLEM

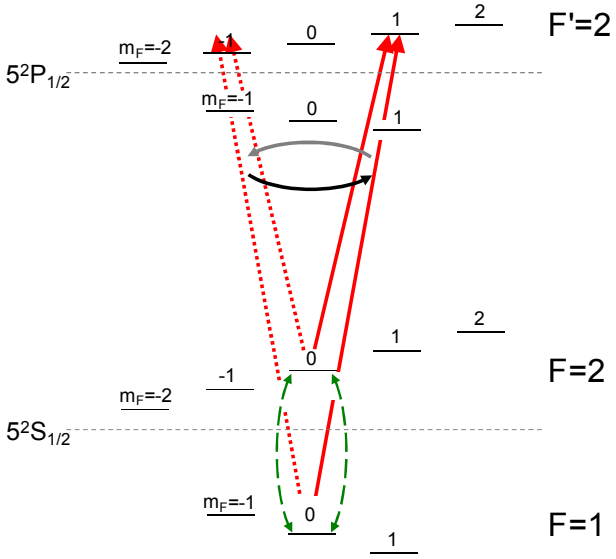

Figure 1: In the typical CPT clock, two modes of a laser couple an atom's two $m_F = 0$ ground-state sublevels to the same excited state; here, the common excited sate is F' = 2, $m_F = +1$. The simultaneous coupling creates a coherence in the ground-state, indicated by the dashed green lines, and it this coherence that is at the heart of the CPT phenomenon. If the laser polarization fluctuates, then the common excited state will momentarily change to F' = 2, $m_F = -1$, and this will affect the ground-state coherence.

In the most typical realization of the rubidium CPT clock, the laser light is circularly polarized and connects the (F = 2, $m_F = 0$) and (F = 1, $m_F = 0$) ground state Zeeman sublevels to the (F' = 2, $m_F = +1$) Zeeman sublevel of the $5^2P_{1/2}$ excited

This work was funded by U.S. Air Force Space and Missile Systems Center under Contract No. FA8802-04-C-0001.

state; this is illustrated in Fig. 1. As is well-known, this "lambda-system" coupling creates a coherence between the two $m_F = 0$ ground state sublevels (i.e., the 0-0 transition), and it is this coherence which is at the heart of the CPT signal. If the circular polarization switches from right-circularly polarized light to left circularly polarized and back again, then a transient will be introduced into the CPT signal since the common excited state changes: $(F' = 2, m_F = +1) \rightarrow (F' = 2, m_F = -1) \rightarrow (F' = 2, m_F = +1)$. If the polarization variations are stochastic [7], then the time series of these CPT transient will appear as noise on the CPT signal.

III. Experiment

Figure 2 shows a block diagram of our experimental arrangement, which is fairly straight-forward. We start with a cleaved-facet Fabry-Perot diode laser, which does not suffer from intrinsic polarization fluctuations [8]. Though not shown in the figure, the laser light passes through an electro-optic modulator (EOM), which places sidebands on the laser at 3.4 GHz. The modulated and linearly polarized field then passes through a ferroelectric liquid crystal (FLC) polarization rotator that has a bandwidth of 10 kHz. This polarization rotator changes the field's polarization by ninety degrees depending on an applied voltage supplied by a function generator. The field then passes through a quarter-wave plate, creating right or left circularly polarized light depending on the sense of linear polarization transmitted by the FLC polarization rotator. With the laser polarization square-wave modulated, the 3.4 GHz sideband spacing is very slowly swept through the CPT resonance (i.e., $2\delta = \Delta\nu_{hfs}$). The CPT resonance is observed as an increase in the transmitted laser light, measured by a silicon photodiode, and we average the CPT resonance lineshape using an averaging oscilloscope. We employ a buffer gas cell, containing 50 torr of N_2, so that the dominant relaxation mechanism in our experiments is electron-spin randomization (also known as S-damping) [9].

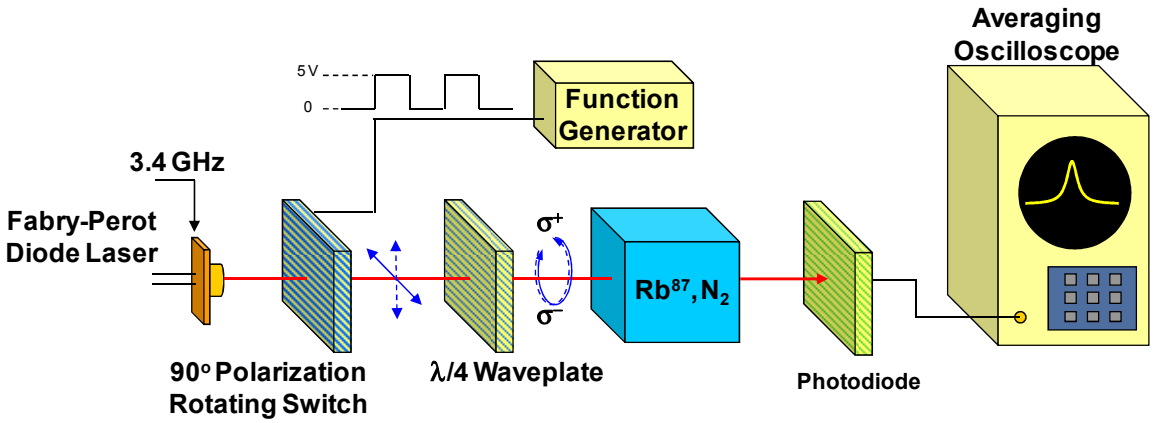

Figure 2: Block diagram of our experimental arrangement. The Rb cell is maintained at 47 °C, corresponding to an alkali density of ~ 10^{11} cm^{-3}, and the Rb atoms are contained with a 50 torr N_2 buffer gas. The laser light passes through an electro-optic modulator (not shown) that places sidebands on the laser at ~ 3.4 GHz. In our experiments the sideband-to-carrier power ratio is 0.17.

IV. Results

Based on our previous work [6] and that of Jau et al. [10], we had certain expectations concerning the results of our experiments. For modulation frequencies, f_m, less than the electronic spin-polarization relaxation rates in our system, we expected the atom to respond quasi-statically to the modulation: the atom would reach steady-state equilibrium between laser polarization changes, and the CPT phenomenon would appear to be unaffected by the polarization modulation. However, as f_m became larger than the rate of spin-polarization relaxation, the atom would not have enough time between laser polarization variations to generate an equilibrium spin-polarization in the vapor. In other words, the laser would not have enough time to put atoms into a "trapping state" [11], and so we expected the CPT resonance to grow in this regime of modulation frequencies. Finally, as f_m became larger than the 0-0 coherence's dephasing rate, we expected the laser polarization variations to begin to have an effect on the CPT lineshape. In particular, we expected the CPT linewidth to grow monotonically (though perhaps not linearly) with f_m in this regime.

Figure 3 shows the main results of our work. There, we show several cases of the CPT resonance for different values of the modulation frequency. At low modulation frequencies, $f_m \sim 3$ Hz, we see the standard CPT resonance. The "noise" on the CPT signal is not noise at all, but a residual of the transients that are induced in the absorption cross section as the laser's polarization changes [6]. At intermediate modulation frequencies, $f_m \sim 30$ Hz, we see an increase in the CPT signal amplitude. As discussed above this is expected, since these modulation frequencies are beginning to exceed the spin-polarization relaxation rate. Surprisingly, however, as f_m exceeds the 0-0 coherence dephasing rate (i.e., $\gamma_2 = 120$ Hz [6]) we don't see the CPT linewidth broaden. Rather, the CPT linesphape splits into a doublet with the separation between the two CPT resonances increasing with the modulation frequency. This is shown more quantitatively in Fig. 4, where we have plotted the center frequency of each doublet component, f_{CPT}, as a function of the modulation frequency. In the figure, the two straight lines correspond to $f_{CPT} = +f_m$ and $f_{CPT} = -f_m$.

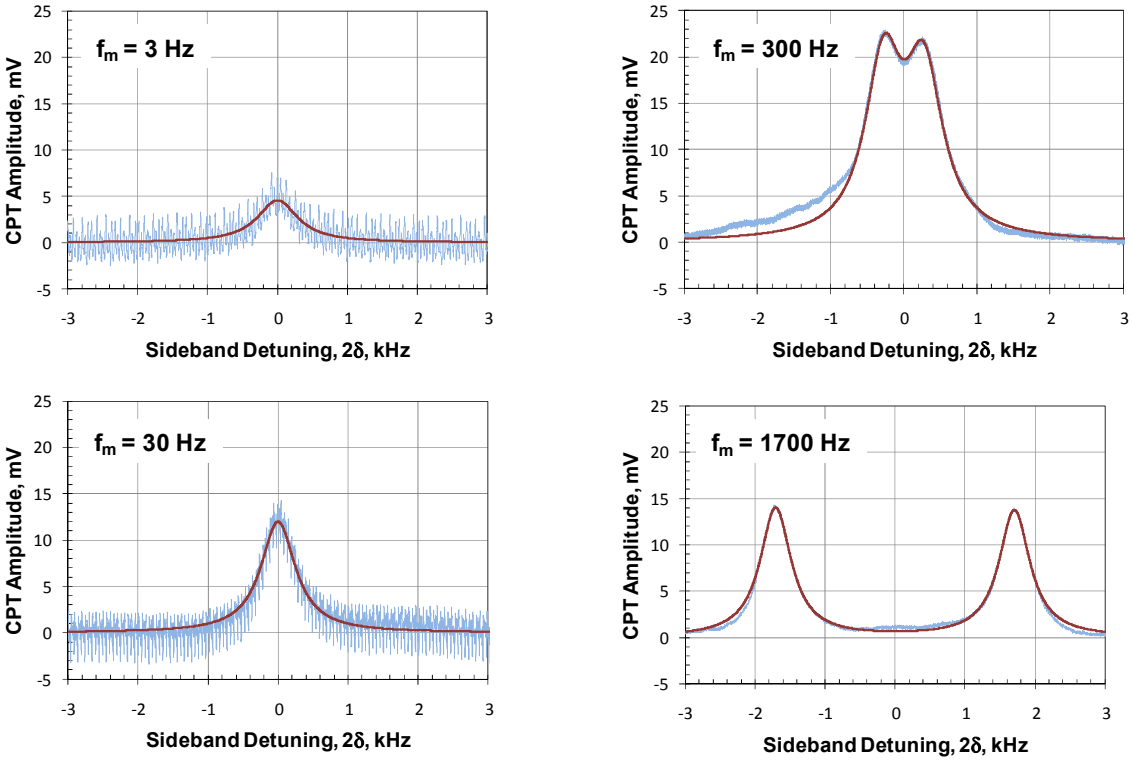

Figure 3: This figure shows our principle experimental results. At low modulation frequencies the standard CPT resonance is obtained. At intermediate frequencies, the CPT amplitude increases since atoms don't have time to be trapped in a non-CPT participating atomic state. At the highest modulation frequencies, our CPT resonance splits into a doublet.

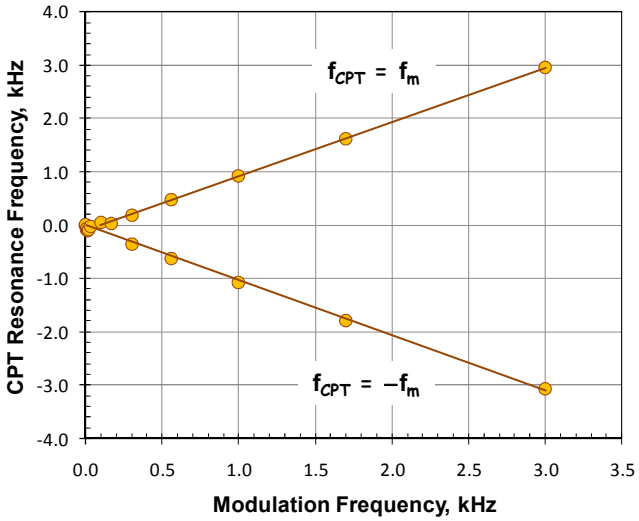

Figure 4: The frequency of each doublet component as a function of modulation frequency. For these results, the laser intensity was four times larger than that yielding the highest contrast CPT resonance in the absence of polarization modulation. Note that the doublet splitting equals $2f_m$.

V. Discussion

As noted in the Introduction, when the laser changes from right-circularly polarized light to left-circularly polarized light the atom is coupled to different Zeeman sublevels of the excited state. As a consequence, the Rabi frequencies change, not in magnitude but in phase. Interestingly, our theoretical analysis (to be discussed in a subsequent publication) shows that only one of the Rabi frequencies changes sign after a laser polarization change, the other is unaffected; and it is this asymmetry in the phase change of the Rabi frequencies that yields the CPT splitting. Briefly, since only one of the Rabi frequencies changes sign, the ground-state 0-0 coherence suffers a phase change following each laser polarization change, which happens twice every modulation period. This modulation of the ground-state coherence at $\pm f_m$ yields a doubling of the CPT resonance frequency: $\Delta\nu_{CPT} = \Delta\nu_{hfs} \pm f_m$. If both Rabi frequencies changed phase, then there would be no net phase modulation of the 0-0 ground-state coherence, and no splitting would occur.

Clearly, the results of the present work have implications for the effect of *random* polarization variations on CPT signals, and these are indicated (very qualitatively) in Fig. 5. For ease of discussion, let f_c be a critical laser polarization modulation frequency: for $f_m < f_c$ no splitting of the CPT resonance occurs; for $f_m > f_c$ the CPT resonance is split into a doublet. As suggested by Noise-Spectrum A, if all Fourier components of the noise spectrum are less than f_c, then laser polarization noise could actually increase the amplitude of CPT resonances. Specifically, those Fourier components less than f_c, but larger than the spin-polarization relaxation rate, would cause the CPT amplitude to increase. In other words, laser polarization noise could enhance a chip-scale atomic clock's signal-to-noise ratio. However, if the high frequency

cutoff of a polarization noise spectrum is above f_c, then as suggested by Noise-Spectrum B the CPT resonance will be reduced in amplitude and it will have an increased linewidth. Thus, for a noise spectrum like B a chip-scale atomic clock's signal-to-noise ratio and its atomic-Q would be reduced. Whether or not these qualitative expectations hold up will be the subject of further research in our laboratory.

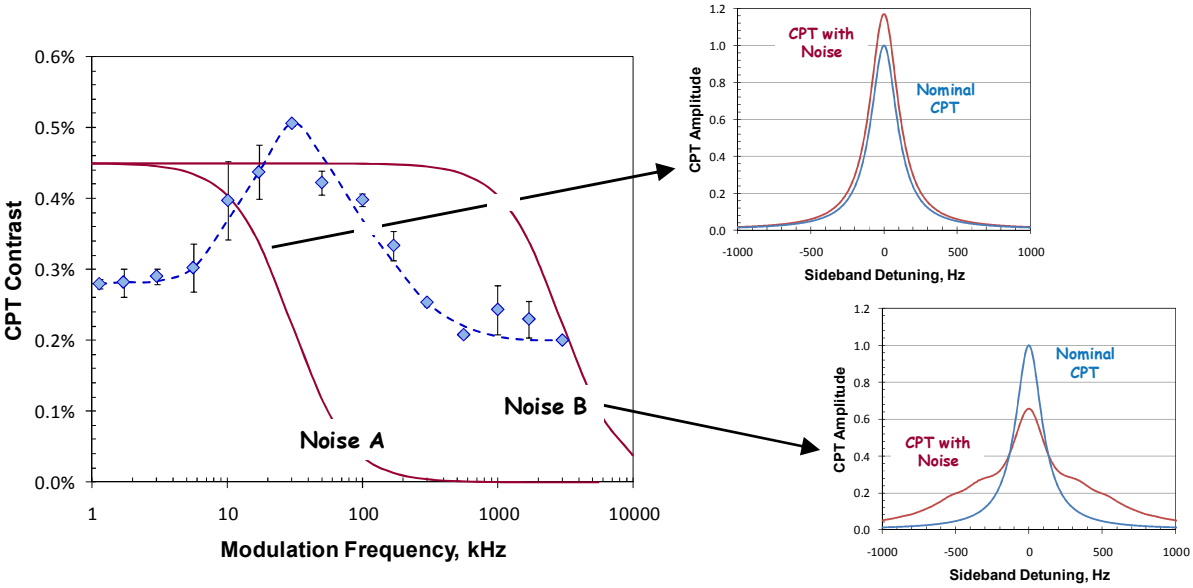

Figure 5: Illustrative considerations of the effect of laser polarization noise on CPT signals. The data points in the figure to the left show the amplitude of the CPT resonance as a function of modulation frequency; for these data the laser intensity maximized the CPT contrast in the absence of polarization modulation. (The dashed line is simply an aid to guide the eye.) In effect, the data points can be thought of as an atomic "transfer function" for laser polarization noise. Assuming that a laser polarization noise spectrum is similar to curve A in the leftmost figure, we would predict the CPT resonance to appear like that shown in the figure to the upper right (nominal implies the absence of laser polarization noise). Alternatively, if the laser polarization noise spectrum was more closely modeled by curve B, we would expect the CPT resonance lineshape to take on the appearance shown in the curve to the lower right.

Positioning FBAR Technology in the Frequency and Timing Domain

Rich Ruby (IEEE Fellow)
Wireless Semiconductor Division
Avago Technologies
San Jose, CA, USA
rich.ruby@avagotech.com

Abstract— this paper will focus on the technical differentiation of FBAR from other mechanical resonator technologies for timing applications. The talk will also touch on a recent modification of FBAR (the Zero Drift Resonator, ZDR) that is temperature compensated. A further technology differentiator is the size of the chip-scale packaged resonator. Using the same technology used in manufacturing Avago Technologies' filter duplexer (over 3 billion sold) allows us to leverage qualified processes and thus go to market quickly. Furthermore, the silicon lid is perfectly suitable for placing integrated circuits and this is being done. All of these factors, (wide tuning range, high Q, high frequency, small size, integrated circuitry) are being used to differentiate potential products for the Time and Frequency Markets.

I. INTRODUCTION

In John Vig's tutorial can be found the salient facts and an excellent overview of the contribution of the quartz resonator in the fields of frequency and timing standards [1]. Highlights include

- Applications and Requirements
- Hierarchy of Oscillators (and thus, their applicability)
- Sources of Oscillator Instability

Between 1930 and 1950, the quartz crystal became the 'heart' of commercial time keeping, and by 1972 wristwatches using quartz resonators become widespread.

Today, required stability for USB 2.0 and 3.0 Host Controllers is +/-300 ppm. Stability for Wi-Fi and other wireless applications is +/- 20 ppm. For GPS, the stability must be on the order of 1 to 2 ppm.

Recently, several technologies have begun to target some of those markets traditionally held by Quartz resonators and oscillators. MEMs resonators and oscillators (in the 50 to 100 MHz frequency range) have gotten a lot of press in the past 3 years. Q's on the order of 60,000 to >100,000 [2,3] have been reported. Another technology, Solid State Oscillators (SSO)[4], have also entered the market. This technology is quite different in that it does not use a mechanical resonator of any kind. Rather, SSOs rely on an integrated LC tank circuit (typically running at 2 to 4 GHz) and taking advantage of the property that phase noise improves by -20 log[N] dB as the frequency is divided down by N.

One of the chief drawbacks of the MEMs oscillator is the lack of any real coupling (i.e. the ratio of the motional capacitance to the plate capacitance). Poor coupling reduces the ability to pull the high-Q resonator. So, given that process and temperature variations determine the final frequency, the MEMs oscillator is used as a non-deterministic reference. The output frequency is generated using a follow-on fractional N synthesizer with programmable offsets to compensate for frequency offsets due to process variation and to compensate for the rather large temperature coefficient of frequency (on the order of -30ppm/C) of the silicon MEMs resonator.

The SSO can be pulled quite easily; as the Q of the inductor L is 10 to 20. The resonant frequency is typically chosen to be 3 -4 GHz and then divided down. The divided down frequency is compared to a pilot tone at the factory and offsets are similarly stored into a look-up table to compensate for temperature variations and frequency offsets due to process variations. A varactor as part of the LC oscillator then adjusts the frequency. Influence from external sources of parasitic capacitance is minimized by fabricating a Faraday cage around the die.

The FBAR is a mechanical resonator more akin to quartz resonators than MEMs type devices. However, there are several key differences between all 3 devices:

i) The mode of operation is a longitudinal motion (sound waves normal to the plane of the resonator) as opposed to a flexure mode used by MEMs devices

ii) The thin sputtered piezoelectric and metal electrode films, set the native frequency which is much higher than quartz resonators with their relatively thick plates

iii) The coupling coefficient for FBAR is at least 30X larger than quartz resonators

978-1-61284-110-6/11/$26.00 ©2011 IEEE

iv) The coupling coefficient for FBAR is at >100X larger than MEMs electro-statically driven resonators

However, the f*Q products of these mechanical resonators in commercial applications are all within a range of 10^{12} -10^{13} Hz.

Another technology has recently been the subject of investigation. This would be the Rayleigh-Lamb wave devices. Here, the MEMs silicon bar is replaced by an AlN piezoelectric film. Inter-digitized fingers patterned on top generate an SO symmetric mode (see Fig. 3). The advantage of this device over a MEMs device is the coupling coefficient is much higher than silicon MEMs devices. The coupling coefficient ranges from 1 to 2% for non-temperature compensated devices and 0.56% for temperatures compensated devices (similar to quartz) [5,6].

II. Thin Film Bulk Acoustic Resonator

A. Background

There are two 'flavors' of FBAR, the Free-standing Bulk Acoustic Resonator (or FBAR) and Solidly Mounted Resonators (or SMR-BAW). FBARs were first developed in the '80's [7,8]. In the mid '90's SMR devices came into vogue [9]. At HP, later Agilent, later Avago, we focused on FBAR and in 2001 announced a PCS duplexer [10,11]. Due to the inherent advantages of Bulk acoustic devices over surface acoustic devices (SAWs), FBAR became a major contributor to many of the cell phone refinements that we take for granted today (e.g. small size, internal antennas, more functionality due to lower power dissipation from the duplexer etc…). Part of the staying power of FBAR at Avago was the introduction of a wafer-scale package technique in 2002 that allowed for an all-silicon chip scale package that was hermetic and could be either integrated directly on the customers board or on a 'molded chip on board (MCOB)' at our factory.

Q enhancements, die-shrinking and new topologies have allowed Avago to be a leading supplier of duplexers, multiplexers and Front-End Modules (FEM) that integrate PA and power coupler with duplexer. Some of the more stringent LTE filter requirements have driven Avago to develop a 'zero drift' version of our resonator, or ZDR. So, besides 'screaming' roll-off, some LTE bands require the filter not move over temperature.

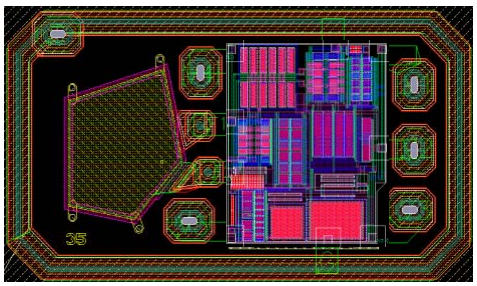

Fig. 1. Diagram of Avago's FMOS Device. Both the resonator and the circuitry are integrated into the same die

Currently, our ZDR resonators can be 'tuned' such that the linear coefficient of frequency with respect to Temperature is zero'd out. This is done with an oxide layer buried inside the stack [12,13]. We target a Turn over Temperature (TOT) in the range of 30 to70°C. The residual quadratic temperature dependance, β, ranges from -15 to -25 ppb/ $^{o}C^{2}$, and depends on stack make up.

More recently, we have begun adding active circuitry in the lid (Fig. 1). The circuitry can either be CMOS (hence, the name 'FMOS') or Bipolar. We have demonstrated both. The circuitry is connected to the resonator by two narrow 'drop-down' posts that form the connection at the same time that the base wafer containing the FBAR is bonded to the lid wafer containing the circuitry. A description of the manufacturing process is given elsewhere [14].

The value of this method of manufacturing (base wafer – FBAR, lid wafer – circuitry) is that all aspects, all process steps, are fully qualified, fully vetted and do not interfere with each other. The latter property is most important, if one has to re-invent each process so as to not interfere with the other technology, then, the whole process must –once again—be fully qualified (an onerous undertaking).

B. FBAR

Experimental data on varying sizes of resonators show that the Q behavior has a $(Area)^{-3/2}$, not $(Area)^{-1}$. The extra -1/2 in the exponent comes from this area-to-perimeter ratio. This power law observation points to where we can find energy losses.

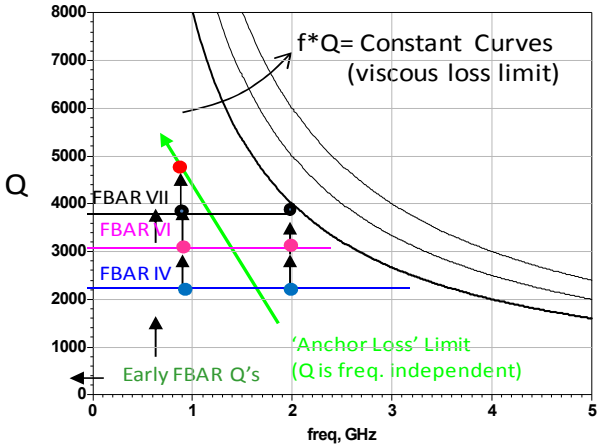

Fig. 2. Measured Q of Avago FBAR Resonators plotted over time and by generation (FBAR IV, V, VI, VII…) suggesting that 'anchor point' losses dominate. At some point resonator Q losses will be dominated by intrinsic or viscous losses.

We have reason to believe that energy leaking out from the perimeter ('Anchor' Losses) is the main loss mechanism for FBAR (at least up to 2 GHz). Figure 2 is a plot of Q vs. Frequency of Avago's standard FBAR resonator (developed over time) and includes a family of f*Q=constant curves (these curves represent the behavior of a mechanical resonator when the losses are dominated by intrinsic, material losses). It is well known that resonator losses due to phonon scattering, friction or heat generation will generate f*Q= constant

behavior. In particular, extracting attenuation, $\alpha(f)$ from the fundamental, the 3rd and the 5th harmonics shows that $\alpha(f) \sim \alpha_1 * f + \alpha_2 * f^2$ [15]. Thus, for a given velocity and resonance;

$$\frac{1}{Q} = \frac{2\alpha(f_o) * v_{ac}}{\omega_o} \sim \alpha_1 + \alpha_2 * f_o$$

(Units of α's assumed to have correct dimensions)

Figure 2 suggests that for fundamental frequencies up to 2 GHz, resonators made in any number of ways (that is the ratio of layers and the materials chosen for those layers – e.g. Mo or W electrodes) have a Q limit that is frequency independent [16].

In an ideal world, an AC voltage applied across the electrodes at or near resonance of an FBAR would generate only a longitudinal motion. However, due to the non-zero cross terms in the piezoelectric stress tensor, lateral modes can and will be generated as well. Specifically, there are a variety of Rayleigh-Lamb (RL) modes that can exist at any given frequency.

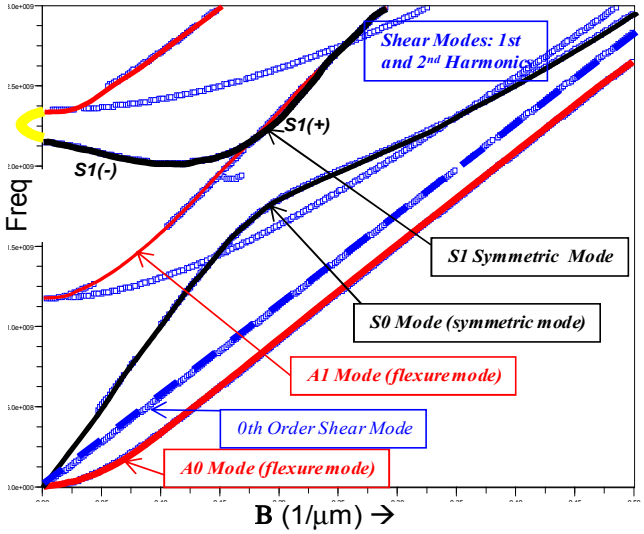

Fig.3. Calculated Dispersion Curves with the Rayleigh-Lamb modes labeled for an AlN Plate 2.5 um thick. Experimental extractions of dispersion curves from spatial Fourier transforms show remarkable agreement between experiment and theory.

Figure 3 shows the modeled dispersion curves of a AlN resonator. All of the allowed mode branches are labeled [17]. The dispersion curves are generated by doing spatial Fourier transforms on measured displacements mapped across a given resonator surface [18]. Longitudinal energy converted into lateral modes can scatter into 'matching' modes in the surrounding silicon substrate (anchor points) [19]. Once energy is deposited into the silicon it is lost and hence, the Q of the FBAR resonator is limited. Various methods exist to improve Q given this reality and some are given in [20]. To date, the maximum Q of an FBAR at 1 GHz is ~5000 (4000 at 2 GHz). The method of measurement is given in [16] and also discusses some of the inherent difficulties when measuring high Q resonators at GHz frequencies.

There are four outstanding attributes of the FBAR resonator that make it ideal for high performance filters; high Q, high kt^2_{eff}, high power handling, and the use of silicon as the substrate (with the attendant advantages of using main stream production tools and the ability to form an all-silicon hermetic package).

Unfortunately, there is a finite temperature coefficient of frequency (TCF) that is on the order of -30 ppm/°C. Thus, to use an FBAR resonator in an oscillator has only limited application, namely modest tuning range VCOs for PLLs. But, that application is still potentially interesting.

Unlike Quartz BAW or SAW devices, FBAR using AlN as the piezoelectric has an effective coupling coefficient on the order of 6.5 to 7.1% (in the crystal world, one uses the variable $r = C_o/C_m$, whereas, FBAR/SMR papers refer to $kt^2_{eff} = 1.2*C_m/C_o$, so a kt^2_{eff} of 6.8% corresponds to an r = 17.7 -in 'crystal' speak). For a Quartz resonator, r typically ranges from 60 to 80 (depending on cut).

The coupling coefficient, kt^2_{eff} can be defined as

$$kt^2_{eff} = \frac{4.8 * (f_p - f_s)}{(f_p + f_s)}$$ where f_s and f_p are the frequencies where the measured Q circle crosses the real axes of the Smith Chart (see Fig. 6a).

With minor modifications, one can 'tune' the kt^2_{eff} down to as low as 2% (this has several advantages: lower pulling range improves at least one source of externally generated phase noise – noise on the varactor, the resonator is less 'influenced' by the variations on the oscillator core (known as PVT, Process, Voltage and Temperature variations), the unloaded Q increases for decreasing kt^2_{eff}, and in simulation, the quadratic term for the temperature dependence goes down.).

The trade-off between Q and kt^2_{eff} can be understood using the 'Bode' equation for Q developed in [21,22]. The unloaded Q is defined by the stored energy divided by the power dissipated in a cycle.

$$Q = \frac{2\pi f \tau_{GD} |\Gamma_{11}|}{1 - |\Gamma_{11}|^2}$$

The stored energy is represented by the group delay τ_{GD} where $\tau_{GD} = -d\phi/d\omega$. The total phase between f_s (the series resonance) and f_p (the parallel resonance) is always fixed at 180 degrees. Therefore, as f_p and f_s get closer in frequency the $-\Delta\phi/\Delta\omega$ term increases. This is partly why low coupling devices have intrinsically higher Q than a device with a large coupling coefficient. [For completeness, the power dissipated in a cycle is $(1 - |\Gamma_{11}|^2)/(2\pi f)$].

C. FBAR Pulling Range

The 'pulling' range of a crystal is a small fraction of its coupling coefficient. Naively, one can think of adding parallel capacitance to the resonator until the parallel resonance matches the series resonance. However, for a variety of reasons that involve the external gain circuitry as well as the $kt^2_{eff} * Q$ product of the resonator plus varactor, one can only 'pull' the frequency a small fraction (<< 30%) of $\Delta f = f_p - f_s$. We have demonstrated a pulling range (while maintaining

high Q) of 8600 ppm using a ZDR resonator with a kt^2_{eff} of ~5%. We believe that with a standard FBAR, we could increase the pulling range to over 10,000 ppm. In the Quartz BAW and SAW world, the pulling range is very small, typically 10 to 50 ppm. The one T&F application where the FBAR looks to very interesting is the use of a high frequency FBAR VCO locked to a low frequency (~10 MHz) quartz crystal [23,24,25,26]. The value of an FBAR PLL locked to an external crystal (where the FBAR resonator is at a much higher frequency) is that the overall phase noise far from carrier can be improved immensely by avoiding frequency multiplication, while close-in, the phase noise is influenced by the quartz reference, as demonstrated in [25,26]. These two properties may find an application where excellent phase noise (jitter) and modestly-wide pulling range are needed.

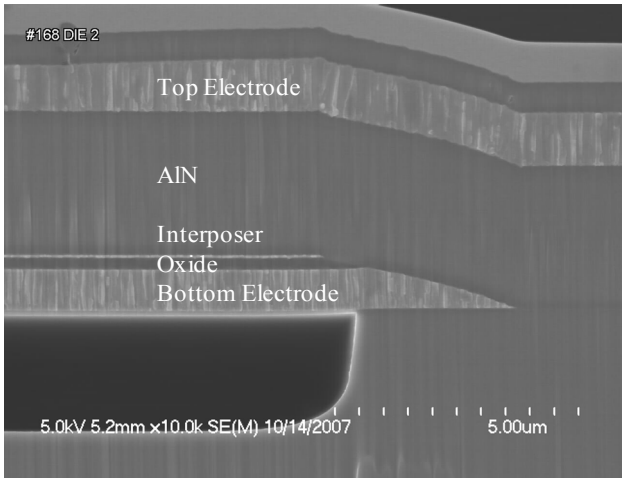

Fig. 4. Cross section of a Zero Drift Resonator (ZDR). The edge of the 'swimming' pool is shown. The layers are labeled.

Many clocking applications need a 'dither' applied to the clocking signal. The 'dither' moves the frequency up and down by a predetermined amount (usually in a saw-tooth fashion) 'spreading' the energy found in each of the harmonics over a finite frequency space. These kinds of products are known as SSXOs or Spread Spectrum Crystal Oscillators. They are used in electronics where some energy of the clock harmonic lies in a sensitive band (e.g. GPS) designated by the FCC or other governing agency as being 'off-limits'. The alternative, a Faraday cage around the electronics, is not always workable.

Typical SSXOs use the Quartz based oscillator as a reference. A Frac-N synthesizer consisting of a LC oscillator in a PLL generates an output frequency that is tied to the Quartz reference. Slowly changing divide ratios move the output frequency up and down. The fractional-n synthesizer can burn as much as much as 20 to 100 mW of power. The phase noise is determined by the LC oscillator and not the Quartz reference. An FBAR PLL dispenses with the LC oscillator and can directly be pulled up to +/- 5000ppm.

D. Zero Drift Resonators (ZDR)

References [12,13] describe a modified FBAR where a layer of oxide is buried inside the bottom electrode. This thin layer has a positive Temperature Coefficient and can be used to 'tune out' the linear TCF term of the FBAR resonator. Figure 4 shows a cross section of such a device (patent pending). To date, the best Q achieved with ZDR devices is on the order of 3000 (768 MHz resonators). Work is in progress to improve this. It is not clear if the device Q is limited by the intrinsic losses of the added oxide layer, or due to non-optimized 'anchor' losses.

Figure 5 shows the temperature dependence of two ZDRs. The TOT (or Turn Over Temperature) can be varied from 0 °C and 100 °C depending on the thickness of the oxide where all other layer thicknesses are fixed.

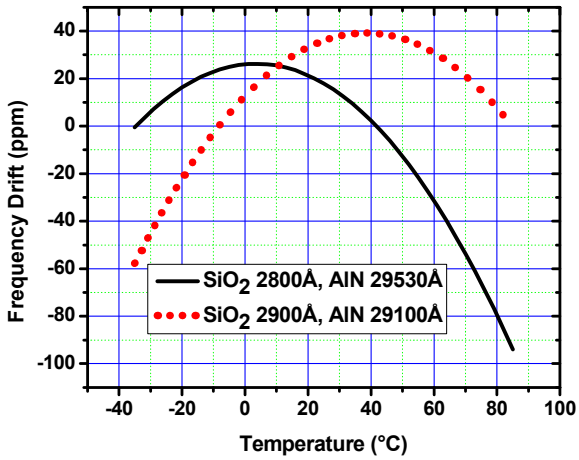

Fig. 5. Frequency Drift (in ppm) vs. Temperature for two ZDR devices with different oxide thicknesses under the metal interposer. Thicker oxide moves the TOT up in temperature. The β for these two devices is ~ -18 ppb/°C

III. ZDR/FBAR Resonators

Both FBAR and ZDR can be fabricated with the fundamental resonance as low as ~400 MHz and higher than 10 GHz. Furthermore, Q and the power handling abilities of FBAR (or ZDR) allow excellent phase noise when used in an oscillator. In an earlier section there was a discussion of FBAR oscillators used as VCOs in PLL type devices. For ZDR oscillators, we aspire to be the frequency source. Thus, the target is accuracy, stability, Q and reliability. Beyond these four 'musts'; the need for product differentiation is also very important. Product differentiation can come from power handling, turn on time and chip-scale integration.

A. Accuracy

Today's quartz crystals and FBAR filters are trimmed to frequency in much the same way. Raw quartz blanks are ion milled with a high energy ion beam of argon atoms – knocking off quartz atoms and thus slowly increasing the native frequency of the quartz blank. A similar process is done on FBAR resonators on wafer; the only difference is the magnitude of the Δfrequency/Δthickness. In the case of a quartz resonator, the quartz is a fraction of a millimeter thick; the thickness of the FBAR resonator is on the order of microns. The native frequency of a quartz plate might be 5 to

50 MHz, the native frequency of an FBAR resonator might be 400 MHz to 10 GHz.

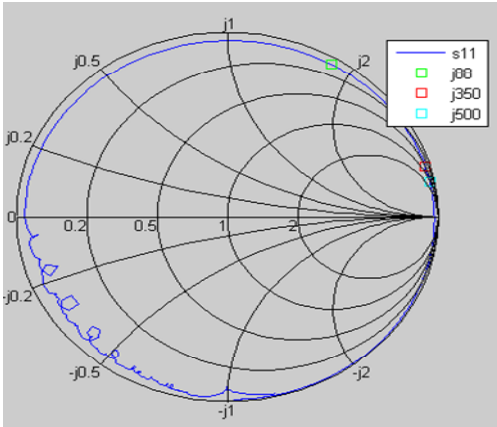

Fig. 6a, Measured Q-circle of a 768 MHz ZDR resonator. Markers show the reactance points where the oscillator core might conjugate match the impedance

A simplistic view of relative accuracy can be described as the ratio of the amount of frequency change, Δf (Hz), per atomic layer removed by argon etching. For a millimeter thick substrate, the Δf (Hz) per atomic layer removed is very small. For a 1 micron thick substrate, the amount of Δf will be three orders of magnitude larger. A quartz resonator can be purchased with a native accuracy of 10 to 30 ppm. An FBAR, after ion milling the resonators can be 'tuned' to 100 ppm 1-σ at 1.5 GHz. If the accuracy required is 1 to 2 ppm (GPS applications), then neither quartz nor FBAR resonators can be 'tuned' accurately enough. External circuitry driving a varactor or switched capacitors must be used to pull the resonator/oscillator. If an FBAR had the same coupling coefficient as quartz, then at most, the pulling range would be 10 to 100 ppm. This is much less than necessary to achieve the needed accuracy due to process variation. However, FBAR coupling is 3 to 6% and allows for 5000 to 10,000 ppm pulling range, compensating for any process variations.

B. Stability

Because the linear term of the TCF in a ZDR resonator can be 'tuned out' and a TOT set to temperature in the center of the operating temperature range, one is left with predictable quadratic temperature dependence. In theory, this can be taken out with electrical feedback, or in some cases, the variation in temperature is allowable for certain applications. External circuitry can be used to counteract the parabolic temperature dependence. This was demonstrated for a ZDR oscillator using a PTAT and a look up table that controls a DAC attached to a varactor [27].

The problem with this technique is that the short term stability is poor due to constant shifting in and out different discrete voltages on the varactor. Future enhancements to this technique might be to add a high frequency 'dither' to the LSB of the DAC. Another circuit approach might be to use an on-chip diode whose voltage (for a fixed current) varies smoothly with temperature and whose output is fed into an Op Amp with programmable gains [28].

One important lesson of ZDR, is that with mechanical compensation only, a small varactor across the resonator is needed to electrically compensate for the residual quadratic error. The tuning range of the varactor need only be +/- 150ppm. Compensation for process errors can be 'tuned' out (for example) by using CMOS switched capacitors in a Pierce oscillator topology (for C_1 and C_2) where the relative losses of the switching caps is relatively small and one can cover a larger frequency range in a linear fashion. This avoids the use of a large and lossy varactor to tune over large frequencies.

C. Quality Factor Q

The Q's of ZDR have not (yet) achieved the same numbers as FBARs made in our traditional line of filters (when comparing comparable frequencies). There are two schools of thought as to why this is so. 1) The oxide is acoustically lossy, bringing the f*Q curves in Fig. 2 lower. 2) Mainstream FBAR filters for duplexers bring in millions of dollars in revenue and due to the competitive landscape; much effort and resources continue to be spent on improving Q. This has not yet been the case for ZDRs. Although many if not all techniques for improving Q for mainstream FBAR are available to ZDR, it still takes time and resources to catch up.

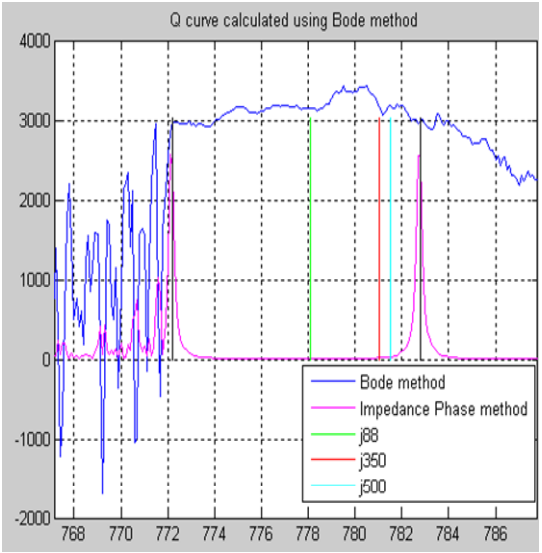

Fig. 6b, The extracted Q vs. freq using the Bode equation [21,22]. The magenta markers show Q at fs and fp using Dicke's equation for Q. The R,B,G markers match the reactance markers shown in Fig. 6a and mark where the frequencies are located for a given reactance.

Figure 6a shows the Q circle measured on our 768 MHz, 54K μm^2 ZDR resonators. The markers highlight points where the oscillator designer may wish to target the conjugate reactance of his oscillator circuit. Simple trade-offs can be made (or made for the oscillator designer). For example, more parasitic capacitance will find the conjugate match of the resonator closer to f_s (even lower than j88 Ω). A 'tightly' designed oscillator with little parasitic capacitance will operate closer to f_p. This in turn, will reduce the power used in the oscillator and allow for more pulling range.

Figure 6b is the Q vs frequency using the Bode equation. Also, the standard Q measurement for Q at f_s and f_p via Dicke's impedance phase technique is presented. Both methods are in agreement at at f_s and f_p [29]. The markers correlate to the markers in Figure 6a.

D. Reliability

The value of having 30,000 to 100,000 die on a wafer is that we can get a very good statistical sense of what the medians, spreads and outliers look like for die subjected to various strife tests. Typical strife is 85 ^{o}C /85% R.H. for hundreds to thousands of hours. Another strife subjects die to temperatures ranging from 125 ^{o}C to 150 ^{o}C in 85% R.H. (but for shorter time than 85 ^{o}C /85R.H.). Vibration tests, autoclave (121C/100%RH for 96 hrs), high temperature storage (125 ^{o}C for 1000 hrs), thermal shock (1000 cycles -65 ^{o}C /150 ^{o}C) are also included in our strife [30]. Strife is a means to force parts to failure to better understand the failure mechanisms. This is done in anticipation of the qualification runs.

Figure 7a shows the combined measurements of 6 control wafers where approximately 2000 resonators per wafer are tested. All wafers are tested twice (wafers measured, removed from the testers, the tester is then re-calibrated and the wafers are place on again and re-tested. This simple algorithm eliminates much grief during strife testing. If the initial cal was bad, then conclusions moving forward become suspect. Test points 1 and 2 are the initial test and re-test. After the rest of the non-Control wafers are strife'd for a period of time (e.g. 120 hours at 125 ^{o}C in 85% R.H. -- HAST), all the wafers are re-tested. The control wafers give an indication if –at the time of testing—there is some issue with the tester. The control wafers are tested at each strife milestone.

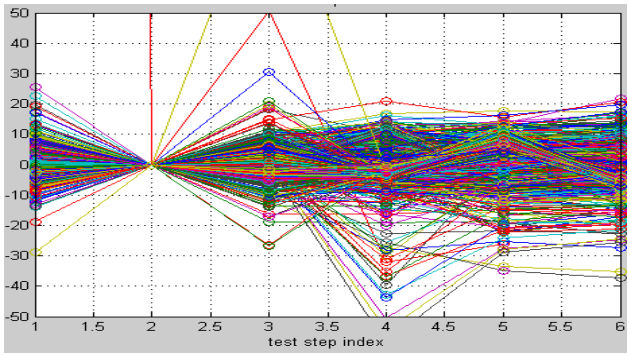

Fig. 7a, The measured frequency differences (in ppm) of 6607 randomly picked die off of 6 control wafers. The x-axes define the 6 test points when the wafers under test are taken out of the environmental chambers and tested. The median does not change (expected), but the spread degrades (presumably from probe damage). We see a 1σ spread going from 2.5ppm to 4.7 ppm. Note that several 'errant' dies go out of spec and then come back to the fold.

Figure 7a shows just how much the spread increases as the wafers are repeatedly tested. This suggests probe damage. In fact, in Fig.7b, the strife'd wafers (non-control) were 'tortured' in HAST environment and although the medians did not move after a 'burn-in' phase the 'spread' in individual resonators grew. The upshot is that guaranteeing an aging number for a raw resonator is limited by the spread. Interestingly, one can trace many individual resonators moving 10's if not 100's of ppm up or down from one test point to the next, but, then 'coming back to the fold'. This suggests another source of error, electro-mechanical interference (EMI) of some kind occurring during test. Going to an oscillator, we expect much better data with less spread and less sensitivity to probe damage and EMI.

One large drawback to qualifying resonators is that the Network Analyzers (NWAs) used to measure the frequencies do not have the necessary guaranteed stability and accuracy of their phase measurement. Comparing resonators on different NWAs can introduce relatively large offsets. Typically, a NWA only offer phase accuracy to a degree and this can translate to large ppm swings. The data showed in Fig's 7 are that measured on the same NWA.

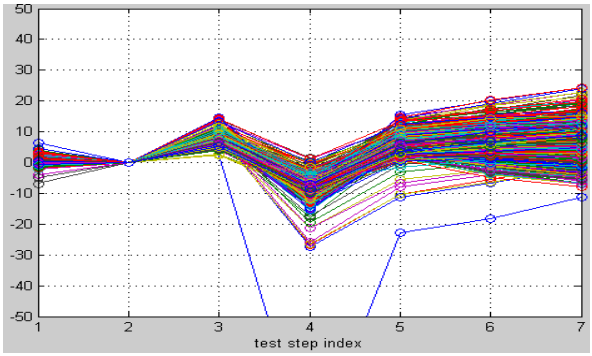

Fig. 7b, The measured frequency differences (in ppm) of 1839 die measured on a wafer undergoing HAST (130C/85%RH). The parts are taken out at stated intervals and measured. Die are screened at testpoint 3 and we see the affect of accrued testing at 48, 96, 192 and 288 hours of HAST. After 96 hours, we see the median stabilize, but, the 1σ spread continues to increase. Hard to explain is the errant die that goes way out of spec, but then returns to the fold.

IV. PROPERTIES OF FBAR, ZDR, AND OSCILLATORS

A. Phase Noise and Jitter

The phase noise measurement of a 600 MHz temperature compensated oscillator built in 2007-2008 gave some indication of the very good performance of ZDR oscillators [12]. The "knee" for the flicker noise onset is between 10 and 20 kHz. The core oscillator is an in-house, CMOS 0.4 um technology node. This oscillator draws 2 mA from a 3.3V supply voltage. Phase noise at 1 kHz offset is -102 dBc/Hz and -156 dBc/Hz at 10 MHz offset. The topology used here was a differential Colpitts design. An Agilent 5052B was used to measure the phase noise and to calculate the integrated rms jitter.

Figure 8a is a plot of SSB Phase Noise for a recently built 1 GHz discrete bipolar oscillator using a ZDR resonator in a Pierce topology. The phase noise was -103 dBc/Hz @ 1 kHz offset and -172 dBc/Hz at 10 MHz. The power was 23.5 mW (4.7V, 5mA). The resonator impedance was ~150 Ω (area =10K um^2). The Q was somewhere ~ 3000. A NEC 851 NPN silicon bipolar transistor was used as the gain element. The integrated jitter (10 kHz to 20 MHz) was measured to 9.4 fs. The better 'far-from-carrier phase noise (an additional 8 dB) comes from using more power.

Figure 8b is a SSB Phase Noise plot of a recently built 3.4 GHz discrete bipolar oscillator using a ZDR resonator with a Q of ~1000. The phase noise was -80 dBc/Hz @ 1 kHz offset. Compared to the 1 GHz oscillator (for the same offset), the difference in phase noise can be mostly accounted by -80 dBc - 20 log[(3.4/1)* (Q @ 1 GHz/Q @ 3.4 GHz)]. Thus, 'normalizing' the phase noise of the 3.4GHz oscillator w.r.t. 1 GHz, phase noise one obtains approximately -100 dBc or only ~3 dB unaccounted for. The point of this exercise is that Leeson's model predicts the behavior of two ZDR oscillators operating at different frequencies and no unexpected surprises.

At a 10 MHz offset, the phase noise was measured to be -156 dBc/Hz. The power was ~20 mW (Vdd=3V, I=6mA). The resonator impedance was ~20 Ω (area=10Kum^2). The RMS jitter was 15 fs. Careful analysis of the Q vs. frequency for our resonators [31] suggests that by further optimization of our circuit, we can take advantage of the region where our resonators' Q is a maximum.

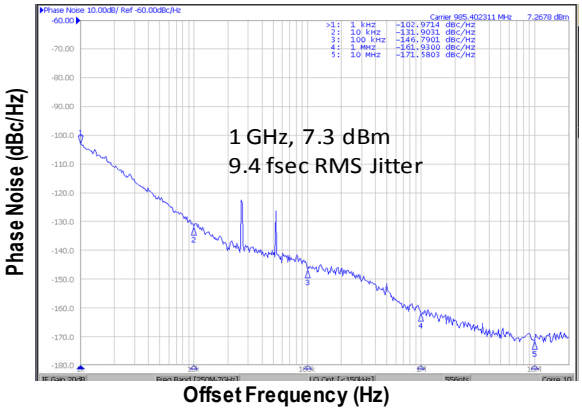

Fig. 8a. Phase Noise measured of 1 Ghz Pierce Oscillator

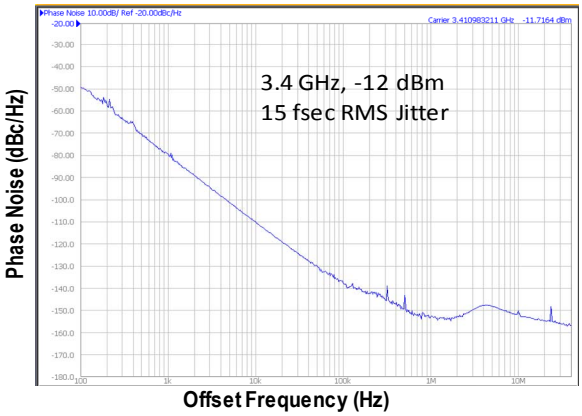

Fig. 8b. Phase Noise measured of 3.4 Ghz Colpitts Oscillator

B. Q ,Power, Area and Frequency Considerations

Given the range of frequencies FBAR/ZDR can cover, it is tempting to target high frequency oscillators and then divide down to the desired frequency; similar to the strategy chosen by the solid state oscillators (we assume that dividers are noise, power and cost free – more on this later). Starting at a 2X higher frequency than our target frequency, f_o, and then dividing by 2X would seem to give -20 log(2) = -6 dB phase noise improvement over a resonator resonating at f_o, for a fixed frequency offset f_m. If Q is dominated by 'anchor point' losses (i.e. Q is constant w.r.t. frequency) then, from Leeson's model, we know that phase noise is proportional to +20 log[f_o /Q] for a given offset frequency, f_m. Therefore, starting at a 2X frequency and then dividing down by 2 does not gain anything. If the resonator losses are intrinsic (1/f dependence), then, starting at 2X higher frequency means that the Q will be 2X worse. Dividing back down to f_o there will be a net 6dB degradation in phase noise for a fixed offset.

Again, comparing the two oscillators in Fig. 8; if one uses the higher frequency oscillator and a 'perfect' divide by 3.4, the improvement in phase noise at 1 kHz offset would be 20 log[3.4] or ~11 dB improvement. Thus the 3.4GHz ZDR oscillator with a divide by 3.4 would have an output frequency of 1 GHz, with -91dBc @ 1kHz offset compared to the ZDR oscillator running at its fundamental 1 GHz and a phase noise offset at 1 kHz of -103 dBc.

It is the additional loss due to Q in the Leeson model (-20 log[3.4] = -10.6 dB) that teaches us to avoid higher frequencies if the loss mechanism is frequency dependent. Other sources of phase noise probably come from additional losses in the oscillator core having to run at 3.4 GHz, and the choice of transistors. The moral of this story is to go for lower frequency ZDR reesonators.

However, the trade-offs in frequency then become the trade–off in area (area goes as f^2 for constant impedance resonators), native accuracy, and impedance matching to the external oscillator circuit. Area is cost sensitive and smaller resonators at higher impedances have their own issues (see earlier discussion). Dividers (if necessary) are not free and cost both power and added phase noise (especially if not designed correctly). High frequency resonators will not be frequency centered as accurately as low frequency resonators, thus, more pulling range is necessary to offset process variations.

A CMOS divide by 2 circuit in 0.4 um technology roughly dissipates 0.5 mW dividing a 800 MHz frequency in half [32]. With each node, the power dissipated decreases linearly, thus a 0.13 um CMOS technology node, the divider might dissipate one third the power, or 0.14 mW etc.. . There is a power/Area trade-off for any oscillator where dividers are used to obtain the final output frequency. To be clear, going to lower frequencies lowers the divider power consumption, but, for the same impedance, the area of the resonator grows as f^{-2}.

Other trade-offs with high frequency oscillators is the power needed to drive the output buffers. A typical load assumed by Quartz oscillator is 10 pF. This will account for both pad capacitance of the CMOS oscillator, any trace capacitance associated with the PCB and the pad capacitance of those ICs requiring ESD. Power is proportional to frequency and capacitance. Lower frequencies and/or means to minimize the pad and trace capacitance will lower the power budget associated with the output driver.

The core oscillator power of an FBAR or ZDR oscillator is proportional to R_p the real resistance seen by the oscillator

circuit at the parallel resonance at f_p (note, f'_p for a resonator in a circuit is 'pulled' down from f_p, of the unloaded parallel resonance due to the capacitance of the circuit and the varactor). It can be shown from the Vittoz equations that the condition for oscillation g_m*R_p ~ 4 means that higher R_p's allow for a lower g_m [33]. The lower the gain needed to sustain oscillation, the lower the power dissipated by the core oscillator. We have demonstrated FBAR oscillators (Q near 5000 and Rp near 7000Ω) dissipating ~ 20 µW at 2 GHz [34].

C. Turn On Time

The turn-on time of an oscillator is proportional to Q/f_{osc}. Thus, for a constant f*Q product, a higher oscillation frequency is desirable from a start-up time perspective. As expected, As expected FBAR/ZDR exhibit a start-up time orders of magnitude faster than a quartz oscillator. Figure 9 shows (in the time domain) the turn on time of an FBAR oscillator. With Q is the 1000 to 5000 range and frequency at or near 2 GHz, the turn on time should be on the order of microseconds (µsec) compared to milliseconds for a quartz crystal resonator with Q's on the order of 60,000 and operating frequency on the order of 20 MHz.

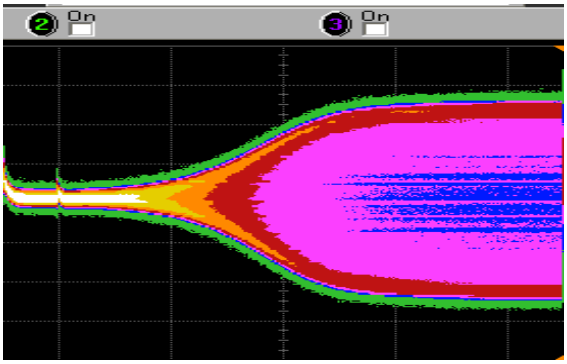

Fig. 9. Turn-on of a 2 GHz Oscillator (measurement courtesy of B. Otis). Each division is 2 us and turn on is ~ 8 us.

This is useful for those applications where the clock can be turned off for power savings, but quickly turned back on when needed.

D. Phase Noise in the Presence of Vibration

Three 1.5 GHz ZDR Oscillators were built up and tested on a shaker table to evaluate the sensitivity to acceleration. Measurements were made by Mike Driscoll and Noah Hughes at Northrup-Grummen. Sensitivity ranged from 1 to 80 ppb/g), and are comparable to SMR-BAWs made by TFR [35] and better than whispering gallery resonators [36]. There were some unexplained 'jumps' in frequency shift measured below 80 Hz and above 800 Hz. It was speculated that this was due to noise from the cables.

To convince ourselves that we were not seeing microphonic-generated noise from the resonator, we used the Acoustic Imaging Microscope [18] to map out each of the flexure modes from 10 KHz to 5 MHz (for the given boundary conditions in x and y) of the A0 mode shown in Fig. 3. As predicted in Fig.3, we expect that the resonant frequency of the fundamental to be inversely proportional to the length squared. We looked at the fundamental 'drum' mode (as it appears in the AIM) for two different areas (35K um^2 and 54K um^2) and saw that these resonances (899 KHz and 542 KHz respectively) did scale inversely with area (length squared).

The area of the resonator/oscillator measured by Hughes and Driscall was 30K um^2 and the first 'drum' mode resonance should occur around 1 MHz. Hence, we believe that the noise seen by their measurement at 1 to 2 KHz and below 80 Hz is not due to microphonics of our device.

V. FMOS

A. Description

In [14], we report a 1.5 GHz bipolar FMOS oscillator with a phase noise of -80 dBc/Hz at 1 kHz offset. The oscillator core uses 0.3 mA of current at 1.8V (0.54 mW). Due to a correctable process error, the Q was quite low and varied from 500 to 800 across the wafer (not the more typical ~1600 for on-chip ZDRs). Thus, we would have expected about -86 to -88 dBc/Hz at 1 kHz offset. Still, this is very good phase noise for a 0.54 mW DC power draw and an oscillator operating at 1.5 GHz. In discrete ZDR oscillators operating at 1.5 GHz, we have obtained ~ -103 dBc/Hz at 1 kHz offset. But, here the power used was ~44X higher; thus, in line with Leeson's model.

FMOS integrates much of the necessary oscillator core into the lid wafer. We have demonstrated working dividers, varactors, temperature sensing diodes, resistors and capacitors integrated into our lid – along with the oscillator core and buffer amplifiers [14]. The area allotted for these circuits is on the order of 300 by 300 μm^2 (as shown in Fig. 1).

Having a temperature sensing diode to monitor temperature directly from the die gives the promise of temperature compensation circuitry placed inside the lid. Thus, the oscillator can be made to both precise and stable over process variations and temperature.

Intuitively, it would seem that the overall yield of FMOS would be the product of the various yielding processes and would therefore be less than if the devices were separately built (note bonding occurs regardless of whether there is circuitry in the lid or not). However, this logic may not follow. An example of how adding circuitry to the lid will increase overall yield is the case where a working FBAR resonator is off-frequency. Parametrically, being off frequency is equivalent to being non-functional. With FMOS, a varactor (or switched capacitors) in the lid circuitry along with some non-volatile memory and a DAC (and of course, the oscillator core) could allow one to measure the FMOS oscillator frequency (on-wafer measurement), load in a correction term and thus have a working die – now on frequency.

At Avago, we are blessed with having both a qualified bipolar process (with an ft ~ 25GHz) and a 0.4 um CMOS process. Using the bipolar process, we can target FMOS toward high frequency and high performance VCOs with excellent jitter and phase noise. Using our CMOS process, we can target the fixed frequency market using NVM, switched capacitor techniques and low power dividers to generate Quartz oscillator frequencies.

B. Aging Data

Avago is in the process of evaluating long term aging properties of our ZDR. One of the inherent difficulties in determining aging is that multiple measurements are needed. Given that the accuracy and repeatability of measurement needs to be in the few ppm range, we are stymied by artificial effects such as accruing pad damage due to multiple contacts.

One elegant way around this problem is to integrate the

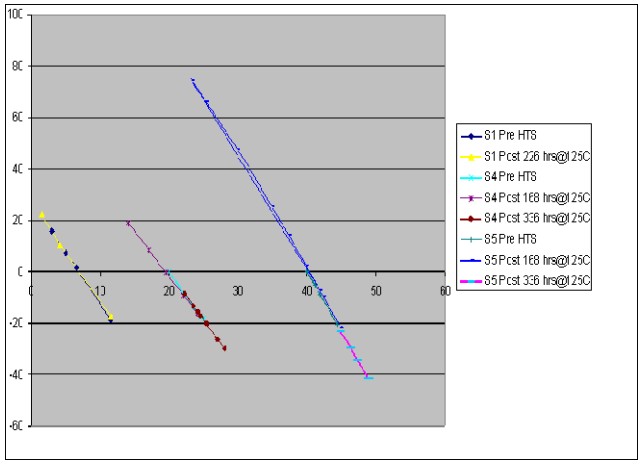

Fig. 10. Three FMOS oscillators measured, re-measured after 168 hours in 125C storage and re-measured again after 336 hours. The x-axes is relative temperature and the 3 devices are offset to better show the individual performances. The y-axes is in Δf/f ppm.

oscillator inside the ZDR microcap lid (i.e. FMOS as described above). Testing FMOS wafers (oscillators); loading correction factors, inking out dead die prior to singulation has inherent advantages over testing raw resonator die on wafer. First, the oscillator frequency (properly biased and buffered) measured on wafer will be the frequency seen by the customer. Testing for aging and/or quality issues (e.g. non-hermetic package) is much simplified since frequency measurement via a counter is inherently more stable and accurate (at the ppm level) than measuring complex impedances of the resonator via a Network Analyzer). Unlike the case of a resonator, probe/pad contact variation will not 'pull' the oscillator frequency. Strife and formal Qualification Runs hopefully can yield more deterministic data than raw microcap'd resonators.

Figure 10 shows three measured FMOS oscillators (individually mounted on pc boards) over a small temperature range before and after 300 hours at 125 °C. By 'dithering' the temperature, we eliminate the possible ppm excursions due to temperature variations that occur over time in the test lab. Temperature was measured using an integrated diode inside the FMOS circuit. Frequency was measured using a spectrum analyzer. As can be seen in Figure 10, the absolute frequency and temperature dependence are nearly indistinguishable between initial test and after 336 hours at 125 °C. We are now in the process of automating the frequency shift vs. strife (i.e. High Temperature Storage, HAST, vibration, etc….) on the wafer level.

C. Comparison to CMOS Solid State Oscillators

In a recent talk at ISSCC, 2011 [37], a 1.2 GHz oscillator using 65 nm CMOS was presented demonstrating 570 fs integrated jitter (Phase noise, here integrated from 1 kHz to 10 MHz) and burning 52 mW of power, the area was 0.12 mm^2. In their paper, they use a Figure of Merit [38]

$$FOM = 10Log[(\sigma/1s)^2(P/mW)]$$

and compare their work along with 7 other results showing FOMs ranging from -210dB to -227 dB.

In contrast, the discrete oscillator shown in Fig. 8b has an FOM of -253 dB, → 26 dB better. This is consistent with the 30dB improvement predicted the side-by-side LC- and FBAR-oscillator comparison presented in [39]. [One caveat; the device in Fig. 8a oscillates at 1 GHz not 1.2 GHz] When the discrete version is integrated in FMOS, we expect an area to be only 3 to 5X larger (including the hermetic package with pads). The conclusion here is that the performance of mechanical-resonator based oscillators still dominates over solid state devices.

VI. Conclusions

Currently, the mobile market has developed a huge thirst for low insertion loss filters with excellent isolation. As more bands open up around the world and the requirements on the filter response is 'tightened', the demand for better quality filters is a unremitting. Since 1993, Q's for FBAR have steadily improved. In the last two years, Qs have gone from 3000 to 5000 in our production lines at Avago.

Riding on the FBAR filter production coattails are our Zero Drift Resonators and in conjunction with in-house CMOS and Bipolar processes, FMOS devices. The goal is to find a technology niche that provides reasonable volume and ASP (average sale price). The value proposition is the small size and relatively high performance of our ZDR and FMOS oscillators. A low end application would be a USB3.0/e-SATA FMOS oscillator. The target area is 0.3 mm^2 with a thickness < 0.16 mm leading to a total volume of 0.04 mm^3. In comparison a commercially available miniature quartz resonator operating at the same frequency is 0.672 mm^3 or 17X larger. This size would allow the ASIC manufacturer to insert this oscillator inside their QFN package or do a 'die-on-die' stacking of the part, which reduces the net BOM of their customers as well as guaranteeing performance and size.

However, longer term, FMOS can be used as critical elements in ultra-small low power radios, GPS receivers, and other electronic devices where small size and low power are key differentiators.

Abstract—**This paper discusses possibilities of tunable radio frequency (RF) surface and bulk acoustic wave (SAW/BAW) filters. First, configuration of RF front-end in current wireless communication systems is surveyed, and research trends of the flexible RF front-end and software defined radio (SDR) are discussed. Second, various RF tunable filters are introduced, and we discuss how high performances are expected by the use of tunable RF SAW/BAW filters provided that above mentioned key technologies are developed. Finally, we explain what kinds of research subjects are going on in our projects for realization of the flexible RF front-end for the SDR.**

I. INTRODUCTION

Adding to ultimate down sizing, supporting multi-band and multi-standard operation is required in current mobile phones. Nowadays high-end phones support eight frequency bands for two communication standards[1]. This makes the radio-frequency (RF) front-end section of the transceiver very complex[2]. It seems very difficult to support further standards and/or frequency bands, although current RF-ICs are powerful enough to support them.

As a possible solution to relax this problem, the software defined radio (SDR)[3-7] in combination with the flexible (tunable) RF front-end[8-10] has been paid much attention. Majority of transceiver functionalities is realizable by skillful use of digital signal processing and digitally-controlled analog technologies. Nevertheless, development of high performance tunable RF filters is mandatory for the realization of really flexible RF front-end. They should be able to change the passband width and/or center frequency, preserving performances achieved by current RF surface and/or bulk acoustic wave (SAW/BAW) devices[11-15]. Although certain number of attempts was reported[16-21], achieved performances were pessimistically low for practical use.

Recently, the author's group proposed a variable RF filter composed of wideband RF SAW/BAW resonators and variable capacitors (VCs)[22], and showed that not only the filter bandwidth but also the center frequency can be tuned for a wide range provided that following three key technologies are developed; (a) interconnection of SAW/BAW resonators with multiple VCs and controlling circuitry, (b) extremely wideband SAW/BAW resonators, and (c) high quality factor (Q) VCs with wide tuning range. Recent advancement of related technologies is going to resolve these hard obstacles. For example, (a) the micro-electromechanical system (MEMS) technologies enables chip-on-chip integration among heterogeneous technologies, (b) new piezoelectric materials with extremely large electromechanical coupling factor were proposed, and (c) high performance ferroelectric VCs were developed.

In collaboration with leading-edge research labs in Japan, namely, SAW R&D division in Murata MFG, Co. Ltd, the wireless communication research center in the National Institute of Information and Communications Technologies (NICT), and other outstanding technical supporters, we started a project to develop a really flexible RF front-end including tunable RF SAW/BAW filters applicable to present and/or future communication systems such as the cognitive radio[23].

This paper reviews current status and future prospects of this project.

First, configuration of RF front-end in current wireless communication systems is surveyed, and research trends of the flexible RF front-end and SDR are discussed. Second, Various tunable RF filters are introduced and compared, and we show how high performances are expected by the use of tunable RF SAW/BAW filters provided that above mentioned key technologies are developed. Finally, we explain what kinds of research subjects are running in our projects for realization of the flexible RF front-end for the SDR.

II. WHY SAW/BAW DUPLEXERS ARE NECESSARY?

Fig. 1 shows a basic configuration of radio receivers. Receive (Rx) signals detected by an antenna (ANT) are down-converted to the base-band (BB) by the frequency mixing with the local oscillation (LO) after the band selection by the RF band-pass filter (BPF) and amplification by the low noise amplifier (LNA). Then target signals are selectively detected by a detector circuit after the channel selection by a BB low-pass filter (LPF).

Most important task of the RF-BPF is to suppress incidence of jammer signals to the LNA and mixer without badly affecting the noise figure (NF) of the receiver. At the frontend, the insertion loss causes NF deterioration of the same amount.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

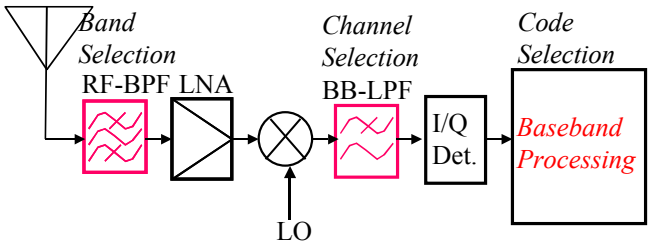

Fig. 1 Simplified receiver architecture

Thus ultimate reduction of the insertion loss is requested to the RF-BPF.

When a strong jammer signal is incident to the LNA and mixer, they may loose their gains (desensitization) and/or may generate in-band signals through the non-linear mixing. Thus the RF-BPF is also requested to offer good out-of-band rejection. However, the insertion loss and the out-of-band rejection are trade-off for the RF-BPF design in general, and we can not optimize both of them simultaneously.

Some wireless communication systems employ the frequency division duplex (FDD), which separate uplink (terminal to base-station) and downlink (base-station to terminal) signals in frequency domain. In the case, the strongest jammer for the receiver is transmit (Tx) signals generated by a transmitter circuit in the same terminal.

Fig. 2 shows the RF front-end of the FDD-mode transceiver. The ANT is also used for emitting Tx signals generated by a power amplifier (PA). An RF BPF is sandwiched between the ANT and LNA so as to reject unwanted signals detected by the ANT and/or those emitted by the PA. Another RF-BPF is sandwiched between the ANT and PA so as to suppress unnecessary signals generated by the PA. The insertion loss of this filter in the Tx band must be also minimized because it results in increased battery power consumption and heat up of the PA and the Tx filter.

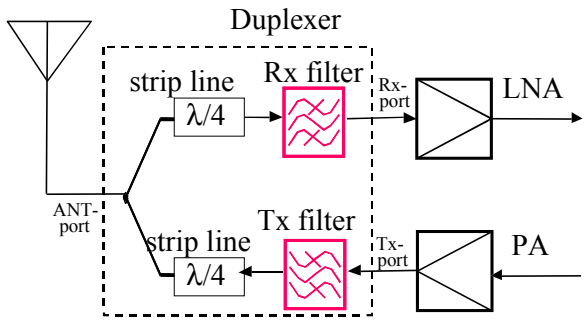

Fig. 2 RF front-end of FDD-mode transceiver.

The circuit block composed of two filters and two λ/4 strip lines is the antenna duplexer (DPX), which is one of the most important applications for RF SAW/BAW devices. Due to the frequency gap between the TX and Rx bands, we can suppress power leakage of the TX signal and noise output from the PA to the LNA to some extent. The strip lines are used to reduce electrical interferences between two filters, and are usually embedded into the DPX package.

Rx signals detected by the ANT can be extremely weak, say in –100 dBm order, which is slightly higher than the thermal noise level [2]. On the other hand, Tx signal emitted from PA can be strong, say in +25 dBm order[2]. From the W-CDMA specification, the receiver function should withstand jammer intensity up to –15 dBm. This indicates that nonlinearity of the DPX should be negligible.

Currently only the RF SAW/BAW DPXs fulfil all of these stringent requirements for the use in mobile phones, and thus are able to occupy the market share. DPXs employing dielectric resonators (DRs) exhibit excellent performances, and are widely used in base-stations. However, they are bulky and do not fit into compact mobile phones.

Until very recent year, interstage SAW filters has been inserted between the LNA and mixer to relax the nonlinear problem. Currently, many attempts so called "SAW-less" have been reported to remove them[2]. Then extremely high linearity is requested to the mixer which is exposed to jammer and leaked Tx signals without attenuation by the interstage SAW filter. This causes self-mixing of the modulated Tx leakage and generates unwanted signals at the baseband in addition to the DC component. This is called the cross modulation. For example, when the Tx output power is +25 dBm and the Tx-Rx isolation in the Tx band is 50 dB, the receiver circuit is requested to have extremely high input referred second-order intercept point (IIP2) close to +46.3 (≈110+2*(25-50-3)+α) dBm to suppress the non-linear output below -110 dBm[24]. In the equation, α (=-7.7 dB) is a correction factor for the modulated UMTS up-link channel[24]. This fact clearly indicates how deeply current mobile phones rely on the isolation given by the DPX.

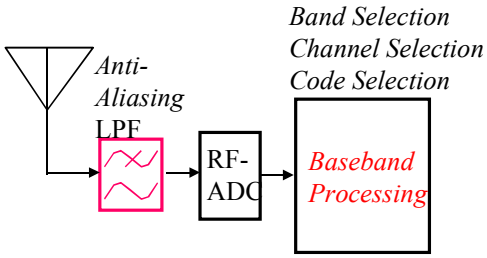
III. Software Defined Radio

An ideal solution to support multi-band and multi-mode operation is introduction of the SDR[3-7]. In an ideal SDR receiver shown in Fig. 3(a)[3], incoming RF signals are directly analog-to-digital converted, and all necessary signal processing including the band and channel selection is carried out in digital domain. Only a broadband low-pass filter (LPF) is necessary for anti-aliasing in the RF section. The operation mode can be changed and upgraded by uploading specific software. In an ideal SDR transmitter, outgoing RF signals are directly generated by a digital-to-analog converter (DAC) from date stream.

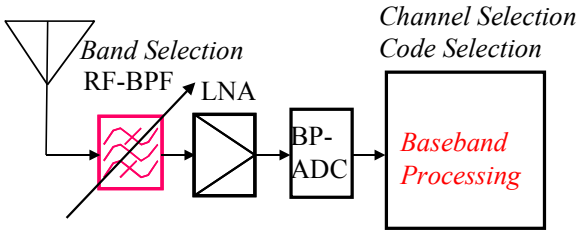
The biggest obstacle for the realization is implementation of high-speed, low-noise and high-resolution analog-to-digital and digital-to-analog converters (ADC/DAC). In high frequency ADC/DAC, the RMS signal-to-noise ratio (SNR) is limited by the clock jitter J_{RMS}[25] rather than the quantization noise, i.e.,

$$\mathrm{SNR} < -20\log_{10}\left[2\pi f_{\max} J_{\mathrm{RMS}}\right], \qquad (1)$$

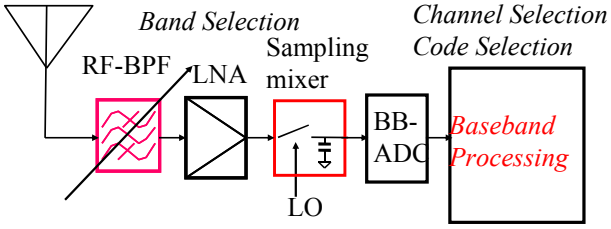
where $f_{\max}$ is the maximum signal frequency. Eq. (1) suggests that even when J_{RMS} is reduced to 0.1 ps, resulting SNR is limited to 58 dB for $f_{\max}$=2 GHz. This value is insufficient for mobile communications. This fact clearly indicates that the ideal SDR is not realistic in GHz range.



(a) Ideal scheme



(b) Under-sampling scheme



(c) Down-conversion scheme

Fig. 3 Software defined receiver architecture.

A little realistic scheme is combination of the tunable RF frontend with the bandpass ADC shown in Fig. 3(b)[8,26]. In this configuration, the band selection is done by RF analog filtering, and remaining channel selection is carried out digitally. Due to under-sampling operation of the ADC, f_{max} in Eq. (1) is given by the bandwidth of the RF filter. In this case, extremely high out-of-band rejection is requested to the RF BPF because the under-sampling does not offer the frequency selectivity and jammer signals must be suppressed to the noise level by the RF BPF alone.

More realistic scheme is combination of the down-conversion with the sampling mixer[27] shown in Fig. 3(c) [5,6,9,10]. Output current of the transconductance LNA is sampled by a CMOS switch and accumulated to a capacitor. This action is equivalent to the boxcar integrator or the infinite impulse response (IIR) filter, and thus the down-conversion, sampling and LPF functions are simultaneously achieved. High-speed (~80 MHz sampling rate) and high-resolution (~14bits) are requested to the ADCs to avoid disturbances caused by strong in-band interferers[6]. Such devices are commercially available, but still expensive and power hungry.

Another scheme is the same as the one shown in Fig. 1 but tunablity is given to the BB-LPF for the channel selection [5,6].

Fig. 4 shows an extension of the sampling mixer called the charge domain filter[5,6,28,29]. Current output of a trans-conductance amplifier is sampled by following N capacitors C_r successively, and summed charges are re-sampled (decimation) and detected by the ADC. This action is equivalent to the N-tap finite impulse response (FIR) filter.

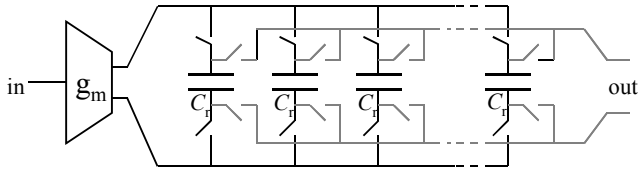


Fig. 4 Charge domain filter

Theoretically, sharp cut-off characteristics can be realized by cascading multiple sections[5,6]. Furthermore, in addition to the CMOS compatibility, the circuit offers adjustability of the filter bandwidth using the sampling clock frequencies. From these features, it seems that RF-BPF can be eliminated provided this topology offers sufficient out-of-band rejection. This is the perfect solution as the analog front-end of the SDR. However, extremely high linearity is required to the LNA in this case because it will be directly exposed to jammer signals[5,6]. In FDD transceivers, lack of DPXs will request the IIP2 higher than +120 dBm.

Thus majority of reported SDRs still equip series of high-performance fixed frequency RF-BPFs based on SAW/BAW technologies, and choose appropriate one(s) for the band selection[4,5,7,30,31].

In current mobile phones, most of all functionalities except RF-BPFs including DPXs and PAs have already been integrated into a single CMOS chip. In addition, use of the fixed RF filters is not flexible enough to introduce new communication standards. Thus such SDRs do not offer practical merit for the use in mobile phones.

IV. Tunable RF Filters

It is clear that tunable RF frontend, especially tunable RF-BPFs, can be an invaluable tool for realization of fully flexible SDRs.

Combination of RF BAW filters with RF micro-electromechanical system (MEMS) switches gives a possibility to integrate them with CMOS circuitry on a single Si chip[32,33]. It is possible, but not practical. This is because the AlN thickness control is too tough to produce multiple RF BAW filters with different design simultaneously.

Use of RF MEMS filters using in-plane vibration can relax the requirement for the AlN thickness control[29,32]. However, achievable filter bandwidth is narrow due to small electromechanical coupling for the vibration mode. It should be noted that small dielectric constant of AlN forces the device area large in order to obtain small input impedance for impedance matching with peripherals such as the antenna.

Various types of continuously tunable filters have been also proposed and developed. Magnetically tunable filters using the ferromagnetic resonance, such as yttrium iron garnet (YIG) spheres and films[34], offer low insertion loss and

multi-octave tuning range, and are widely used in tele-communication systems[35]. However size, weight, price and current consumption do not fit to the use in handy terminals. Intrinsic non-linearity is also a problem.

Mechanically tunable filters are also commercially available. But they are too large, too heavy and too slow for the current purpose[36].

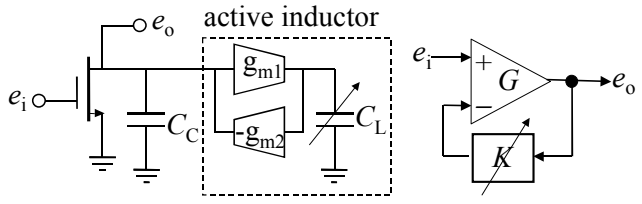
Certain number of attempts was reported on electrically tunable filters and some of them have already been mass produced[36]. Basic idea is to combine inductive circuit elements with VCs[36-38]. When lumped-element inductors are used, achievable Q is limited. On the other hand, when micro-strip lines are used, achievable Q is better, but the device size is large in a few GHz range.

As VCs, various types have been used. The GaAs VCs has been used because of its large tuning range[36]. However its Q is not so high and nonlinearity is large. VCs based on MEMS technologies[39,40] offer high Q while their physical size is relatively large and tuning range is relatively narrow. Currently, VCs employing ferroelectric ceramics such as bismuth strontium titanate (BST) are paid attention for their wide tuning range and relatively high Q[41].

Combination of CMOS (or MEMS) switches with fixed capacitor arrays is an interesting approach[42,43]. This offers large tuning range and high Q simultaneously. In addition, the total capacitance can be set digitally, and the device can be integrated with driving and control circuitry.

DRs offers extremely high Q but bulky in a few GHz range. A widely-tunable BST-based DR filter was reported, but it operates in 30 GHz range[44].

RF active filters have been also investigated extensively. There are two types. First one composes a resonator circuit using the gyrator-based active inductor[45] (see Fig. 5(a)). It causes the parallel resonance with C_C, and the voltage gain e_o/e_i becomes large. The resonance frequency and Q can be tuned by C_L and the trans-conductance g_m, respectively. Another one employs the positive feedback loop and acts as the IIR filter[46,47] (see Fig. 5(b)). The resonance frequency and Q can be tuned by adjusting phase shift in K and the gain G of the amplifier, respectively. These devices can be implemented into RF-ICs. In addition, they offer wide tuning range and high Q. In fact, Q can be infinite, and the situation corresponds to the self-oscillation. Thus we must apply fine gain setting to achieve high Q. Another problem is nonlinearity. Since the total gain becomes large when Q is high, the input-referred intercept points will be small due to output saturation.



(a) Active inductor-based filter (b) Recursive filter

Fig. 5 RF active filters embedded in LNA

Several types of tunable RF SAW/BAW filters were also proposed. Use of ferromagnetic, ferroelectric, and intrinsic and induced piezoelectricity has been discussed extensively to adjust acoustic wave velocities[48,49]. However, reported tuning ranges are limited to less than a few percents. Fancy one is to place an acoustic load above the RF BAW resonator using a movable hinge of the MEMS switch[17]. Although change of the center frequency more than 10% is expected, experimental results were not reported until now.

The author's group proposed another approach, which employ combination of VCs with extremely wideband SAW resonators[22]. Fig. 6 shows its topology. Basic design is exactly the same with the conventional ladder-type filter, and VCs connected in parallel with SAW resonators shift their anti-resonance frequencies while VCs connected in series shift their resonance frequencies. Thus proper VC setting enables us to adjust location of upper and lower edges of the filter passband independently.

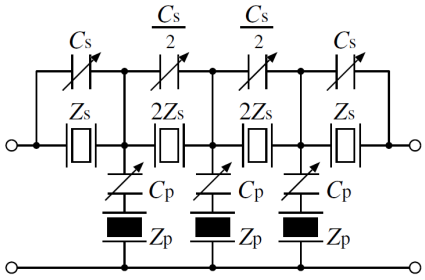


Fig. 6 Tunable filter configuration employing acoustic wave resonators and variable capacitors

We fabricated two SAW filters with identical resonator design but different capacitance values, and action of the tunable filter was simulated experimentally[22]. For achieving wide tunable range, SAW resonators on a Cu-grating/15°YX-$LiNbO_3$ (15-LN) substrate structure[50] were employed. Shear-horizontal (SH) SAWs on this structure possess extremely large k^2 (~30%).

Figure 7 shows the measured frequency responses of these two filters. It is seen that the passband can be translated. An

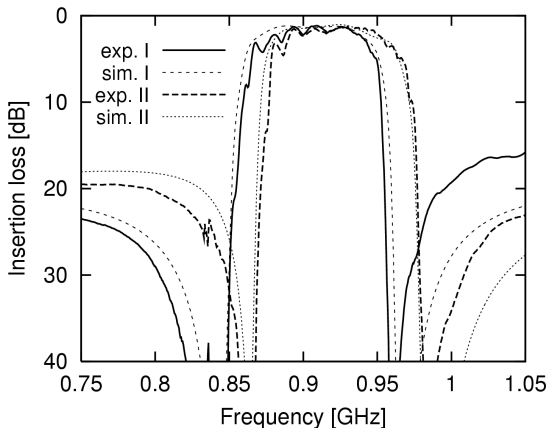

Fig. 7 Frequency response of a variable filter composed of wideband SAW resonators.

interesting feature is the fact that the passband characteristic is insensitive to the Q factor of VCs. A drawback of this design is limited tunability due to existence of a certain frequency range which is always included in the filter passband.

We also showed that passband width and location can be adjusted more flexibly by using the topology shown Fig. 8 [22]. One drawback of this configuration is sensitivity of filter performances to the Q factor of VCs. Namely that of C_s^s and C_p^p in Fig. 8 influences the filter insertion loss and steepness of the passband edges significantly.

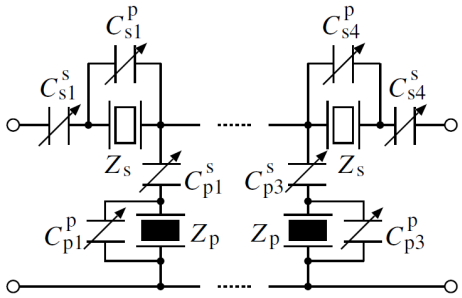

Fig. 8 Another tunable filter configuration employing acoustic wave resonators and VCs.

It is clear that wide tunability is realizable when we adopt variable inductors and/or fixed inductor with switch arrays in this configuration[51]. However, this approach seems not feasible because the Q factor of conventional inductors is pessimistically low in GHz range.

Tunable frequency range of these filters is inherently limited by the capacitance ratio γ of employed RF SAW/BAW resonators, and thus use of piezoelectric materials with extremely large k^2 is essential for its realization.

An interesting attempt for high k^2 realization is use of the piezoelectric layer prepared by polishing a ferroelectric single crystal plate[52,53]. This approach allows us to use arbitrary materials with arbitrary crystal orientation. Presently, the plate thickness can be reduced close to 1 μm. When the technology is applied for fabrication of RF BAW and Lamb wave resonators, small γ and moderate Q factor are achievable simultaneously in GHz range using commercially available high-quality and large-size $LiNbO_3$ wafers.

Use of highly piezoelectric materials such as PMN-PT[54], PIM-PMN-PT[55] and $KNbO_3$[56] is also a possible approach. For example, Matsushima, et al reported development of an FBAR with high k^2 (~0.5) and relatively high anti-resonance Q (~150) using a sputter-deposited $Pb(Mn,Nb)O_3$-$Pb(Zr,Ti)O_3$ film[57].

V. Integration of MEMS and SAW Filter

For realization of practical tunable SAW/BAW filters, multiple VCs and control electronic circuitry must be interconnected in high density with RF SAW/BAW resonators, which are very sensitive to parasitic impedance. Because use of highly piezoelectric ferroelectric materials is mandatory, the chip-on-chip integration seems to be most feasible and pragmatic.

There are two possible configurations: (a) VCs are fabricated at first on a piezoelectric substrate with SAW electrode patterns, and then the flip-chip interconnection is done with a Si chip where RF and control circuits are made [58], and (b) VCs and RF BAW resonators are fabricated on a bare Si substrate at first, and then it is flip-chip bonded with another Si chip with RF and control circuits.

As a first trial for the configuration (a), integration of MEMS VCs on $LiNbO_3$ was investigated[59]. Fig. 9 shows top and side views of the device structure, which consists of 5 SAW resonators, 2 VCs and one fixed capacitor. Fig. 10 shows the fabrication process. First, SAW resonators and fixed capacitors are fabricated using Au electrodes (110 nm) on a 15°YX-$LiNbO_3$ wafer by the lift-off process (Steps 1 and 2). The lift-off process is again applied for the fabrication of Au stopper posts, on which the capacitor bridge lands when pulled in (Step 3). Next, a sacrificial layer is formed using

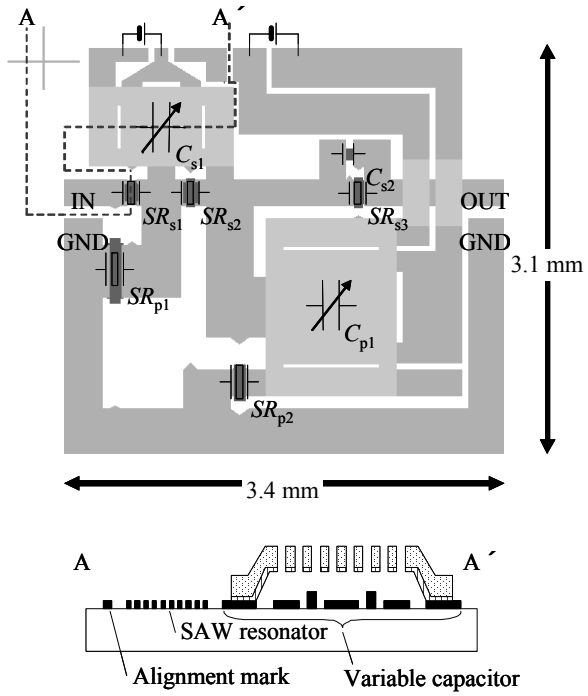

Fig. 9 Device layout and cross sectional views of tunable filter.

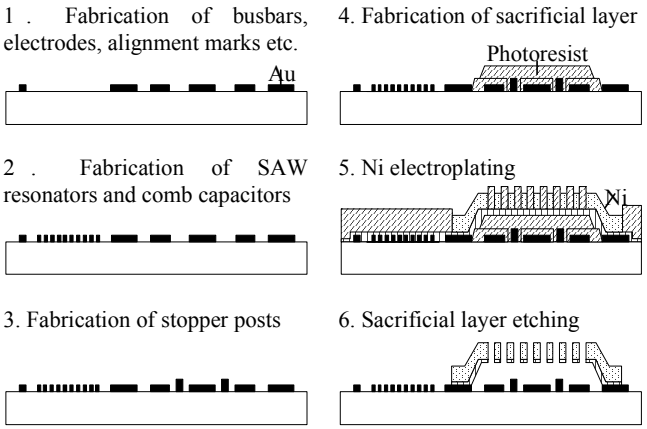

Fig. 10 Fabrication process for the tunable SAW filter.

negative photoresist, and a Cu seed layer is sputter-deposited (Step 4). To make the capacitor bridge, a positive photoresist is patterned for a mold, and 2 μm thick Ni is electroplated in the mold (Step 5). The photoresist mold is removed by organic stripper, and the Cu seed layer is removed by ammonium persulfate. Finally, the double sacrificial photoresist layer is removed by O_2 ashing to release the capacitor bridge (Step 6).

Figure 11 shows the measured and theoretical transmission characteristics of the filter. Although relatively wideband width of about 13% was achieved both theoretically and experimentally, experimental insertion loss (12 dB) was much larger than the theory. This deterioration is mainly due to surface contamination by the photoresist residue, which could not be completely removed by O_2 ashing at the Step 6.

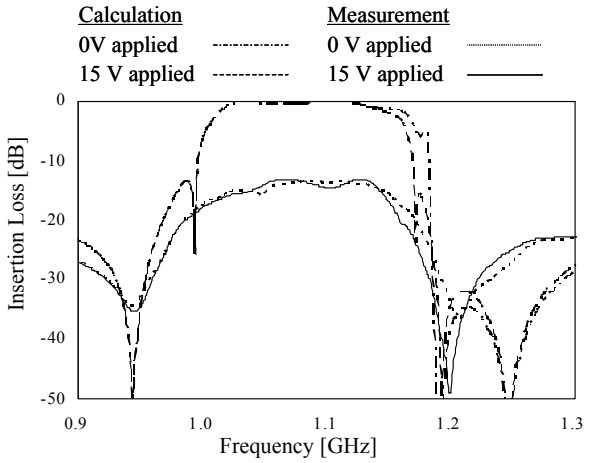

Fig. 11 Measurement and Simulation

For the passband tuning, DC voltage was applied to both C_{s1} and C_{s2} (see Fig. 9a). The application of 15 V made C_{s1} pulled in, and -3 dB bandwidth was reduced from 146 MHz to 130 MHz, as shown in the figure. On the other hand, C_{p1} could not be actuated even when 100 V was applied. This may be due to the buckling of the capacitor bridge, which might be caused by the stress of electroplated Ni.

It is seen from Fig. 9 that the MEMS VCs are much larger than the SAW resonators. This is because vacuum is used as the dielectrics for the MEMS VCs. For the size reduction, we also investigate on-chip integration of BST VCs on the SAW substrate. The result will be presented in future.

We also need to develop driving and control circuitry for the VCs on a Si chip, which will be interconnected with the SAW substrate using the flip-chip technology. These research topics are also involved in this project.

VI. CONCLUSIONS

This paper reviews current status and future prospects of the project aimed at developing tunable RF SAW/BAW filters.

Although we only discussed use of RF SAW devices in this paper, we also investigate integration of RF BAW resonators and VCs on a Si chip.

Applicability of the on-chip technologies is not limited to tunable filters. For example, we are also interested in RF oscillators and amplifiers.

Although the tunable filter under concern is expected to offer low loss and wide tunability, its performances are still not enough for the replacement with current RF SAW/BAW DPXs. Especially, high isolation between their TX and RX ports is hard to realize.

Currently, various approaches are investigated extensively to relax the isolation requirement given to DPXs. Integration of an interstage notch-filter for the TX signal leakage[24] and its active cancellation[60] are their examples. Use of RF active filters described in Section IV seems also effective for the purpose. IMD cancellation using base-band signal processing is also investigated[61]. These technologies may make tunable DPXs more realistic.

Our goal is far beyond the horizon. But the strong demand is the enough reason to challenge this difficult task.

ACKNOWLEDGMENT

The authors thank members of the project and anonymous students in Chiba and Tohoku Universities for their supports and discussions. This research is supported by the Japan Society for the Promotion of Science (JSPS) through its Funding Program for World-Leading Innovative R&D on Science and Technology (FIRST Program).

***Abstract*—This work presents a novel cascaded filter array architecture for large-scale MEMS filter arrays that overcomes the limitations associated with the large shunt capacitance to efficiently scale the number of filters in the array. The proposed architecture effectively reduces the capacitive loading at the input by utilizing a series connection of the filters, resulting in improvement in the return loss and stopband rejection for large arrays. This work demonstrates the feasibility of large-scale filter arrays without the need for additional costly isolation strategies for real-time spectrum monitoring applications.**

I. Introduction

On-going research and development of high quality factor (Q) RF MEMS resonators and filters has allowed their use in a number of RF applications, such as timing references and front end band-select filters [1-4]. Many of these devices have been designed to fit the specifications of current communication system architectures as direct replacement components for quartz or SAW devices with notable success. Currently, most radio architectures use the concept of band-select filtering followed by heterodyning to a lower intermediate frequency, where further signal processing and channel-select filtering is performed. This architecture has been established as the standard for most radio front ends since its invention by Armstrong [5]. It, however, involves a number of tradeoffs between various performance metrics, including linearity, power consumption, and noise, which have been unavoidable largely due to the lack of extremely narrowband filtering capability at RF frequencies using conventional resonator technologies. RF MEMS resonators may be able to relax some of these tradeoffs due to their ability to realize extremely high Q exceeding 10,000 on chip, providing the potential for extremely narrowband filters even at VHF and UHF frequencies. Furthermore, this capability may even enable new types of communication standards and radio architectures for specific applications. One such application is cognitive radio, systems that are able to scan the spectrum and setup a communication link on relatively unused channels or identify and filter blocker signals before they saturate other sensitive electronics [6,7]. Large scale RF MEMS filter arrays have emerged as a key technology which may enable cognitive radio for mobile applications due to the unique ability of this technology to provide both channel-select filtering and lithographical definition of resonant frequency on an integrated platform. However, the number of filters necessary for such applications is on the order of hundreds to thousands.

Recent work has demonstrated arrays each with two and ten separate filters [8,9]. In both cases, the filters were connected in the conventional parallel configuration that is normally envisioned for such an array. While these works demonstrated arrays with multiple filters, they left unanswered questions about how the performance of such arrays would scale as the number of filters is increased. This is a problem due to the shunt capacitance present at the input of any RF MEMS resonator or filter, regardless of the transducer used. As the size of the array increases, the input loading from these shunt capacitors will increase in proportion to the number of filters in the array, significantly degrading performance. The first example [8] shown above was able to circumvent these negative effects by using a differential architecture and a

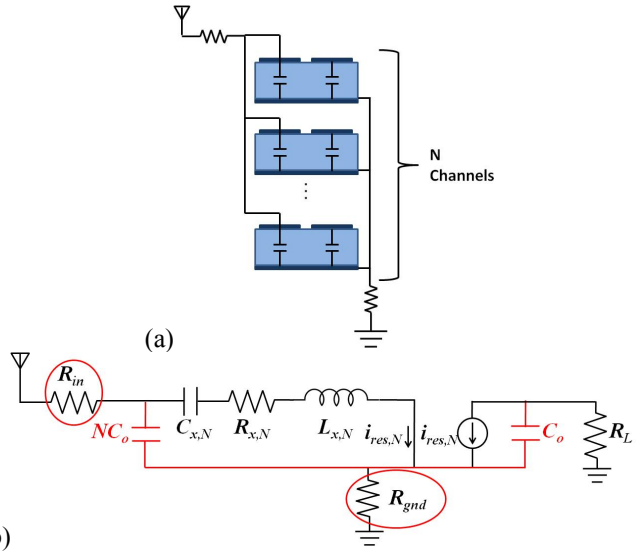

Figure 1. (a) Simplified schematic of the conventional parallel filter array architecture. (b) Equivalent circuit model used for analysis with feedthrough path highlighted in red and important parasitic resistances circled.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

parallel inductor to resonate with the shunt capacitance. The utility of such methods, however, are severely limited when it comes to scaling to hundreds of filters. On the other hand, the second example [9] used an AlN transducer, which is known to be a very efficient transducer, and thus is relatively unaffected by the shunt capacitance at such low frequencies and small array sizes. However, as the filter array increases in size and is designed to operate at higher frequency, it will also suffer from the input loading presented by the shunt capacitance. Others have suggested alternative methods of alleviating this problem by added isolation using integrated switches [10] but mechanical switches have yet to be successfully integrated into radio systems or cellular phones, making their use difficult in large scale arrays.

While the problem of shunt capacitance has been raised as an issue potentially limiting the use of MEMS filter arrays, to the authors' knowledge, a rigorous analysis of its effects on filter array performance for arbitrarily large array sizes has not yet been reported. In this paper, we present an analysis based on Butterworth-Van Dyke (BVD) equivalent circuit models with relevant parasitic elements and find that these parasitics combined with the large shunt capacitance severely limit filter performance when using a simple parallel array architecture. We then propose a novel series cascaded filter array architecture that provides a means of alleviating the increasingly negative effects of the shunt capacitance as the array increases in size. Experimental results will then be presented to verify our analysis and we will conclude with a summary and implications of this work.

II. Conventional Parallel Architecture and Effects of Shunt Capacitance

While the MEMS community has been focusing much of its energy on trying to interface directly to a 50 Ω environment (i.e., obtaining motional resistance of 50 Ω), in many cases this has been achieved naively by increasing the transduction area, which also increases the shunt capacitance. In general though, unless the filter array interfaces directly to a 50 Ω distributed system (e.g., antenna), this is not a necessary requirement. In fact, for a given motional resistance, it is always possible in the ideal case (i.e., no parasitic shunt capacitance) to terminate the filter with an optimal impedance which will result in nearly ideal filter characteristics, as long as the Q of the resonators is sufficiently high (i.e., $Q_{res} >> Q_{filter}$). Systems terminated with impedances on the order of 1 kΩ or lower have been demonstrated with low insertion loss and suitable shape factor, indicating that this is not the fundamental limitation [9]. The main problem in the context of large scale filter arrays then is not the motional impedance but the loading of the shunt capacitance. Even the work in [9] achieves its well-behaved filter response only after using the methods previously discussed to mitigate the negative effects of the shunt capacitance. Some of the well-known effects include large insertion loss and passband return loss due to a large impedance mismatch with the source that increases with array size. There are, however, other seldom considered effects – particularly in the stopband response – that arise due to parasitic routing resistances that become increasingly important as array size increases. As a starting point for analyzing these effects, we use a model based on the illustration in Fig. 1(a). An equivalent circuit model is shown in Fig. 1(b). Here, N represents the number of channels in the filter array (i.e., array size), R_{in} models any parasitic interconnect losses, and R_{gnd} models imperfect grounding that results from interconnect losses in the ground plane. The input is loaded by the parallel combination of the shunt capacitances of N filters. We will discuss in this section specifically how a number of important filter metrics – return loss, stopband rejection, and insertion loss – are affected by the shunt capacitance loading and parasitic resistances.

Before discussing the simulation results, note that the following simulations are based on data collected from individual 20 MHz PZT-on-Si filters fabricated at the U.S. Army Research Laboratory. The transduction area of these devices is scaled to achieve 50 Ω motional impedance. These devices are used specifically because the extremely high dielectric constant of PZT makes the loading effects significant at relatively low frequencies and small values of N. This significantly reduces the burden on fabrication and measurement setup for experimental demonstration. This does not, however, restrict the generality of this analysis. While these loading effects in other strongly coupled transducers may become significant at higher frequencies or larger N, this problem cannot be avoided by simply choosing a different transducer, especially when the goal is to design a large scale

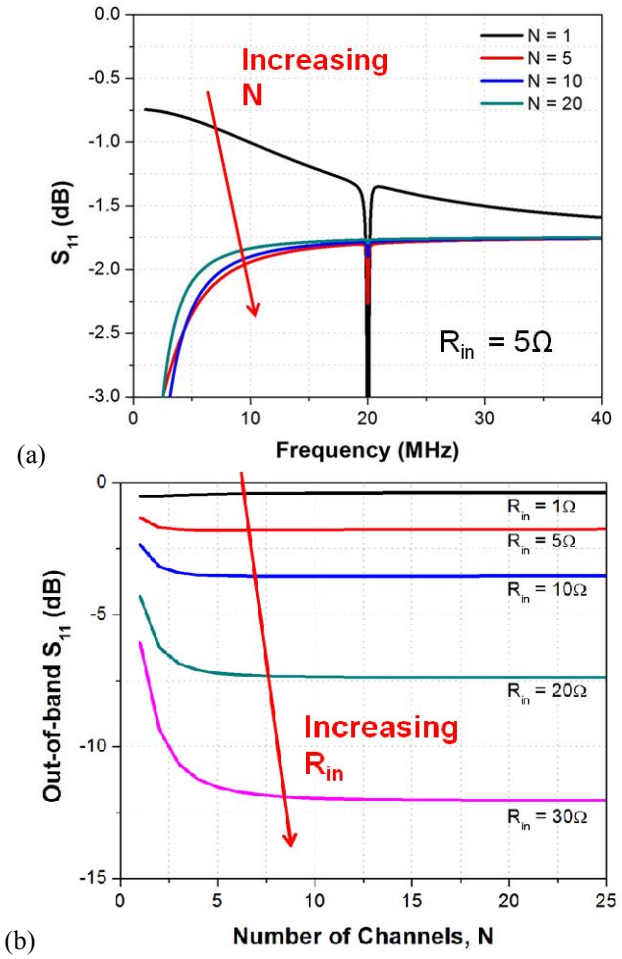

Figure 3. Return loss simulation results (a) as a function of frequency for R_{in} = 5Ω and varying N and (b) stopband return loss as a function of N at 20 MHz.

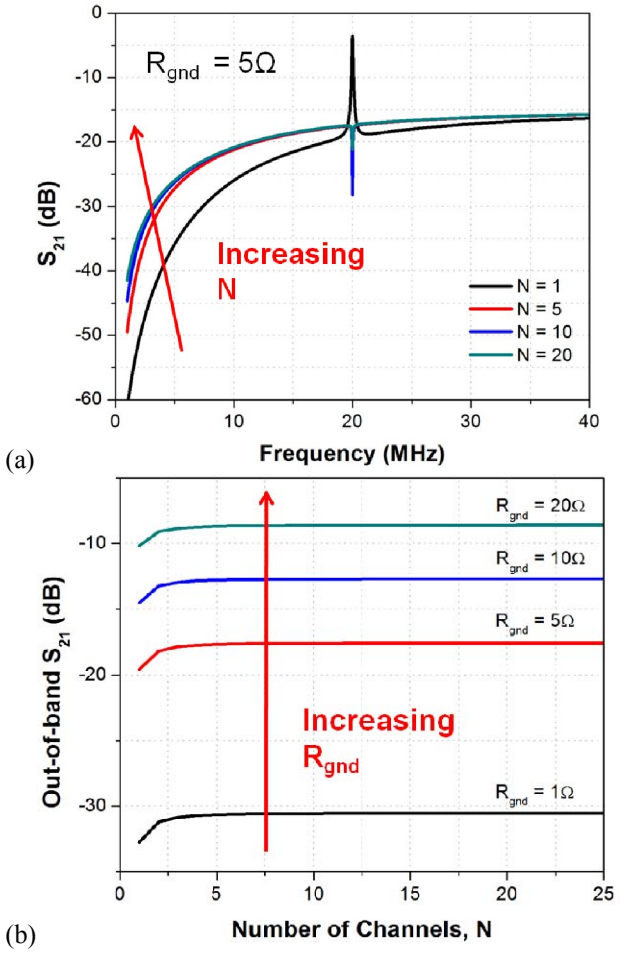

Figure 4. Transmission simulation results (a) versus frequency for R_{gnd} = 5Ω and varying N and (b) feedthrough signal as a function of N at 20 MHz.

filter array with hundreds or thousands of filters.

A. Return Loss

For filters, a large value of return loss in the stopband and a small value in the passband are typically desired. While the need for small passband return loss is well known, it is also important that the stopband return loss be large, a fact often overlooked by designers of MEMS filters. This requirement ensures that energy at these frequencies is not intercepted and wasted in the filter array – even -1 dB of return loss in the stopband means 20% of the incident power is absorbed. Also, nonlinearities may cause interference to appear in the filter passband if strong signals interact with one another. To see how this parameter is affected as the array size increases, we simulate the frequency response of the return loss for a fixed value of R_{in} = 5 Ω and various values of N (Fig. 3(a)). We see that as N increases, the stopband return loss converges to a certain value. This is due to the decreasing impedance of the effective shunt capacitance with increasing N, which virtually terminates the parasitic resistance R_{in} to ground. This provides a path for stopband energy to be absorbed by the filter array and dissipated in R_{in}, in contrast to the case when R_{in} = 0 where this energy was completely reflected. This is also illustrated in Fig. 3(b), which plots the stopband return loss as a function of N for different values of R_{in} at 20 MHz and shows that the stopband return loss converges to a value for large N that is highly dependent on R_{in}. Interestingly, Fig. 3(a) also indicates that the notch depth in the passband decreases as N increases. This indicates that as N increases, less passband energy is absorbed in the filter and any energy that is absorbed is dissipated in the parasitic resistances.

B. Stopband Rejection

Another common problem for RF MEMS filters is the feedthrough signal which limits the stopband rejection. This is often the result of imperfect grounding of the device. The path though which this signal may flow is highlighted in red in Fig. 1(b) and includes the shunt capacitance. Thus, we expect that this feedthrough signal will also be affected as the filter array increases in size. The simulated transmission results for R_{gnd} = 5 Ω and different values of N shown in Fig. 4(a) confirm that the feedthrough signal increases with N, and for certain values of R_{gnd} and N, the feedthrough may even exceed the insertion loss, eliminating the filter response. As in the case for the stopband return loss, the feedthrough converges to a value which is highly dependent on the parasitic resistance R_{gnd}, as shown in Fig. 4(b). This, again, is due to the decreasing impedance of the effective shunt capacitance as N increases, making the feedthrough signal a very strong function of R_{gnd}.

C. Insertion Loss

As previously mentioned, the main reason why insertion loss increases with N is because of impedance mismatch – energy is reflected away rather than flowing into the filters in the array. When these parasitic resistances are now added to the analysis, it is evident that energy dissipation through them – which was also found to impact stopband return loss – is an additional mechanism that prevents energy from reaching the filters. As the previous simulation results show, this dissipation increases with N for given values of the parasitic resistances R_{in} and R_{gnd}, and as already discussed, beyond a threshold value for N depending on R_{in} and R_{gnd} the filter response is practically lost. Again, this behavior is highly sensitive to these parasitic components for large N, setting a limit to the achievable array size. Of course, it is always desirable to minimize these parasitics through good fabrication. However, there may be certain limits to how low they can be made in practical systems. For increased robustness and insensitivity to process variations, it would therefore be desirable to also employ architectural methods of reducing the sensitivity of the filter array to these parasitic components. We see, however, that because of the large capacitive loading at the input, the parallel filter architecture does not provide any robustness to these parasitic resistances, especially as the size of the array increases.

III. Series Cascaded Filter Array Architecture

The analysis in the previous section indicates that the main issue limiting the performance of large scale MEMS filter arrays using the parallel architecture is the large effective shunt capacitance at the input. This combination of N shunt capacitances results in an impedance that decreases with

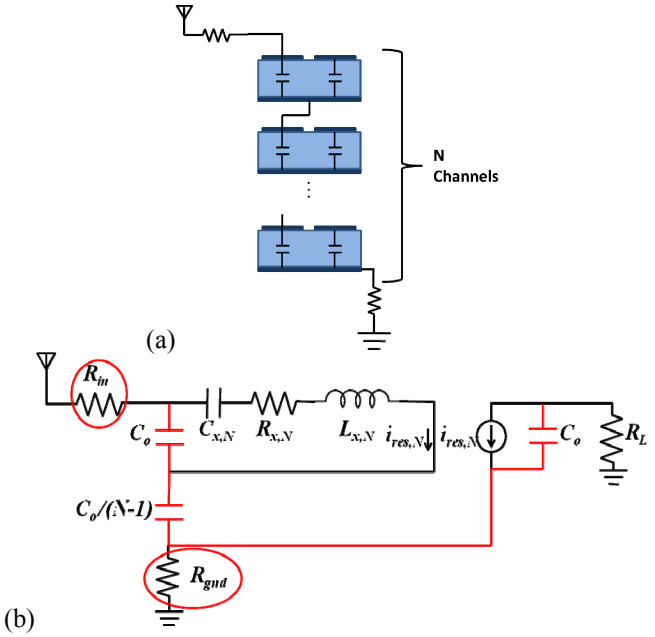

Figure 5. (a) Simplified schematic of proposed series cascaded filter array architecture. (b) Equivalent circuit model used for analysis with feedthrough path highlighted in red and important parasitic resistances circled.

increasing N, leading to a large feedthrough signal and allows the wasteful dissipation of energy through parasitic resistances. Furthermore, the filter response for large N becomes very sensitive to these parasitic resistances, which is undesirable. To avoid this problem, we propose an array architecture where the filters in the array are connected such that a series connection of their shunt capacitance is realized. This will be referred to as the series cascaded filter array architecture and Fig. 5 shows a simplified illustration of this architecture with its equivalent circuit model. For this architecture, since the filters are now connected in series, we expect the effective shunt capacitance to be inversely proportional to N, which results in an impedance that actually increases with array size. It is then expected that both the stopband return loss and feedthrough signal should improve as the array size increases.

We verify the improvement in stopband return loss, by simulating the return loss as a function of frequency for a constant value of R_{in} = 5 Ω and for different values of N (Fig. 6(a)). The results show that the stopband return loss approaches 0 dB as N increases, as expected. More significantly, Fig. 6(b) shows that this is true regardless of the value of R_{in}, as opposed to the parallel filter array architecture in which this parasitic resistance determines the value of return loss for large N. This indicates that the high impedance of the series cascaded array architecture effectively prevents stopband energy from being dissipated in R_{in} and allows it to be reflected back to the source.

Next, the transmission behavior of the series cascaded architecture is simulated as shown in Fig. 7 to verify the improvement in the stopband rejection and feedthrough signal. Fig. 7(a) shows the filter transmission as a function of frequency for R_{in} = 5 Ω and different values of N. This graph shows that as N increases, the feedthrough signal decreases as expected. Fig. 7(b) also confirms that the relationship is

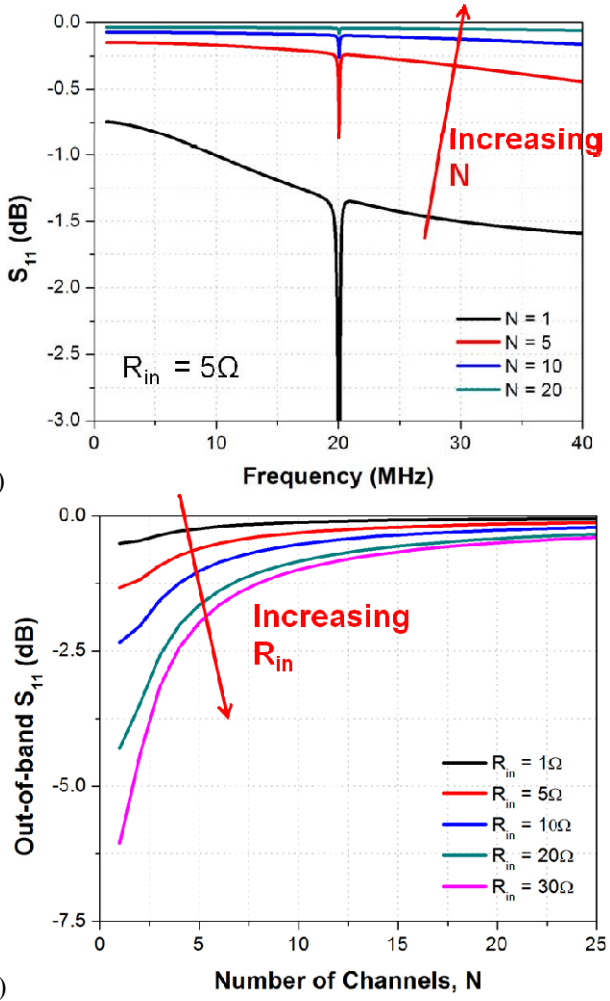

Figure 6. Return loss simulation results (a) as a function of frequency for R_{in} = 5Ω and varying N and (b) stopband return loss as a function of N at 20 MHz.

inversely linear with N, in contrast to the case of the parallel array architecture, where the feedthrough signal increases to some constant level for large N. Since the insertion loss also increases with N due to the voltage division occurring from the series connection of the N filters in the array, the result is a stopband rejection that is relatively insensitive to the array size and, more importantly, a transmission response that does not lose its filter behavior beyond a certain value of N. These simulation results all indicate that the series cascaded array architecture significantly improves the stopband return loss and filter transmission characteristics over its parallel counterpart for large arrays.

IV. Experimental Setup and Results

In order to demonstrate the performance enhancement that results from the use of the series cascaded filter array architecture, two 9-channel arrays of PZT-on-Si filters – one using the parallel architecture, the other using the series cascaded architecture – designed for center frequencies around 20 MHz with channel spacing of 30 kHz were fabricated in the process described in [11]. As previously mentioned, this technology was chosen due to the high dielectric constant of

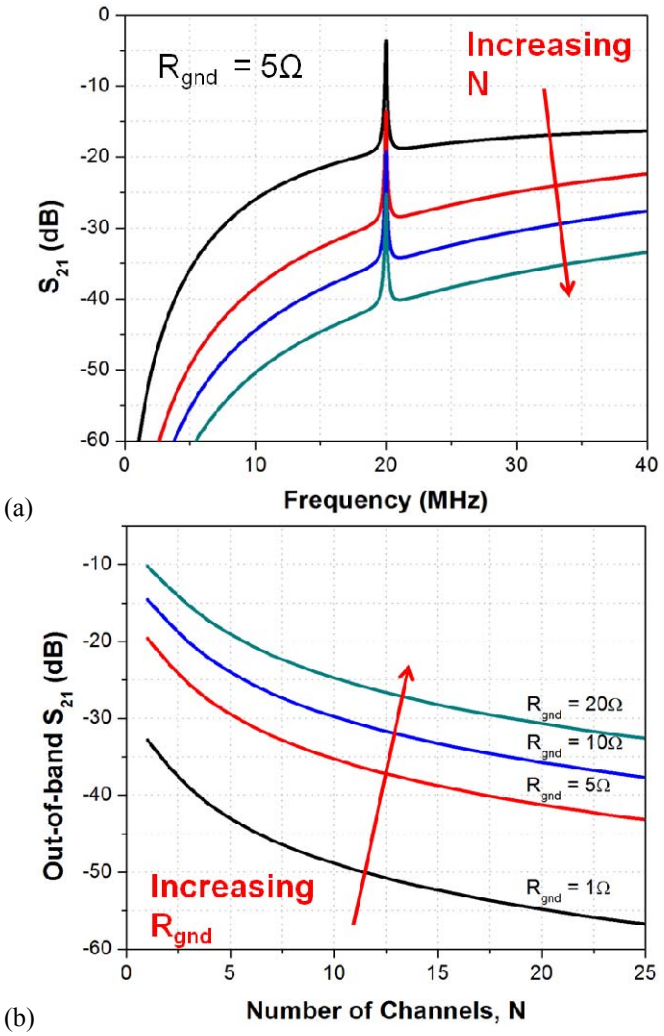

Figure 7. Transmission simulation results (a) versus frequency for R_{gnd} = 5Ω and varying N and (b) feedthrough signal as a function of N at 20 MHz.

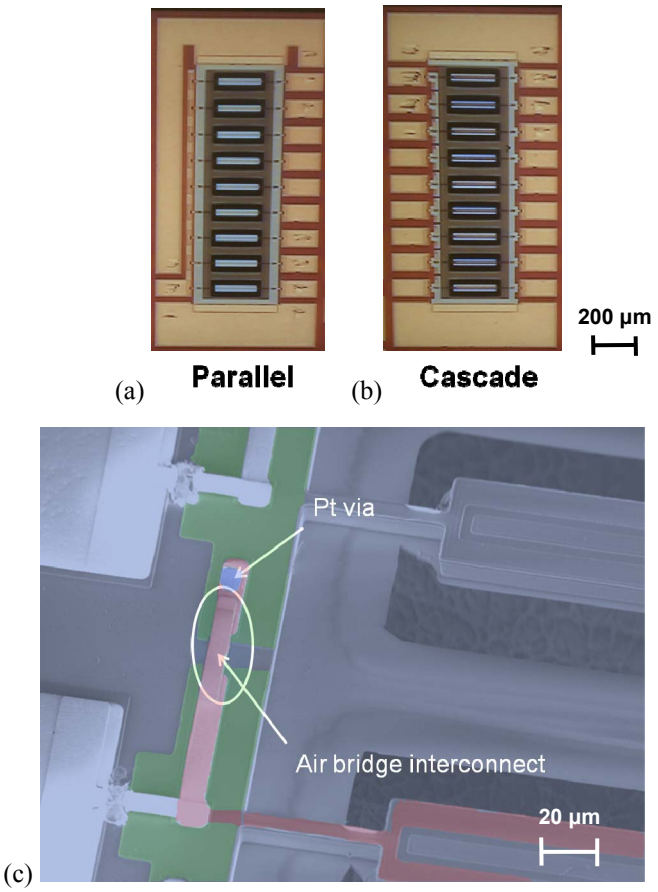

Figure 8. Chip micrograph of 9-channel filter array centered around 20 MHz implemented with (a) conventional parallel architecture and (b) series cascaded architecture using PZT-on-Si filter technology presented in [11]. (c) SEM image showing the routing between filters in the series cascaded architecture.

PZT enabling this work to demonstrate the capacitive loading effects at lower frequency using fewer filters, reducing the burden on fabrication and testing. Micrographs of these arrays are shown in Fig. 8(a) and (b). The SEM image in Fig. 8(c) shows how the series connections are implemented. The area shaded in green indicates the bottom electrode layer of the top filter underneath the PZT layer. A via, shaded blue, is opened to route to the gold air-bridge, which is then connected to the top electrode of the next filter, all of which is shaded in red. This connection is repeated for all filters except the last one in the chain, whose bottom electrode is connected to ground.

Fig. 9 shows the details of the two-port testing setup used to characterize these filter arrays. Port 1 of the vector network analyzer is connected to the GSG probe on the left and provides the input stimulus to the array. The outputs are probed using a 9-point probe structure whose connections are routed to a switching matrix. This matrix selects one filter output to be connected to port 2 of the network analyzer while all others are terminated with 50 Ω impedances. Typical two-port measurements are then repeated to characterize the response of each filter in the array.

Experimental results for the return loss and transmission are shown in Fig. 10(a) and (b), respectively. First, in Fig. 10(a), we see that the parallel filter array has a stopband return loss of roughly -3.5 dB while the notch depth is only about 0.1 dB, indicating that a majority of the absorbed energy is dissipated in parasitic resistances rather than passing through the filters. On the other hand, the series cascaded array shows a larger stopband return loss of roughly -0.7 dB with a notch depth of 0.4 dB, indicating a larger portion of passband energy is reaching the filters. In total, the stopband return loss is improved by roughly 2.9 dB.

Fig. 10(b) shows the results of transmission measurements again confirming the benefits of the series cascaded architecture. The parallel filter array has filters with only 7 dB stopband rejection compared with a roughly 23 dB rejection and 20 dB lower transmission floor for the series cascaded array. The insertion losses are also similar between the two arrays, which is expected. The series cascaded filter array has somewhat higher insertion loss, but this may be due to lower quality factors and non-zero routing resistance between filters. These have been noted and will be improved in future designs. In general, while these filter characteristics have room for improvement, they do indicate that the series cascaded filter array is favorable in terms of both return loss and transmission response of large scale filter arrays.

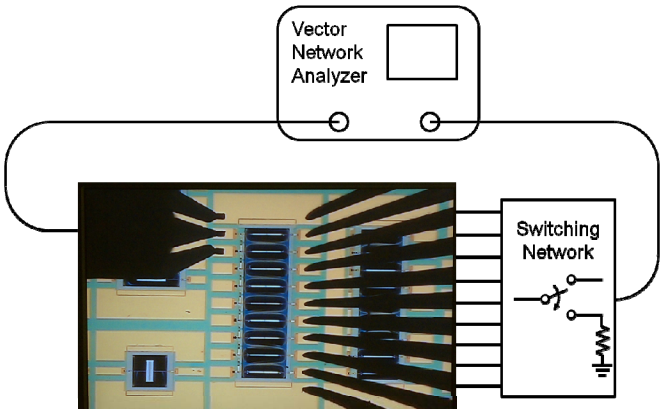

Fig. 9. Two-port measurement setup with switching network used for characterization of the two filter arrays.

V. Conclusions

In summary, this paper presents a detailed analysis of how the performance of the conventional parallel filter array architecture scales with array size using BVD equivalent circuit models. Through this analysis, the large effective shunt capacitance which increases with array size for the parallel array architecture was found to be the main factor limiting the performance of the array, specifically the stopband return loss, stopband rejection, and insertion loss. In addition, it was found that the filter performance was also extremely sensitive to parasitic routing resistances. While it is always desired to minimize these parasitic losses, some might be unavoidable, especially when targeting the design of very large scale filter arrays. Thus, any architectural changes that may reduce this sensitivity would be very beneficial. In response, the series cascaded filter array architecture was proposed to improve the scaling of filter performance with array size by making the effective shunt capacitance now inversely proportional to array size. Simulated results also indicate that this architecture reduces the sensitivity of the filter array to parasitics. This performance improvement was experimentally verified using 9-channel filter arrays with PZT-on-Si filters around a frequency of 20 MHz. While this technology was chosen to demonstrate this concept without the excessive burden of fabricating and testing much larger arrays, the validity of this analysis and architecture is not limited by the type of transducer. This problem of capacitive loading for the parallel array will become an issue even for more efficient transducers when frequency and/or array size is increased. The proposed architecture presents a system-level solution to one of the inherent device limitations of RF MEMS filters, thus opening up the potential for realizing chip-scale spectrum analysis for cognitive radio applications.

Acknowledgment

The authors wish to thank Rockwell Collins and the DARPA MTO ASP and ART programs for their support and the U.S. Army Research Laboratory, specifically Joel Martin and Brian Power, for fabrication. The authors also would like to thank the Cornell Nanofabrication Facility for help with post-processing and measurements.

***Abstract*—This work is devoted to the development of laterally coupled filters built on compound single crystal substrates. High overtone bulk acoustic resonators are built on $LiNbO_3$ thinned films bonded on thick $LiNbO_3$ or Quartz substrates. Two resonators are coupled via a narrow gap between their electrodes, yielding the possibility for their modes to interact and to produce coupled mode resonance conditions. The coupling efficiency is shown to be dependent on the frequency (wavelength), yielding well defined coupled-mode filters at intermediate frequencies (300 – 800 MHz) and single mode transfer functions above 1 GHz. The implementation of an oscillator stabilized by such a filter at 1.7 GHz is demonstrated.**

I. Introduction

Radio-Frequency (RF) filters generally are built using surface acoustic wave resonating devices or bulk acoustic resonators exhibiting single resonance behavior well-suited for the definition of high spectral purity filter capable to answer the drastic system specification generally imposed for telecommunication applications [1]. Hence, a rather small interest was devoted to RF filters based on high overtone bulk acoustic resonators (HBAR) apart from pioneer work by Lakin in early nineties [2]. However, these devices were mainly based on impedance element and required a very large number of resonators in series and parallel (6 "L" stages) for achieving a rejection of about 40 dB. Although developing filters based on HBAR yields the replication of the corresponding transfer function more or less for each resonator harmonics (at least those exhibiting similar coupling than the mode considered for the filter design), their capability to accurately select given frequencies finds some interest for oscillator or sensor purposes. Therefore, the possibility for manufacturing compact filter structures with reduced number of cells compared to the above-mentioned solution appears relevant. Particularly, structures comparable to those used in monolithic filters would be particularly interesting if transferable to HBAR because of their capabilities to produce very large rejection with a limited number of poles. Until now, only few attempts for developing such filters on thin film based material stacks have been successfully achieved [3].

In this work, we investigate the possibility for manufacturing laterally coupled filters using thinned single crystal lithium niobate layers acting as HBAR transducer, bonded on lithium niobate or quartz substrates. The idea consists in exploiting dispersion properties as well as the presence of a thick resonating structures (i.e. the substrate) to exhaust the lateral coupling between two resonators placed very close one another to favor their modal interaction. (YXl)/36° and (YXl)/163° $LiNbO_3$ cuts have been chosen to allow for the excitation of very high overtones, taking advantage of their strong electromechanical coupling (k_s^2 respectively equal to 20 and 45%), and to excite either longitudinal or shear waves. The substrates were respectively $LiNbO_3$ (YXl)/36° for filter demonstration and AT Quartz for temperature compensation purpose [4].

Many structures have been manufactured and have allowed for filter characterization in the vicinity of 300, 500 and 700 MHz (respectively the third, fifth and seventh harmonics of the transducer thinned film alone). Rejection in excess of 20 dB are demonstrated with a single filter cell. Corresponding Insertion losses of about 15 dB are emphasized and could be easily improved by impedance matching. Coupling two cells consequently provide rejection in excess of 40 dB with insertion losses of about 10 dB once matched. In the case of the Niobate/Quartz structure however, a single-mode response is obtained near 1.7 GHz, as the coupling conditions obviously are less efficiently met at this frequency than in the previous case. As a shear mode is exploited here, temperature compensation is obtained, yielding favorable conditions for using the device to stabilize an oscillator loop near this frequency. The four-port structure was easily looped using a wide band amplifier and the corresponding phase noise was found at 130 dB at 10 kHz from the carrier,

978-1-61284-110-6/11/$26.00 ©2011 IEEE

competing well with state-of-the-art solutions. In the following sections, the paper then shows the analysis of the proposed device, its implementation and tests and concludes on its interest for signal processing applications

II. Device description and analysis

The principle of the device is inspired from the so-called monolithic filters based on coupled bulk waves in single crystals and illustrated in Fig.1. This is achieved by setting two resonators very close one another. The gap between these resonators must be narrow enough to allow for evanescent waves apart the resonator electrodes to recover and hence yielding mode coupling conditions. As both resonators operate similarly, they do present the same spectral distribution and each harmonic bulk mode of the structure is identically coupled at almost exactly the same frequency. The above mentioned coupling condition then favors for each coupled mode the existence of two distinct resonances corresponding to symmetrical and anti-symmetrical coupled modes in the structure composed by the two resonators. The width of the separation area then controls the spectral distance between the two coupled modes. This operation principle only holds if the resonator actually traps the wave under its electrode, and therefore this condition must be validated by the analysis of dispersion modes, as shown in many text books and papers (see for instance [5]). Although this analysis was not conducted for this paper, the evanescent conditions are attested by the extremely high Q factor obtained using the tested configuration ((YX*l*)/36° $LiNbO_3$ thinned plate on (YX*l*)/36° $LiNbO_3$ substrate [5]), i.e. more than 50 000 at 1.5 GHz.

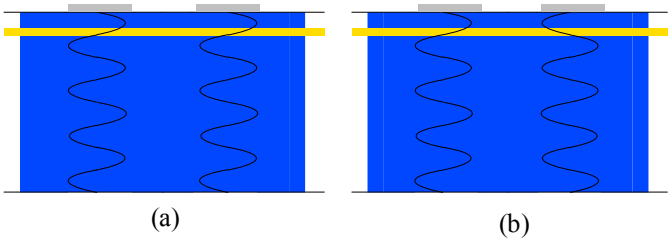

Figure 1. Principle scheme of the laterally-coupled-mode HBAR filter (a) symmetrical mode (b) antisymmetrical mode

The above presented principle has been applied for frequency filters in the rang 1-30 MHz using standard bulk wave resonators exploiting the fundamental mode of a single-crystal or ceramic piezoelectric plate compliant with the above-discussed coupling conditions. Higher frequencies are hardly reachable using these devices because of the thinning conditions required for such a purpose, yielding fragile devices poorly suited to industrial processes together with significant difficulties to match the frequency target. Recent developments have shown however that the principle could be applied in some extent to film bulk acoustic resonators (FBARs) by adapting the resonator structures for meeting the expected coupling conditions. In this work, we exploit the possibility for manufacturing HBARs based on thinned single crystal layers atop any substrate to check the possibility for fabricating such filters at high frequencies, i.e. near or above 1GHz. Preliminary to manufacturing and test, computation work has been conducted to check the actual capability of such a structure to behave as expected and to allow for coupling modes similarly to what happens in monolithic filters. Therefore, a periodic 2D-finite-element-analysis (FEA) coupled with a boundary radiation condition (so_called BEM) has been disorientated to address the problem of non periodic structures, adding absorbing conditions (Perfectly Matched Layers – PML) at the edge of the meshed period [8]. The thinned $LiNbO_3$ plate then is meshed with the two top Al electrodes separated by a 10µm gap. The BEM parts represents the finite thickness substrate accounting for the bottom Au electrode (the bonding layer). Mainly based on PML, the model requires some parametric adjustment but realistic operating conditions were tested in the vicinity of 300 MHz. Figure 2 shows the admittance parameters of the corresponding contribution (Y_{11} and Y_{21}). The first one clearly shows the existence of two modes very close one another whereas the second gives a prediction of the pass band of the 2-pole filter when using the structure as a quadrupole. To definitely confirm the actual operation of the device, the deformed mesh corresponding to each mode also has been plotted in Figure 3, showing the mode phase alternation.

This theoretical work tends to demonstrate the actual possibility for the fabrication of laterally-coupled HBAR filters. The manufacture of such devices is addressed in the next sections.

III. Implementation and Characterization

The fabrication of single crystal wafers devoted to HBAR applications has been already published several times and is not described here in details. Information about the process can be found in [4]. We have been using first a material stack consisting of (YX*l*)/36° lithium niobate wafers, one being thinned down to 30µm and operating as the HBAR transducer, the other acting as resonator (mechanical tank) because of the very high Q factor obtained with such structures, assuring a high quality of energy trapping under the top electrode. These first tests have been achieved by splitting the top electrode (aluminum), thus giving rise to two resonators separated by an insulating strip of 10µm, with dimensions 145 × 200 Mm ². The contact mass is obtained by returning it on the upper surface of the substrate, to actually achieve the quadrupole of Figure 4 shows a SEM photograph of this achievement.

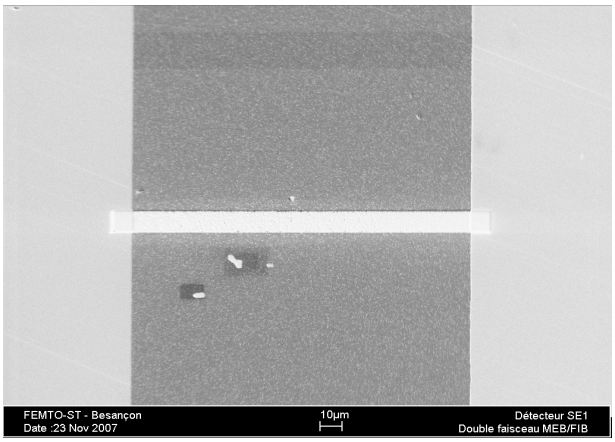

Figure 4. SEM picture of the filter structure with two coupled resonators stacked laterally-coupled LiNbO3 (34µm) / Au (300nm) / LiNbO3 (350µm). The dividing line drawn on the FIB

We were able to characterize the filter response in terms of transfer function for different frequency bands, corresponding course to areas of high spectral coupling of the longitudinal mode. Figure 5 shows the type of spectral response in the vicinity of the 3rd harmonic of the fundamental mode of the transducer.

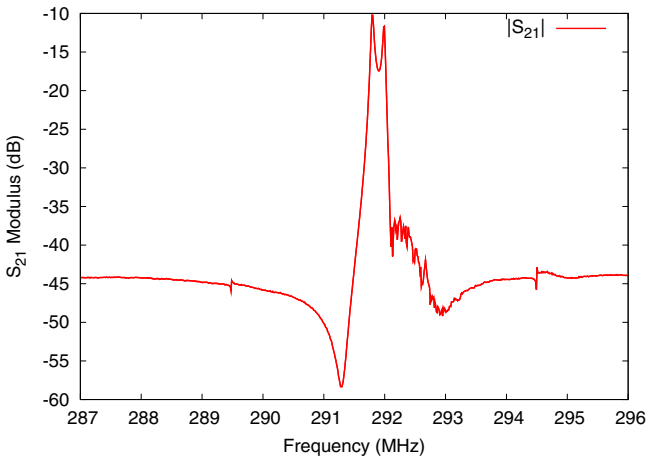

Figure 5. Transfer function of the filter at around 300 MHz.

Several filtering functions are visible, separated by 10 MHz from each other, with a maximum dynamic range around 500 MHz as shown in Figure 6. We then see a rejection out of band approaching 30 dB (for a single filtering cell) and losses approaching 10 dB (no impedance matching), but also a strong ripple in the band rendering inoperative the filter given specifications generally effective for this application. However, there are very clearly the two poles forming the filter, which seems to prove clearly enough by the operation

mode coupling of the device. We also conducted these measurements in the vicinity of 500 MHz and 700 MHz, as shown in Figures 6, 7 and 8. In particular, we see that with the increasing frequency, filter bandwidth is less hollow and more regular, with a slight reduction of-band rejection (25 dB at 500 MHz and 22 dB at 720 MHz) recalling all the same it is only a single cell. The losses in the band from 12 to 15 dB, but we recall once again that every effort has been dedicated to the impedance matching of the two resonators. We finally remark on many measures a contribution of undesired shear mode (each 6 MHz) although very low. The transfer function of the filter at 720 MHz yet reveals a parasitic contribution more pronounced in low band whose origin is not yet identified. The 3dB bandwidth of such filters covers 200 kHz, a value fairly modest to link to the coupling measured for the corresponding modes, reaching at most a few thousand. Efforts remain to be done to improve this situation. We attempted to identify the upper limit in operating frequency of the structure. Figure 9 shows the transfer function of the filter in the vicinity of 1.5 GHz. It is clear that at this frequency, the filtering function is no longer provided by the structure, which appear with difficulty out of band rejection of 8 dB loss clearly increased (again without effort impedance matching) .

IV. Conclusion

In this paper we showed the development of very narrow band filters based on HBAR. This contribution brings an original and simple to implement cross-coupled filters. Indeed, the quadrupole structure lends itself well known in the manufacture of filters whose parameters may be imposed by the planar shape of the electrodes and the spacing between two coupled resonators. It offers a significant simplification of the structure of the filters by its essentially planar, although it requires access to the underlying electrode in one way or another. The quality factor displayed by the quadrupoles show that it would be possible to stabilize an oscillator. However before using this solution, it is necessary to identify the parametric influences using simple models.

***Abstract*—The use of phase modulation in lieu of the typical amplitude modulator in an optoelectronic oscillator (OEO) has not yet been extensively investigated. In this paper we present the first experimental demonstration of a phase-modulated OEO using a fiber delay-line demodulator with balanced detection. Preliminary phase noise and frequency stability measurements are also demonstrated.**

I. Introduction

The optoelectronic oscillator (OEO) has attracted a great deal of interest for its potential to generate ultra-low phase noise microwave signals. In the years since the publication of the seminal work on this topic by Yao and Maleki [1,2], there has been a rapid proliferation of new OEO systems widely varying in design and sophistication. However, the vast majority of previous demonstrations have relied upon an intensity-modulated direct-detection (IMDD) approach within the resonator. An architecture based on phase modulation instead of intensity modulation offers several advantages that can enable improved phase noise performance. In this paper, we introduce a novel architecture for an OEO based on phase modulation, and present phase noise and frequency stability characterization of the oscillator at 10 GHz. To our knowledge, this work constitutes the first experimental demonstration of a phase-modulated OEO using balanced detection.

II. Phase-Modulated OEO: A Novel Architecture

A simplified diagram of a conventional IMDD-based OEO is shown in Figure 1(a). One main advantage of using a phase modulator instead of an amplitude modulator is that $LiNbO_3$ phase modulators have lower optical insertion loss. Typically the difference is approximately 2-3 dB. In order to generate a feedback signal from the photodiode, there must be a phase-to-amplitude conversion element within the loop. One previous demonstration of a phase-modulated OEO has used fiber-Bragg-gratings (FBG) to filter off one of the phase-modulation sidebands, thereby allowing the other sideband to beat directly with the optical carrier to produce an intensity modulated signal [3]. A more efficient method is to make use of a dispersive element within the loop, which changes the phase relationship between the two modulation sidebands. The sidebands on either side of the carrier are initially exactly out of phase; introducing a dispersive element allows the mixing products between each sideband and the carrier to add constructively instead of destructively, thus generating an intensity modulation. One group has achieved this using a chirped FBG [4], while another has used a whispering-gallery-mode (WGM) resonator as the dispersive element [5]. Both of these methods suffer from high optical insertion loss, in the first case due to the necessity of using an optical circulator (which typically have 1-3 dB of excess loss), and in the second case due to the losses incurred when coupling to the WGM. Our system instead uses a delay-line demodulator to convert from phase to amplitude modulation, an interferometric process that can be made nearly lossless by using fiber couplers.

The intensity modulation is then detected using photodiodes; for our system this is accomplished via balanced detection, in which the two complementary interference products from the demodulator are each detected and then

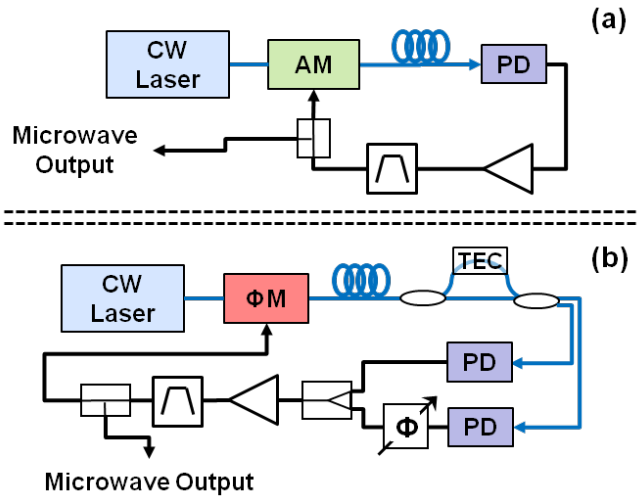

Figure 1. Diagram of (a) the typical intensity-modulated, direct-detection OEO architecture; and (b) the phase-modulated, balanced detection architecture using a delay-line demodulator. Abbreviations are as follows: CW – continuous-wave, AM – amplitude modulator, PD – photodiode, ΦM – phase modulator and TEC – thermoelectric heater.

This material is based on independent work supported in part by the Stuart S. Janney Program at the Johns Hopkins University Applied Physics Laboratory.

combined in phase using an RF phase shifter. This architecture is shown in Figure 1(b), and is similar to the design proposed (but not implemented) in [6]. The immediate advantage of balanced detection over the standard IMDD architecture is that for the same laser power, twice as much optical power is converted to RF signal, so the total RF power generation within the loop is greater by 6 dB. Including the reduced insertion loss for phase modulators compared to intensity modulators, this yields a net advantage of approximately 10 dB. This increase in loop gain enables the possibility of operating the OEO without an RF amplifier [7]. This in turn can significantly reduce the phase noise of the oscillator.

III. Theory: Threshold and Expected Phase Noise

A. Oscillation Threshold Condition

The mathematical expression for the threshold condition can be easily derived for the architecture described above. The derivation proceeds very similarly to that described in [1], and so is not presented here. For a phase-modulated OEO using a delay-line demodulator with balanced detection, the oscillation threshold is given by:

$$\sqrt{G}\alpha\eta P_0 R \sin(\omega_0 \Delta t_d) \geq V_\pi / \pi , \qquad (1)$$

where G is the net power gain (including RF losses) of the amplifier, α is the optical insertion loss through the loop, η is the photodiode responsivity, P_0 is the optical power at the input to the phase modulator, R is the photodiode resistance, ω_0 is the optical angular frequency, Δt_d is the differential delay of the demodulator, and V_π is the half-wave voltage of the modulator. When the delay-line demodulator is held at the quadrature condition using the proper temperature control settings, the sine term becomes unity, and this expression differs from the canonical case in [1] only by a factor of two. This reduction in the required threshold power with respect to an IMDD architecture is due to the fact that balanced detection captures both interference products from the demodulator and adds them in phase.

B. Expected Phase Noise Performance

The expression for the RF power spectral density can be used as a good approximation for the phase noise spectral density when phase noise processes dominate over amplitude noise processes. For the loop lengths used in our system, this is a reasonable assumption. Therefore using the expression derived in [2] for the RF spectrum, we can expect the phase noise to be given by:

$$\mathcal{L}(f) = \frac{G\rho_N}{(2\pi\tau_l f)^2 P_{osc}} , \qquad (2)$$

where G is again the net gain of the amplifier, ρ_N is the noise spectral density at the input to the amplifier, τ_l is the round-trip time in the loop, and P_{osc} is the RF power in the oscillating mode. In the simplified model presented here, ρ_N includes thermal noise, the photodiode shot noise and the laser relative intensity noise (RIN) evaluated at the rms photodiode operating current. We approximated the laser RIN as a white noise process, choosing a representative value of -145 dBc/Hz. Substituting the various system parameters into (2) gives an expected value of -89 dBc/Hz at 1 kHz offset for a 120 m loop, and -108 dBc/Hz at 1 kHz offset for a 1 km loop. Note that the amplifier gain acts to increase the noise in (2). Therefore if the power in the oscillating mode was sufficient to achieve threshold without the amplifier, a considerable reduction in the phase noise would be possible.

IV. Experimental Setup

A picture of the experimental setup for our oscillator is shown in Figure 2. The optical input was a 1550 nm laser followed by an erbium-doped fiber amplifier. The RIN for this laser was specified to be <145 dBc/Hz at 100 Hz offset. For our system, the required input optical power to reach threshold is approximately 20 mW. The typical operating power used was 60 mW at the input to the phase modulator. The modulator had a half-wave voltage of approximately 3 V at 10 GHz, and an optical insertion loss of 2 dB. For the 120-m loop configuration, the output of the modulator was connected to a fiber stretcher, for use in length stabilization. For the 1-km loop configuration the fiber stretcher was omitted from the setup. The main fiber delay line and the delay-line demodulator were housed in a box lined with foam to provide a limited degree of acoustic and thermal isolation. The delay-line demodulator was of a type widely used in differential phase-shift-keyed optical receivers, and had a differential delay of 125 ps. The phase was manually controlled by heating one arm of the interferometer with a thermoelectric element. The two outputs of the demodulator were then detected by the photodiodes, which had a responsivity of approximately 0.7 A/W. The photodiodes were internally terminated with a 50 Ω resistor, and had a 3-dB bandwidth of 12 GHz. The RF outputs were combined in phase using a microwave phase shifter, and passed to the RF amplifier. The amplifier had 20 dB of gain at 10 GHz. Following the amplifier was an RF filter with a 3-dB bandwidth of 100 MHz centered at 10 GHz, and 4 dB of RF insertion loss. The output of the filter was then passed through a 6-dB tap coupler to provide access to the 10 GHz microwave signal, and finally fed back onto the RF input port of the modulator.

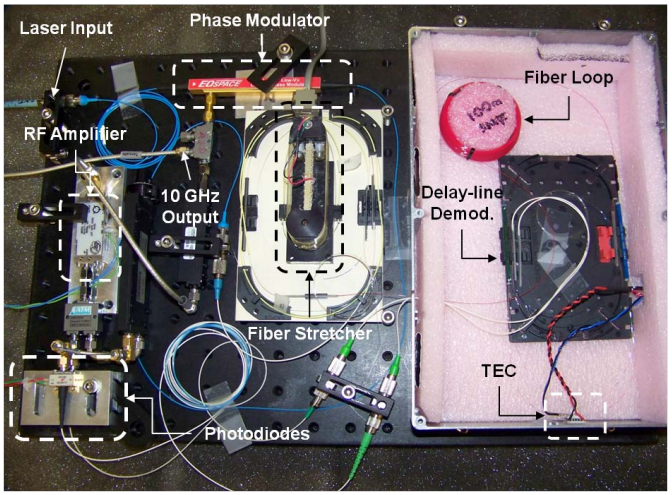

Figure 2. Picture of the oscillator setup in the 120-m fiber loop configuration. For the 1-km loop configuration, the fiber stretcher was not in the loop.

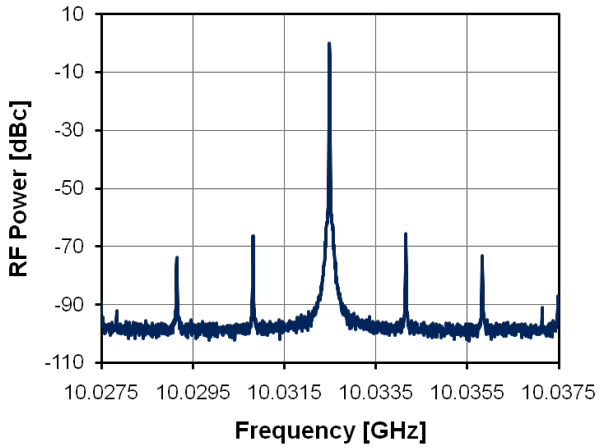

Figure 3. RF spectrum of the OEO with a 120-m fiber loop. The frequency span was 10 MHz, the resolution bandwidth was 10 kHz, and 16 averages were taken.

V. Results & Discussion

A. Phase Noise for a 120-m Fiber Loop Resonator

Figure 3 shows the RF spectrum of the OEO with a 120-m loop of fiber in the resonator. The central tone of the oscillator is at 10.032 GHz, and the spurs are side modes of the resonator separated by the inverse of the round-trip time. For 120 meters of fiber this corresponds to 1.67 MHz, as can be seen from the spectrum. The stability of the OEO in this configuration was poor; thermal fluctuations in the surrounding environment caused the oscillator frequency to drift on the order of a few hundred hertz per second. This was greater than the capture range of the phase-locking hardware for our commercial phase noise test set (Agilent E5500). While a measurement of the absolute phase noise with the two-oscillator technique was not possible, we were nonetheless able to characterize the phase noise of the OEO by closely examining the RF spectrum. Strictly speaking a measurement with a spectrum analyzer will yield the total integrated phase and amplitude noise of the system, but in our system the oscillator phase noise is far dominant over amplitude noise processes.

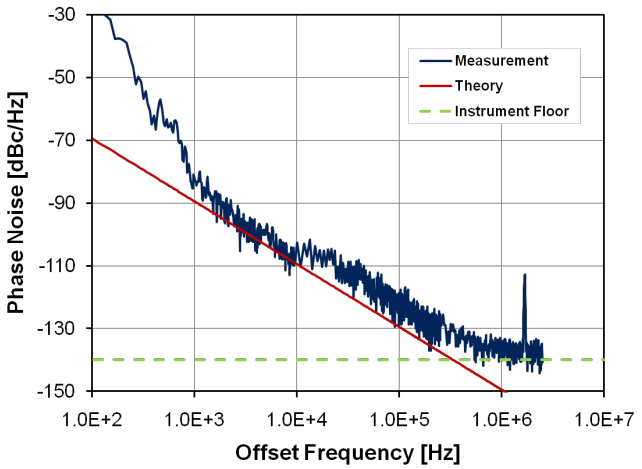

Figure 4. Composite spectrum for phase noise approximation of the OEO with a 120-m fiber loop (solid blue). Predicted phase noise performance from theory (solid red) and instrument noise floor (dashed green) are also shown.

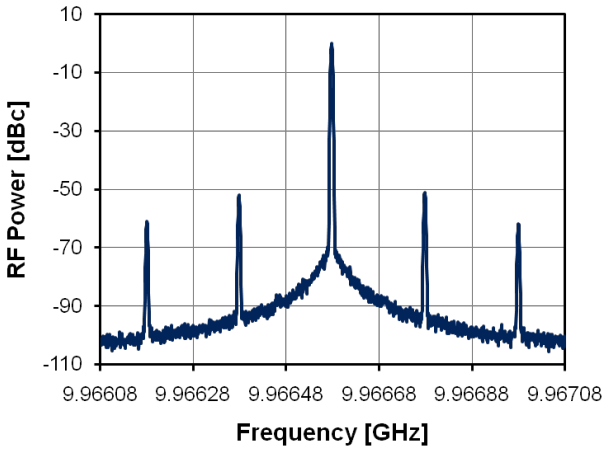

Figure 5. RF spectrum of the OEO with a 1-km fiber loop. The frequency span is 1 MHz, the resolution bandwidth is 3 kHz, and 16 averages were taken.

Shown in Figure 4 is a composite phase noise picture constructed from several measurements of the spectrum at different frequency spans and resolution bandwidth settings. The composite is normalized to a 1-Hz resolution bandwidth for ease of comparison with traditional phase noise measurements. Shown in red is the phase noise performance predicted by the theory in Section III. Below 1-kHz offset from the carrier, the random-walk and frequency drift induced by thermal fluctuations is readily apparent, and manifests as a $1/f^4$ slope. Above 500-kHz offset the measurement begins to be limited by the noise floor of the spectrum analyzer. The first side mode of the resonator appears again at 1.67 MHz offset, although for the measurements of that portion of the spectrum, the resolution bandwidth (30 kHz) was too broad to properly resolve the peak. This accounts for the discrepancy in the spur level between Figures 3 and 4.

B. Phase Noise for a 1-km Fiber Loop Resonator

The oscillator was reconfigured using a 1-km long fiber delay instead of 120 m, with the expectation that a longer loop would result in a more stable output frequency. We posit that the dominant source of frequency instability for the 120-m system was most likely thermal fluctuations. This implies that a longer loop delay would lead to increased stability due to statistical averaging of local temperature variations over the length of the fiber delay. A system with a longer delay would thus benefit from a greater degree of averaging, decreasing the net variance in frequency due to inhomogeneity in the temperature distribution. From (2), we also expect to achieve an improvement in the phase noise of ~18 dB. Figure 5 shows the RF spectrum for the 1-km loop system. Here the side modes appear at 200-kHz offset, corresponding to the longer round-trip time. The significant improvement in stability over the shorter loop allowed us to phase-lock a microwave reference oscillator to the OEO, enabling a measurement of the absolute phase noise. The method used for this measurement was the standard two-oscillator technique, in which the device under test is held in quadrature with a stable reference source via a phase-locked loop (PLL). Using a double-balanced mixer as a phase detector, the phase error between the two oscillators is then measured with a spectrum analyzer for offset frequencies outside the bandwidth of the

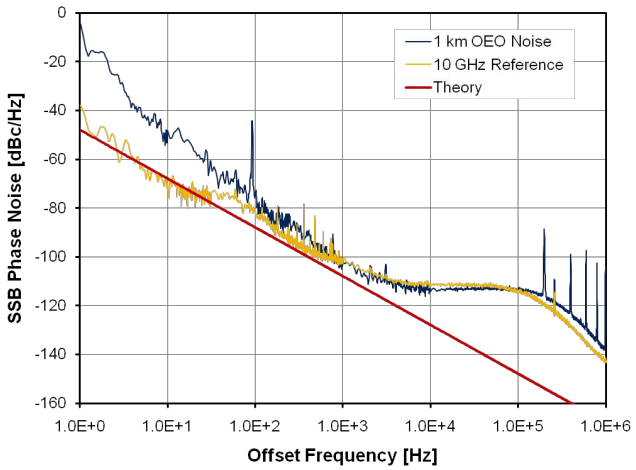

Figure 6. Single-sideband phase noise measurement of the OEO noise for a 1-km fiber loop (dark blue) and the 10-GHz reference oscillator (orange). Expected phase noise performance from the theory is shown in red.

PLL. Within the bandwidth of the PLL, a fast Fourier transform (FFT) analyzer measures the FFT of the correction signal that is applied to the reference oscillator in order to keep the two signals phase-locked. The results are shown in Figure 6, where the OEO noise is in dark blue. To measure the contributions of the reference oscillator, we used two frequency synthesizers that had similar performance and measured them against one another. Unfortunately the noise of the reference oscillator dominates over the OEO noise for almost the entire measurement, as is seen by the orange trace. Shown in red is the theoretical performance that we would expect to measure for the OEO if a higher-quality reference was available. Below 100-Hz offset, the $1/f^3$ slope indicates flicker frequency noise, which could be caused by acoustic vibrations, added noise due to the RF amplifier, or potentially by the photodiodes.

C. *Frequency Stability for a 1-km Fiber Loop Resonator*

To characterize the free-running stability of the oscillator, we measured the output frequency with a spectrum analyzer, operating as a frequency counter. The counter recorded the peak frequency in 1-s intervals for approximately 30 minutes.

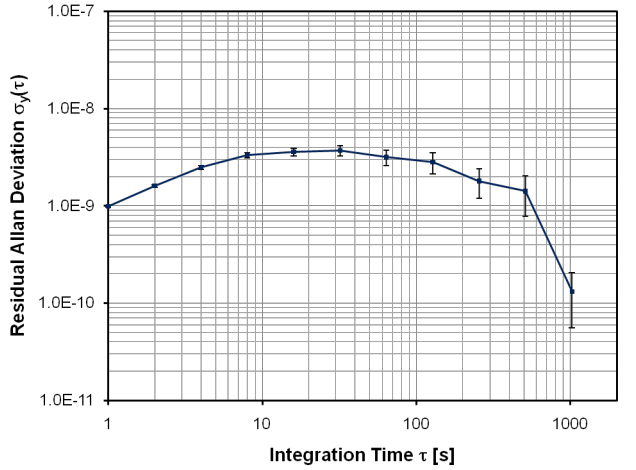

Figure 7. Allan deviation of fractional frequency fluctuations for the 10 GHz output of the 1-km OEO. The Allan deviation was calculated after subtracting out the effect of linear frequency drift.

To calculate the Allan variance, we first fit the data to a line, and subtracted out the linear frequency drift caused by global temperature changes in the laboratory. The drift rate was found to be ~17 Hz/s, corresponding to an approximate temperature drift rate of 2 mK/s during the length of the measurement. The Allan deviation of the residual frequency fluctuations is shown in Figure 7. The predominantly flat shape of the curve is consistent with the flicker frequency noise effects observed in the phase noise plot. The average frequency stability (without linear drift) is $\sigma_y = 3\times10^{-9}$.

VI. Conclusion

We have presented the first experimental demonstration of a phase-modulated optoelectronic oscillator using a delay-line demodulator with balanced detection. The noise characteristics of the OEO were investigated in two configurations, with a 120 m fiber delay and with a 1 km fiber delay. Measurement of the phase noise of the 1-km loop OEO was primarily limited by the noise of the microwave reference oscillator, as well as flicker noise sources close to the carrier. The RF amplifier is likely to be a significant contributor of flicker noise. As such, a primary goal of future work on this project will be to generate sufficient gain within the OEO loop such that the amplifier is unnecessary. This can be readily achieved with the proper choice of photodiodes and phase modulator. Photodiodes without internal terminations will provide 6 dB greater RF output power, and high-optical-power-handling photodiodes are also commercially available. Another method for improvement would be to use a phase modulator with a lower half-wave voltage, such as a modulator with a double-pass waveguide architecture. The frequency stability of the oscillator is limited primarily by thermal drift and fluctuations, which in turn change the length of the fiber delay. Thermal isolation and length stabilization techniques are potential areas of further investigation.

***Abstract*—We describe and experimentally demonstrate an optomechanical oscillator where light drives a surface mechanical mode of a spherical resonator, using a combination of photoelastic scattering and optical electrostriction. These oscillators are shown to have discretely-selectable frequencies ranging from 50 MHz to 1.5 GHz on a single silica microsphere device. We also report on initial measurements of phase noise and continuous frequency tuning of these oscillators.**

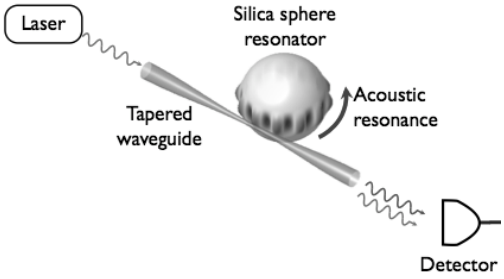
I. Introduction

In recent years, oscillators based on parametric mechanical vibration in optical microresonators have emerged as promising candidates for compact and low power photonic frequency references [1]–[4]. While prior work has focused on the use of radiation pressure and gradient forces [5] in order to drive mechanical vibration, here we exploit optical electrostriction [6] to stimulate (as in a laser) an acoustical whispering gallery resonance of the microsphere. These acoustical modes are concentrated at the equator of the sphere, and have been calculated through finite element modeling to be shear type and Rayleigh type [7] surface acoustic waves (SAW).

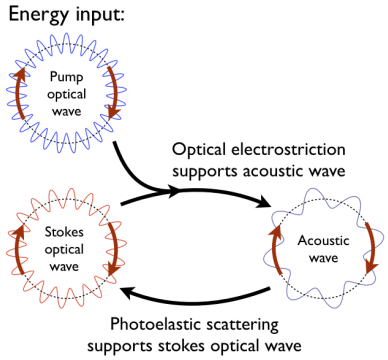
Such SAW-based optomechanical oscillators (OMO) have been theoretically proposed in the past [8]. In this new class of optomechanical oscillator, incoming light drives and interacts with the surface acoustic mode, resulting in two optical signals at the output of the device (Figure 1(a)). The beat note between these optical signals is measured with a photodetector, and is at the acoustical frequency of the surface mode that we excited.

II. Surface Acoustic Wave Optomechanical Oscillators

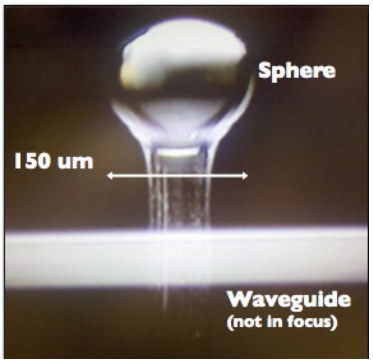
We will now describe the process of exciting optomechanical oscillations within these spherical resonators. An incoming pump photon scatters from an acoustic phonon occupying a mechanical eigenmode of the spherical resonator, resulting in a scattered Stokes photon that is down-shifted to a lower frequency. The scattered Stokes light together with the incoming pump light generates electrostrictive pressure which amplifies the initial acoustic wave. Energy and momentum are conserved in this process through the generation of phonons at the same acoustical frequency from which the pump light was initially scattered. The process is illustrated in Figure 1(b) and is similar to stimulated Brillouin scattering that takes place in bulk materials [6].



(a) Schematic of the oscillator. The detector outputs the beat note between the two optical signals, which is at the mechanical frequency.



(b) Optical electrostriction and photoelastic scattering drive the mechanical oscillations of a traveling acoustical mode



(c) Microscope image of the oscillator

Fig. 1. Surface acoustic wave optomechanical oscillator: Theory and practical realization

978-1-61284-110-6/11/$26.00 ©2011 IEEE

The experimental realization of a SAW-OMO (Figure 1(a)) requires two optical whispering gallery modes that have extremely close frequencies (in relative optical terms) but at the same time have different wavevectors. This requirement can be expressed as follows

$$M_P = M_S + M_A \tag{1}$$

$$\omega_P = \omega_S + \omega_A \ . \tag{2}$$

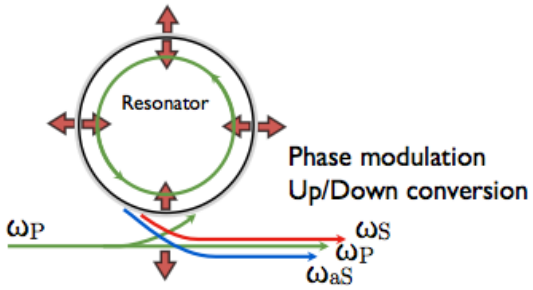
Here the M_i parameters are the number of periods of the optical modes ('P', 'S' subscripts) and of the acoustical mode ('A' subscript) around the circumference of the sphere, and their relationship describes momentum conservation. The simultaneous frequency relationship ω_i describes energy conservation. This phase matching requirement is the result of solving for a synchronous solution [9] to the optical and acoustical wave equations that describe the processes of photoelastic scattering and optical electrostriction within the sphere. Light is coupled in and out of the microsphere resonator [10] using a tapered optical fiber [11]–[13]. Optical quality factors are in the range of 10^8.

Previous demonstrations of oscillations induced via Brillouin scattering, shown in CaF_2 [14] and in silica [15], depended on back-scattering from the acoustical wave to close the internal feedback loop in the above described process. When we consider momentum conservation in back-scattering, the resulting phonons have a wavelength that is approximately half of the pump light used. For a 1.5 um wavelength pump propagating in silica, this translates to an optical wavelength of 1 um within the resonator, and an acoustical wavelength of 0.5 um resulting in frequencies in the 11 GHz range [15] for when silica is the host material. However, the lifetime for such hypersonic phonons is extremely short, resulting in low acoustical finesse. The acoustical frequencies are primarily dictated by material properties in this case.

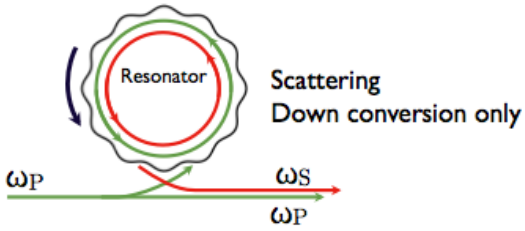
A question arises whether lower frequencies, dictated to some extent by geometry, can be targeted instead. Lower frequency phonons would have much longer lifetimes within the host material, and would have a much higher acoustical finesse within the microsphere. As opposed to previous demonstrations of backward scattering, here we rely on forward scattering [8], [16] to generate lower frequency phonons. Momentum conservation for forward scattering dictates that the acoustic frequency is significantly smaller, and is of the order of 100 MHz.

III. Identification of Mechanical Modes

Previous OMO demonstrations, have primarily been based on mechanical parametric oscillation of optical microcavities. The standard varying parameter in these cases is the optical path length and the mechanical modes can be described as breathing modes (Figure 2(a)). The resulting optical spectrum at the output thus shows modulation effects (phase and amplitude) with sidebands at both higher and lower frequencies. Higher frequency harmonics of these sidebands are also present [4].



(a) Breathe modes generate both upper and lower sidebands (with higher harmonics) to the optical input.



(b) Surface acoustic modes only generate a single red-downshifted sideband.

Fig. 2. Differentiating mechanical modes through optical output signals.

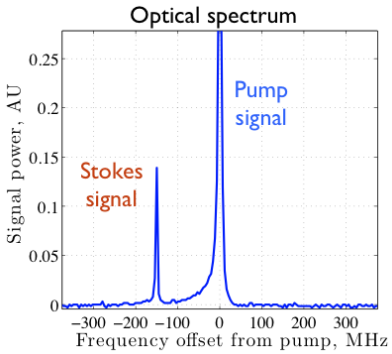


Fig. 3. Verification of the surface-wave nature of a 150 MHz oscillation. Only one Stokes red-shifted optical line is present adjacent to the pump.

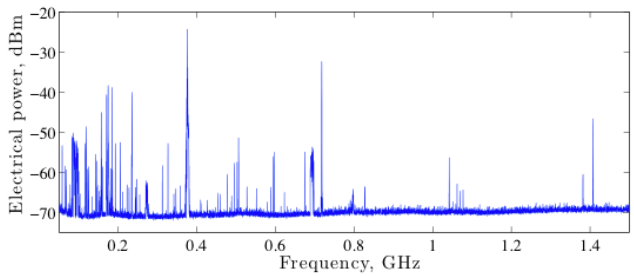
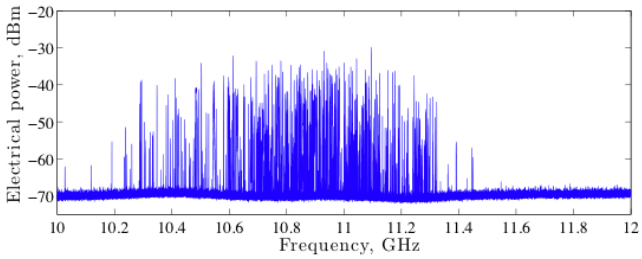
In the case described in this work, the mechanical excitation is a surface mode that travels unidirectionally along the equator (Figure 2(b)). Light that is scattered from this traveling mode is always downshifted from the pump due to the always-receding nature of the mode. The optical path length does not change. As a result, there is only a single Stokes-frequency optical sideband that appears at the output.

Since there is a difference between the optical signatures of the two types of mechanical modes, we can distinguish between them by resolving the spectra of the output light using an optical spectrum analyzer. We have experimentally studied the optical spectra to confirm the generation of surface mechanical modes (Figure 3).



(a) Many low frequency oscillations (50 MHz - 1.4 GHz) can be excited (this work)



(b) High frequency oscillations around 11 GHz can also be excited (prior art)

Fig. 4. Excitation of various oscillation frequencies while slowly scanning the pump laser from 1520 - 1570 nm.

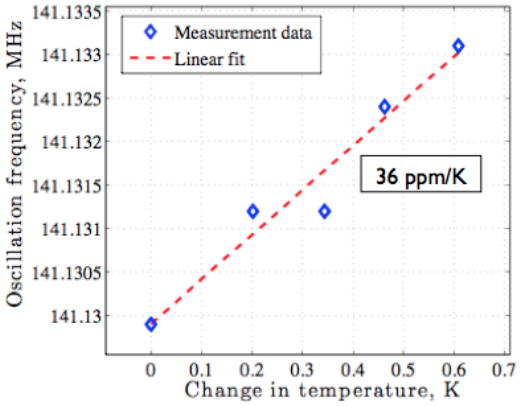


Fig. 5. The capability for continuous frequency tuning using temperature exists. The tuning slope for a given oscillation depends on the specific combination of optical and mechanical modes that participate in the process. The pictured measurement is for a 141 MHz oscillation.

IV. Experimental results

A. Oscillation frequency and tuning

We have experimentally determined (Figure 4) that a single device can show hundreds of discretely-selectable oscillation frequencies through the described process. In the experiment shown in Figure 4(a), we scanned the pump laser from 1520 nm – 1570 nm in order to probe many pump modes, while keeping the electrical spectrum analyzer on the 'peak hold' setting. In the low frequency regime that this paper describes, we were able to capture oscillations ranging from 50 MHz up to 1.4 GHz.

We can combine this result with the previously demonstrated ability to excite acoustical modes in the X-band (11.5 GHz) frequency regime via Brillouin back-scattering (Figure 4(b)). The implications of this combined result are that a single device can produce oscillations ranging from 50 MHz–1.4 GHz, and also from 10 GHz–11.5 GHz. Indeed there is a large gap between these frequency ranges where oscillations have not been experimentally demonstrated. We can, however, begin to fill this gap by using different pump wavelengths and different materials.

Beyond the capability for discrete frequency selection with this oscillator, we can also thermally tune the oscillation frequency (Figure 5). Here, the major effect responsible for tuning is the positive temperature coefficient of material stiffness for silica. The tunability however does appear to depend on the specific mechanical and optical modes that participate in any given oscillation. It must be noted that temperature change also affects the optical modes.

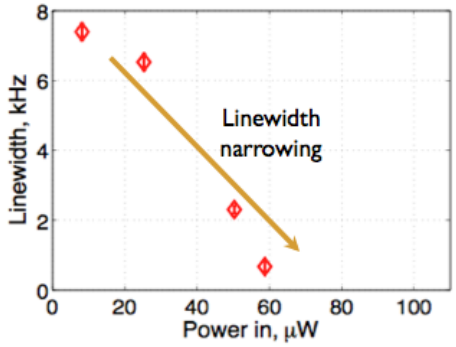

Fig. 6. Oscillation linewidth narrows with increasing optical pump power, consistent with the narrowing of laser linewidth.

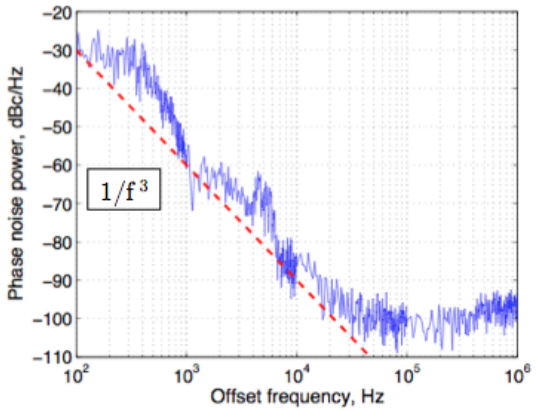

Fig. 7. Initial phase noise measurements indicate a $1/f^3$ slope. The phase noise measurement from a 94 MHz oscillation at -35 dBm signal power is pictured here.

B. Noise performance

We have performed several experiments studying the noise performance of these oscillators. Our data shows narrowing of the oscillation linewidth as a function of increasing pump optical power (Figure 6). The linewidth narrowing is consistent

with lasing processes. This line narrowing behavior should continue until the system reaches the Schawlow-Townes limit. We also have preliminary phase noise measurements which indicate a $1/f^3$ characteristic close to carrier (Figure 7).

V. Conclusions

We have experimentally demonstrated a class of optomechanical oscillators that excite surface acoustic waves on silica microspheres through electrostrictive pressure generated by light. While SAW are typically generated on planar piezoelectric substrates, with metal electrodes used for applying electric fields, here we apply the electric field through a set of virtual electrodes formed by light which co-propagates with the traveling acoustical mode. Additionally, the excitation mechanism of electrostriction is available in any dielectric material, opening up broad possibilities in material selection. Since SAW-based sensors are well-studied, the potential applications of this technology extend beyond oscillators into various sensing techniques.

Low-phase-noise and stable microwave signals are of prime importance in a variety of scientific and technological fields, such as, for example, atomic frequency standards[1,2], radar and remote sensing, and very long baseline interferometry. The combination of ultra-stable lasers [3] and low noise optical frequency division by use a femtosecond laser presents a possibility to realize extremely low phase noise microwave source with reliable and operational-level technology. We have previously reported phase noise levels at -120 dBc/Hz at 1Hz from a 12 GHz carrier, with white phase noise plateau approaching -140dBc/Hz [4,5,6].

We present here new strategies to improve the phase noise of our generated microwave signal and increase reliability of the system. A 250MHz repetition rate fiber-based femto-second laser system with an Electro-Optic Modulator inside its cavity is realized at a quasi-industrial level, in close collaboration with RD teams from MenloSystems GmbH. This system was characterized to allow about 500 kHz control bandwidth with moderate amplitude modulation cross-talk. Using this unique feature, we were able to reach the ultra-stable regime, where the spectral linewidth of the optical comb is limited by that of the continuous laser reference it's locked to, instead of its intrinsic noise properties. This very large bandwidth improves significantly our capability to generate low-noise microwave signals with a scheme simpler than previously reported. Incidently, it also renders direct optics-to-optics comparission simpler and more stable.

We have also improved significantly the relative intensity noise (RIN) of the fiber-based optical frequency comb, and studied extensively how to decrease its impact on low-phase noise microwave generation via photo-detection. A thorough characterization of the amplitude-phase conversion factor of several commonly used photodetector has been realized (see [7] for more details). Amplitude-phase conversion factor below 0.03 rad per relative intensity change can be realized reliably for a given set of operating conditions when generating 12 GHz microwave signals. The currently achieved intrinsic RIN (below -135 dBc/Hz in the 10Hz-100kHz Fourier frequency

range) [8] of our laser leads us to state with confidence than the residual amplitude phase conversion is a negligible compared to other sources of excess noise, in particular shot noise which arise from limited microwave signal to noise ratio.

To finish, and in order to improve the shot noise limit of our system, we have implemented experimentally a repetition rate multiplication technique [9] which allows us to go from 250 MHz to 4 GHz repetition rate with a simple and compact device based on a ladder Mach-Zender Interferometr topology. This multiplication is realized with minute degradation in low Fourier frequencies phase noise spectrum as we confirmend experimentally. The resulting increase in useful signal at 12 GHz (up to -4 dBm obtained with a High Linearity Photodiode from Discovery Semiconductor) allows us to obtain a white residual phase noise plateau at ~156dBc/Hz (for a very preliminary result), at the very best level of performance ever achieved for microwave generation with femtosecond frequency combs.

These three techniques put together pave the way to a very simple and compact microwave generator with ultra-low phase noise on a very broad part of the Fourier frequencies spectrum. We can therefore envision in a close future to generate a microwave signal at 12 GHz with a phase noise at -120 dBc/Hz flicker noise at 1Hz from the carrier, $10^{-16}\tau^{-1}$ Allan deviation (with $\tau>1$ the number of averaging seconds) and a white phase noise plateau approaching -160dBc/Hz.

***Abstract*—Scattering mechanisms in optical fiber induce noise in the spectra of optical signals travelling through the fiber. This fiber-induced noise limits the quality factor of optical fiber resonators and degrades low-noise signals transmitted via optical fiber. In this work, we present preliminary data from our systematic study of optical scattering in fiber. We present noise spectra for Rayleigh and Brillouin scattering. We also demonstrate suppression of these scattering mechanisms via laser frequency modulation.**

I. INTRODUCTION

Length dependent noise in optical fiber limits the performance of radio frequency (RF) photonic systems [1,2]. The sources of this optical-fiber-induced noise must be indentified and mitigated in order to optimize RF-photonic systems. Optical scattering represents one class of fiber-length-dependent mechanisms that can induce noise in optical signals transmitted via fiber. Interactions between incident light and density fluctuations in optical fiber can alter the wave vector and frequency of portions of the incident light. These interactions alter the phase delay and loss experienced by light in the fiber in a random fashion. These random variations in phase and amplitude amount to noise imprinted on the incident optical signal.

In this work, we present preliminary data from our systematic study of optical scattering in fiber. The data we present exhibits evidence of both Brillouin and Rayleigh scattering in fiber. Our data demonstrates that both mechanisms can contribute to the noise induced on optical signals transmitted via fiber. Furthermore, we demonstrate that this optical noise converts to electrical noise after photodetection, thereby increasing the noise of any RF signals imprinted on the optical beam. Finally, we demonstrate the suppression of both Brillouin and Rayleigh scattering by frequency modulating the incident optical signal.

II. OPTICAL SCATTERING MECHANISMS

A. Rayleigh Scattering

Rayleigh scattering can be described as scattering of incident light off of stationary density fluctuations in the optical fiber [3]. Whenever light approaches the boundary between two regions with different indices of refraction, a portion of the light is reflected off of the interface. Since the dimensions of these density fluctuations are on the order of the wavelength of the incident light, the light can be scattered in many directions. Since these density fluctuations are located randomly along the length of the fiber, the induced scattering generates phase and amplitude noise.

The density fluctuations can themselves be induced by the incident light via electrostriction leading to stimulated Rayleigh scattering (STRS) [4]. The limited data in the literature on Rayleigh scattering in optical fiber suggests that the Rayleigh gain bandwidth is on the order of 10 kHz [5]. In addition, because the density fluctuations are nearly stationary, Rayleigh scattering does not induce a significant frequency shift in the scattered light. The scattering data we present at power levels below 10 dBm are consistent with the above characteristics of Rayleigh scattering.

B. Brillouin Scattering

Brillouin scattering is caused by the interaction between the incident light and phonons within the fiber [6]. These phonons can be thought of as moving density fluctuations as opposed to the stationary density fluctuations that cause Rayleigh scattering. Because phonons have a finite energy, the interaction induces a frequency shift in the scattered light. This frequency shift is approximately 11 GHz in optical fiber. Due to the conservation of both energy and momentum, the finite phonon momentum causes Brillouin scattering to occur primarily in the counter-propagating direction.

At approximately 10 MHz, the Brillouin scattering bandwidth is significantly greater than that of Rayleigh scattering. As in the case of Rayleigh scattering, the incident light can amplify phonons via electrostriction thereby leading to stimulated Brillouin scattering (SBS). The data we present in this work shows that SBS requires significantly greater power levels than STRS. This result is consistent with the literature [5].

This work was funded by the U.S. Defense Department Coalition Warfare Program.

C. *Backscattered versus transmitted spectra*

Our ultimate goal is to determine the effects of both Rayleigh and Brillouin scattering on the spectrum of the light transmitted through a length of optical fiber. It is this transmitted spectrum that is converted into electrical phase noise in RF-photonic systems. However, we first characterize both scattering mechanisms by measuring the spectrum of the backwards scattered light. Both Rayleigh and Brillouin scattering contribute to the backward scattered light whereas most other fiber length dependent noise mechanisms do not. Therefore, the backward scattered spectrum allows us to analyze the effects of both scattering mechanisms separately from other noise phenomena such as Kerr interaction or dispersion.

III. Optical Domain Measurements

We began our study with broadband optical domain measurements. These measurements were performed with an optical spectrum analyzer with a bandwidth greater than 300 nm at 1550 nm. Performing broadband measurements allowed us to determine the spectral regions in which the backscattered light was concentrated.

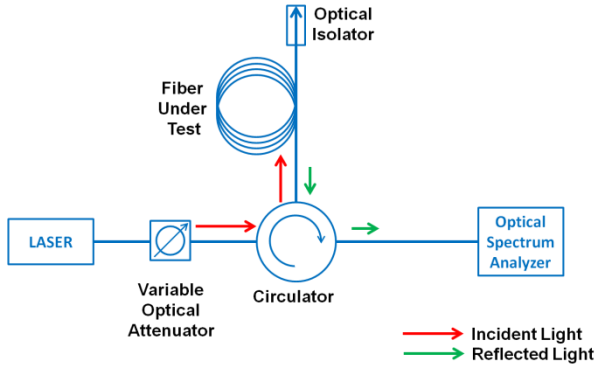

Figure 1. A schematic diagram of our optical-domain backscatter measuremets.

A. *Experimental Setup*

Fig. 1 shows a schematic diagram of our optical-domain backscatter measurement setup. We used a 100 mW distributed feedback (DFB) semiconductor diode laser. The variable optical attenuator (VOA) was used to alter the optical power into the fiber without changing the relative power spectrum of the incident light. The circulator separated the incident light from the backscattered light. The latter was sent to our optical spectrum analyzer.

B. *Experimental Results*

Fig. 2 shows the optical spectra of the back-scattered light from a 6 km spool of single-mode fiber with varying input power levels. The data highlights three regions of interest: the spectral region around the wavelength of the incident light, and the regions approximately 0.1 nm above and below the wavelength of the incident light. The latter two regions correspond to the anti-Stokes and Stokes wavelengths induced by Brillouin scattering [6]. The increased optical power measured in the Stokes region for input power levels above 11 dBm is due to SBS. However, the bandwidth of the Stokes spectrum shown in Fig. 2 is limited by the resolution bandwidth of the optical spectrum analyzer (0.01 nm). We require higher resolution measurements to properly resolve the SBS bandwidth and determine the effects of Rayleigh scattering.

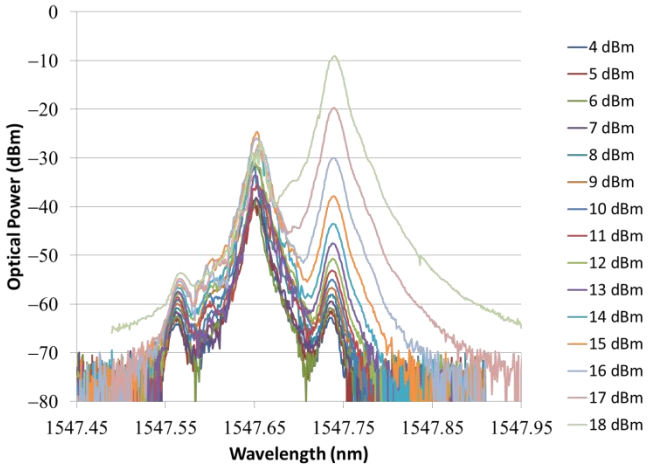

Figure 2. A plot of the optical spectra of the backscattered light from a 6 km spool of single-mode fiber with varying input power levels.

IV. Electrical Domain Measurements

In order to gain greater resolution, we performed electrical-domain measurements on the backscattered optical spectrum. By down-converting the backscattered signal into the electrical domain, we sacrifice bandwidth but increase spectral resolution. Since we had already determined the spectral regions of interest using our optical domain measurements, we could perform narrow-band high-resolution measurements around these regions.

A. *Experimental Setup*

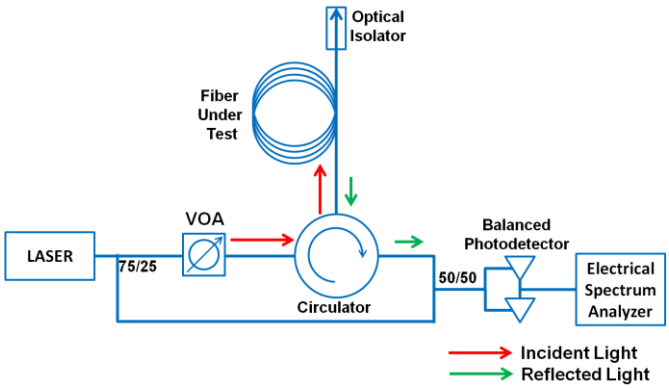

Figure 3. A schematic diagram of our electrical-domain coherent backscatter measuremets

We use the same laser, VOA, and circulator used in the optical-domain measurements. We use photodetectors to convert the backscattered light into electrical currents which we then transmit to a high-resolution electrical spectrum analyzer (ESA). However, the backscattered optical power can be as low as –60 dBm. At such low power levels, the photodetector output is dominated by shot noise. To increase the sensitivity of our electrical domain measurement, we used a coherent detection scheme. We split off 25% of the laser

power and sent it into one input of a 2-by-2 optical combiner. This portion of the laser power was used as a local oscillator (LO) signal. The backscattered light from the circulator was sent into the other input of the combiner. The combined optical signal was then sent to a pair of balanced detectors. The output current from the balanced detector pair was proportional to the product of the backscattered and LO field amplitudes. In other words, we used the LO signal to coherently amplify the backscattered signal above the shot noise level of the photodetectors.

B. Experimental Results

In the electrical domain, the spectral regions of interest are: the region around the Stokes-frequency shift (approximately 11 GHz), and the region around DC where which corresponds to the region around the incident light central frequency in the optical domain.

1) Brillouin Scattering Data

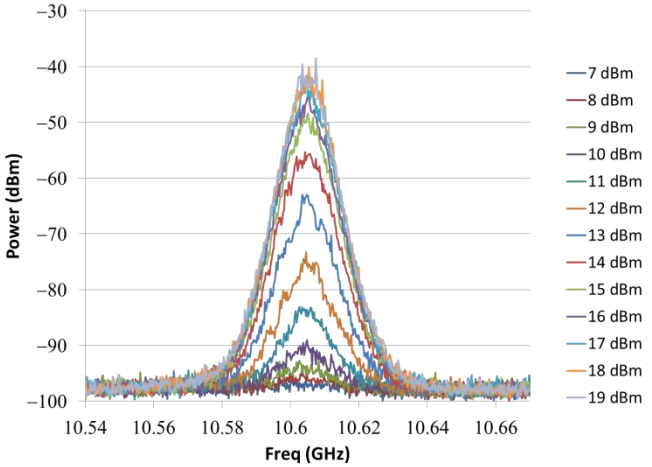

Figure 4. A plot of the backscattered power spectra from a 6 km spool of single-mode fiber measured in the electrical domain for varying input power levels. These spectra was measured in the frequency range around the Brillouin-induced Stokes shift.

Fig. 4 shows a plot of the backscattered power from a 6 km spool of single-mode fiber measured in the electrical domain. The peak backscattered power for all input power levels was approximately 10.61 GHz. The bandwidth of the Brillouin scattered spectra was on the order of 10 MHz. We were able to measure Stokes-shifted signals above the shot noise level for input power levels above 8 dBm. Due to the limited bandwidth of the SBS spectrum, we expect that the Brillouin scattered light will only directly interfere with RF-signals with frequencies within 10-20 MHz of the 10.6 GHz Stokes frequency.

2) Rayleigh Scattering Data

To investigate the Rayleigh spectra, we measured the spectrum of the electrical signal from the photodetectors around DC. In particular, we focused on the range of frequencies between 10 Hz and 1 MHz. This range corresponds to the frequency range shifted between 10 Hz and 1 MHz from the central frequency of the incident optical beam.

Fig. 5 shows a plot of the backscattered power spectra from a 6 km spool of single-mode fiber. We measure significant levels of power-dependent noise for incident power levels as low as –10 dBm.

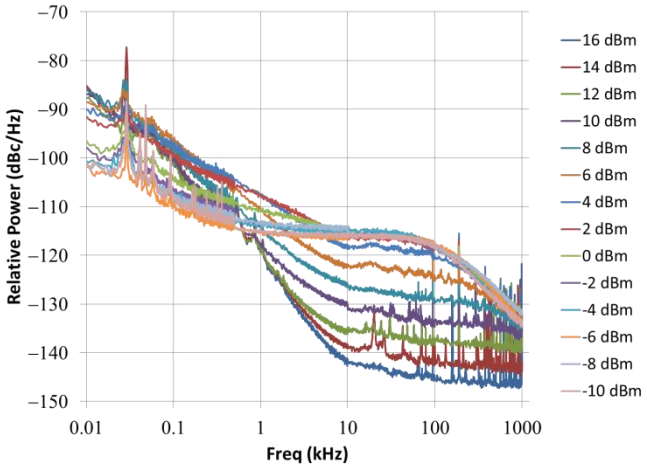

Figure 5. A plot of the backscattered power spectra from a 6 km spool of single-mode fiber measured in the electrical domain for varying input power levels. These spectra were measured in the frequency range around DC.

At offset frequencies less than 10 kHz, the relative noise power increases with increasing input power. However, for offset frequencies greater than 10 kHz, the relative noise power decreases with increasing optical power. This gain filtering suggests a Rayleigh scattering bandwidth of approximately 10 kHz. This result is consistent with the literature on Rayleigh scattering in optical fiber [5].

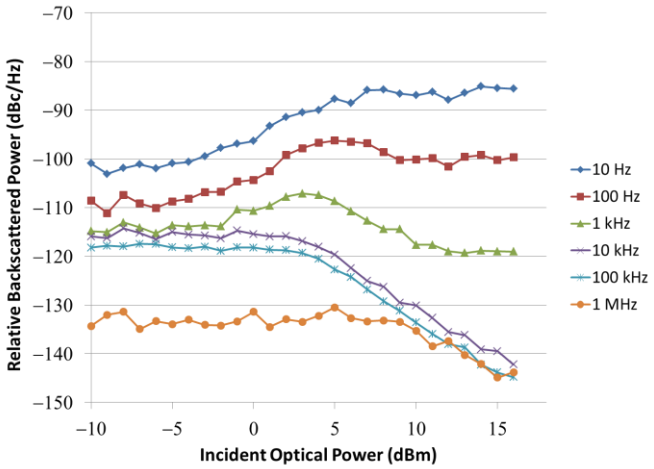

Figure 6. A plot of the relative backscattered power versus incident optical power for varying offset frequencies.

Fig. 6 shows a plot of relative backscattered power versus incident optical power for varying offset frequencies. These level curves highlight the gain filtering induced by STRS. At 10 and 100 Hz offset from the central frequency of the incident light, the scattered power increases with the incident power until approximately 8 dBm. At incident power levels greater than 8 dBm, the relative backscattered power spectral density remains fixed at approximately –85 dBc/Hz at 10 Hz

offset frequency. It is at this power range that we begin to observe significant Brillouin scattering. This data suggests that at power levels above 8 dBm, SBS draws power away from the Rayleigh scattering process, thereby clamping the STRS gain.

V. Transmission Spectra

Having characterized both Brillouin and Rayleigh scattering in our fiber spools, we then measured the spectra of the transmitted light through the same spools. We focused on the region between 10 Hz and 1 MHz from the central frequency of the incident light. This region will be converted to electrical noise at the photodetector regardless of the RF frequency of the specific RF-photonic system. The Stokes frequency range, on the other hand, will only be relevant for RF-photonic systems operating at or near 10. 6 GHz.

A. Experimental Setup

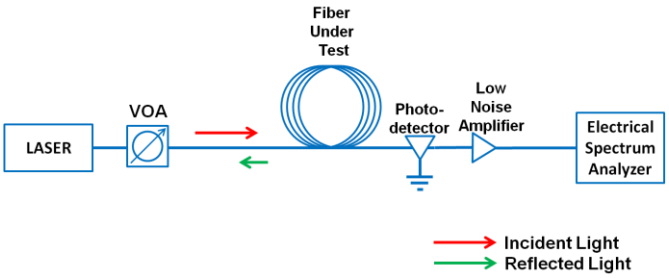

Figure 7. A schematic diagram of our electrical-domain transmitted spectrum measurement setup.

Fig. 7 shows a schematic diagram of our transmitted spectrum measurement setup. We use the same laser and VOA used in our previous measurements. However, we remove the circulator and measure the transmitted optical power from the fiber under test. After the photodetector, a low noise amplifier (LNA) is used to increase the sensitivity of our measurement system. The LNA is AC-coupled with a 0.2 Hz corner frequency. This AC-coupling effectively filters out the DC current from the incident light beam. Suppressing this DC current allows us to measure the much lower noise levels in the range between 10 Hz and 1 MHz around the central carrier.

B. Experimental Data

We varied the optical power into the fiber from –4 dBm to 17 dBm. We found two qualitative regimes: a low-power regime where the noise spectra were dominated by Rayleigh scattering; and a high-power regime where Brillouin scattering affected the noise spectra. We present experimental data for these two regimes separately in the following subsections.

1) Rayleigh Scattering Regime

Fig. 8 shows a plot of transmitted power measured in the electrical domain from a 6 km spool of single-mode fiber. The input power levels ranged from –4 to 11 dBm. For input power levels below 11 dBm, the spectra resemble the Rayleigh backscatter data we presented in previous sections. We observe the same gain-filtered noise spectrum with a 10 kHz bandwidth. This is consistent with our initial hypothesis that Rayleigh scattering in optical fiber is largely isotropic, producing scattered light in both the forward and backward directions.

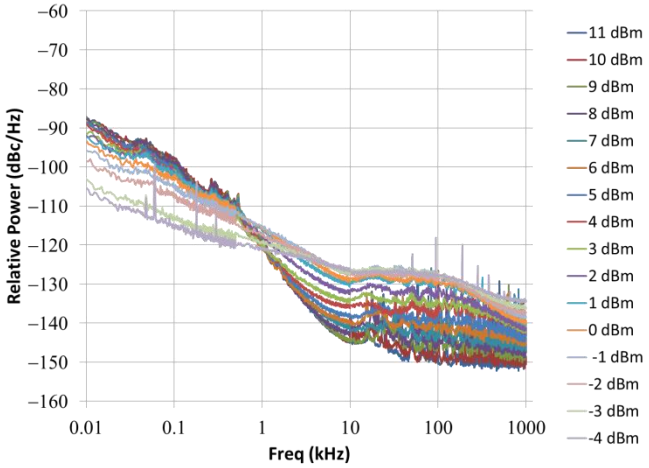

Figure 8. A plot of transmitted power spectra through a 6 km single-mode fiber spool for varying input power levels. This input power range from –4 to 11 dBm is dominted by stimulated Rayleigh scattering.

2) Brillouin Scattering Regime

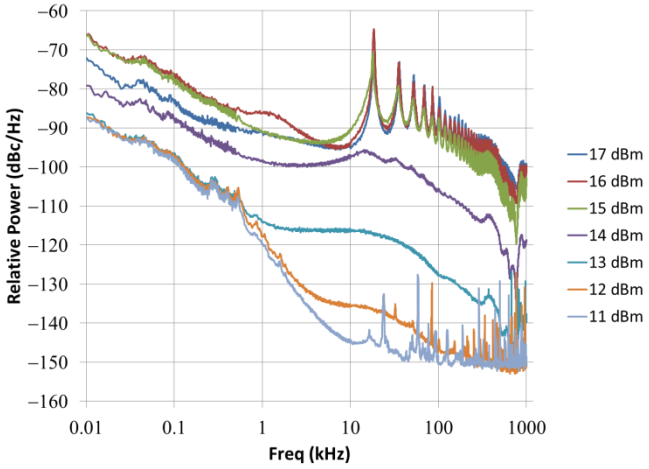

Figure 9. A plot of transmitted power spectra through a 6 km singl-mode fiber spool for varying input power levels. This input power range from 11 to 17 dBm is dominated by stimulated Brillouin scattering.

Fig. 9 shows a plot of the transmitted power measured in the electrical domain from a 6 km spool of single-mode fiber. The input power levels ranged from 11 to 17 dBm. For this range of input power levels, we found that the spectra deviate significantly form backscattered spectra for the same spool. We find that for offset frequencies beyond the Rayleigh scattering bandwidth, the transmitted noise increases with increasing optical power. This increased noise can be explained by pump depletion due to SBS. The SBS effect randomly removes power from the incident light and transfers it to the Stokes beam. This random power modulation results in an increase in the noise spectra of the incident light beam.

At power levels above 13 dBm, we observe Fresnel fringes in the transmitted spectra. The frequency spacing of these Fresnel fringes (~17 kHz) corresponds to a cavity length equal twice the length of the fiber spool under test. These Fresnel

fringes can be explained by double Brillouin scattering. As the incident light travels down the length of the fiber, SBS generates a Stokes beam that travels in the opposite direction. This backscattered Stokes beam in turn generates an anti-Stokes beam with the same frequency as the original incident light beam. This Stokes-induced anti-Stokes beam then reflects off connectors at the other end of the fiber and travels back down to the photodetector. At the detector, the double-scattered beam interferes with the original incident beam to generate Fresnel fringes. Our data demonstrates that, despite the Stokes frequency shift, SBS can contribute indirectly to the noise in the frequency range close to the original incident optical beam's central frequency.

VI. Scattering Suppression

Our ultimate goal is to characterize fiber-length-dependent noise in RF-photonic systems and investigate means of suppressing this noise. It is well known that length dependent noise is present in optoelectronic oscillators (OEOs) [1]. Maleki et al. have demonstrated that frequency modulation of the laser in an OEO can suppress some of this fiber-length dependent noise [7]. Fig. 10 shows the phase noise from a 6 km OEO with and without frequency modulation. The data shows that frequency modulation can suppress the phase noise of the OEO by more than 10 dB.

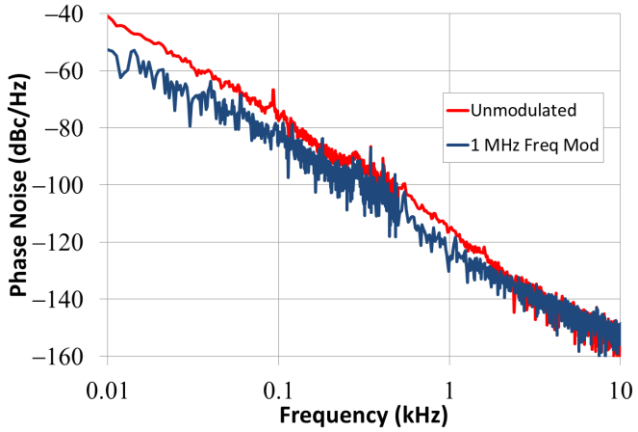

Figure 10. A plot of the phase noise from a 6 km OEO with and without laser frequency modulation.

If the fiber-length-dependent noise observed in the OEO is caused in part by either Brillouin or Rayleigh scattering, we would expect that laser frequency modulation would also suppress the Rayleigh or Brillouin scattered power.

A. Brillouin Scattering Suppression

To determine the effect of frequency modulation on the Brillouin scattered spectrum, we repeat our optical-domain measurements while modulating the incident light into the fiber. The incident light is modulated in two ways. We modulate the drive current into the laser. Doing so modulates both the amplitude and the frequency of the laser signal. To separate the effect of laser amplitude modulation from frequency modulation, we also amplitude modulate the laser output using an external amplitude modulator.

Fig. 11 shows the peak optical Stokes power (relative to the input power) versus input optical power for three cases: no modulation, external amplitude modulation, and direct frequency modulation via modulation of the laser drive current. The data shows that frequency modulation is the most effect means of suppressing SBS. In both cases, a 10 MHz RF modulation tone with 10 mW of power was used. Frequency modulating the laser led to a SBS suppression factor of 50 dB, whereas amplitude modulation only reduced the SBS gain by 15 dB.

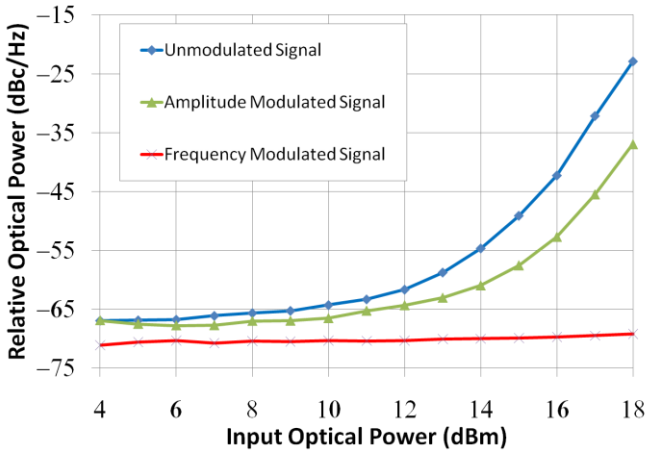

Figure 11. A plot of the peak Stoke power from a 6 km spool versus input optical power for various modulation schemes.

B. Rayleigh Scattering Suppression

To determine the effect of laser frequency modulation we measure the backscattered power in the electrical domain at 10 Hz offset frequency for varying input power levels with and without laser frequency modulation. This measurement allows us to estimate the peak Rayleigh scattered noise power versus input power in a 6 km single-mode fiber spool.

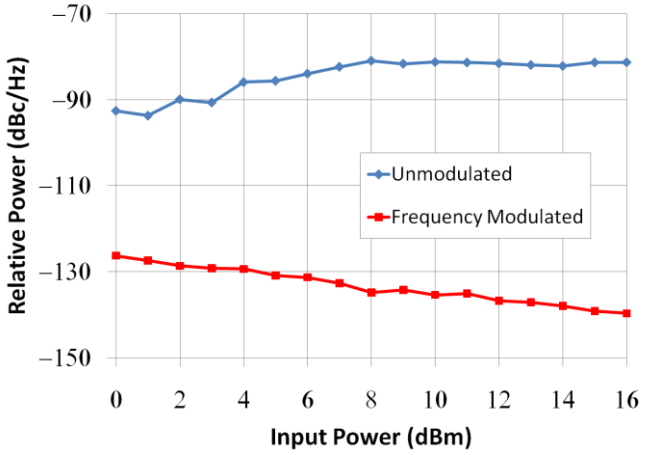

Figure 12. A plot of the peak Rayleigh-scattered power from a 6 km spool versus input optical power with and without laser frequency modulation.

Fig. 12 shows a plot of the peak Rayleigh-scattered power form a 6 km spool of single-mode fiber versus input optical power with and without laser frequency modulation. The data shows that frequency modulation suppresses the Rayleigh-scattered power by more than 50 dB. Like SBS, STRS is

suppressed by frequency modulation of the incident optical beam.

VII. Conslusions

In this work, we present data demonstrating the effects of Brillouin and Rayleigh scattering on both the backscattered and transmitted spectra of light incident on a length of single-mode optical fiber. Our data shows that both Rayleigh and Brillouin scattering contribute to the noise within 1 MHz of the central frequency of the transmitted optical beam. This scattering-induced optical noise is converted to RF noise after photodetection. Our data shows that Rayleigh scattering dominates the scattering-induced noise at input power levels below 11 dBm. Stimulated Brillouin scattering dominates the noise at input power levels above 11 dBm. At input power levels above 13 dBm, we observe evidence of noise induced by double-Brillouin scattering in a 6 km fiber spool. Finally, we show that laser frequency modulation reduces the magnitude of both Rayleigh and Brillouin-induced noise in optical fiber.

***Abstract*— Optical fiber-length-dependent flicker phase noise has been identified as a major limit to the reduction of phase noise in opto-electronic oscillators (OEOs). We outline a systematic approach to model the optical path of the OEO, and investigate the sources of length-dependent phase noise in the optical path and how they are effected by the dispersion and Kerr nonlinearity of the optical fiber.**

I. Introduction

Optical fiber-length-dependent flicker phase noise is a major limit in opto-electronic oscillators (OEOs) and other RF photonic devices [1]. Identifying the sources of this effect and mitigating them is important to increase the performance of RF photonic systems using long fiber lengths. A number of different phenomena can in principle contribute to this effect, these include: the conversion of laser frequency noise into RF phase noise via fiber dispersion [2]; the conversion of laser amplitude noise into RF phase noise via third order dispersion and Kerr nonlinearity; parametric amplification of the laser noise, which is then converted into RF phase noise in the photodetector or RF amplifiers; and the conversion of laser noise into RF phase noise via scattering processes in the optical fiber, including Brillouin and Rayleigh scattering and scattering from end-faces and connectors [3].

Due to the increase in the system Q as the length of the optical fiber is increased, the RF phase noise of an OEO should decrease with increasing fiber length; however, in experimental systems this expected decrease is not observed at lower frequencies. Fig. 1 shows the experimentally measured RF phase noise in an OEO with three different fiber lengths. While the phase noise around 10 kHz decreases with increasing length, the phase noise below 1 kHz is considerably higher than that the expected phase noise (shown as the dashed lines); indeed, in the measured system at frequencies around 10 Hz there was essentially no improvement in the phase noise when the fiber length was increased by an order of magnitude, from 500 m to 6 km. This has been found to be consistent with a flicker noise source that increases as the fiber length is increased [5].

In order to understand the sources of this length-dependent flicker noise and their relative effect on the RF phase noise in the OEO we model the optical transfer of both signal and noise through the optical path, including the effects of laser noise, fiber loss, dispersion, and Kerr nonlinearity. We show that for physically realistic noise powers the effects of laser amplitude noise amplification and conversion to RF phase noise are much smaller than the white noise floor of the system and are not candidates for sources of length-dependent flicker noise.

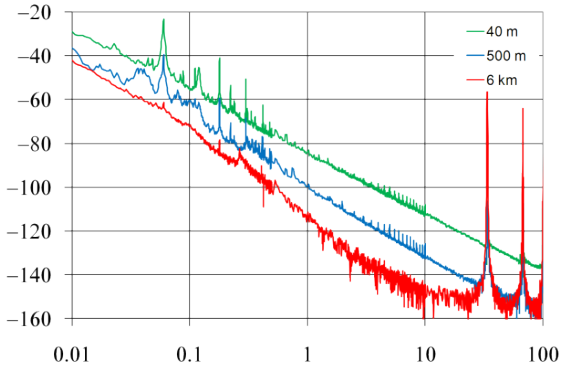

Fig. 1. The experimentally measured phase noise in an OEO (solid lines) and the theoretically expected phase noise (dashed lines) for three different lengths of fiber illustrating the length-dependent flicker noise in the OEO [4].

II. Modeling the Optical Path

A typical OEO system configuration is illustrated in Fig. 2 which shows the evolution of the signal and the noise sources in both the optical and electronic domains. These noise sources include the shot noise of the photodetector, the thermal and flicker noise in the amplifier, the laser noise, and spontaneous scattering noise induced in the optical fiber.

The RF signal undergoes a complex nonlinear evolution as it travels through the optical path from point (1) in Fig. 2 where it is AM modulated onto the optical carrier (2) by the electro-optic modulator (EOM) and travels through the optical fiber (3). The photodetector (4) converts the optical signal to the RF domain again, and mixes the multiple harmonics of the RF signal around the optical carrier, giving multiples of the RF signal frequency, which are then amplified and filtered in the RF domain to produce a single RF frequency, and lastly fed back into the modulator.

A. The electo-optic modulator

Firstly, the electro-optic modulator imprints the electronic input signal onto the laser output. The generic expression for

978-1-61284-110-6/11/$26.00 ©2011 IEEE

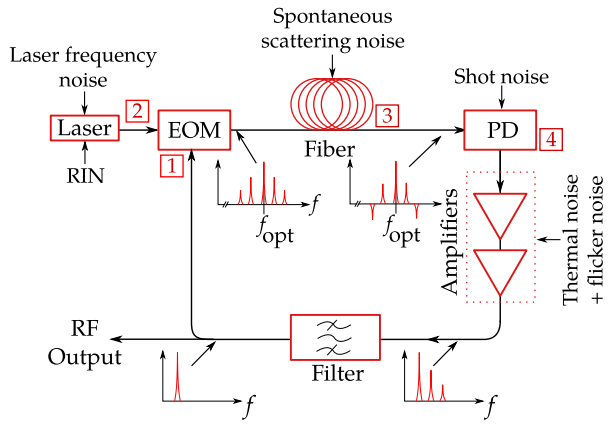

Fig. 2. The OEO system showing the sources of noise and the harmonics of the RF signal at different points in the loop.

the electric field at the output of the modulator is given by the equation,

$$E_{\text{opt}}(t) = \frac{1}{2}E_{\text{laser}}(t)\{\eta_1 \exp[jv_1 A_{\text{in}}(t)] + \eta_2 \exp[jv_2 A_{\text{in}}(t) + j\psi]\}, \quad (1)$$

where $A_{\text{in}}(t)$ is the RF input signal, $\eta_{1,2}$ are determined by the extinction ratio, $v_{1,2}$ are determined by V_π and the modulator chirp, and ψ is determined by the bias.

Directly after modulator the optical power is given by,

$$P(t) = \frac{P_0}{4}\left(\eta_1^2 + \eta_2^2 + 2\eta_1\eta_2 \cos[(v_2 - v_1)A_{in}(t) + \psi]\right), \quad (2)$$

where P_0 is the laser input power.

These modulator parameters of Eq. 1 can be related to the physical device parameters the half-wave voltage V_π, the bias voltage V_B, and the modulation depth η by the following relations

$$\begin{aligned} \eta &= 2\eta_1\eta_2 \\ V_\pi &= \frac{\pi}{v_1 - v_2} \\ V_B &= \frac{V_\pi}{\pi}(\psi - \frac{\pi}{2}) \end{aligned} \quad (3)$$

with the restriction that $\eta_1^2 + \eta_2^2 = 1$.

Using these parameter definitions Eq. 2 is equal to the standard formula for optical power after the modulator that was given in Yao-Maleki [6], Furthermore, we assume the RF input to the modulator is a cosine with amplitude $V_{\text{in}}(t)$ noise and $\phi(t)$ phase noise given by

$$A_{\text{in}}(t) = V_{\text{in}}(t)\cos\big[\omega_0 t + \phi(t)\big].$$

Then we use the Jacobi-Anger expansion and write the optical signal as a multi-scale expression for the harmonics of the RF oscillator around the optical carrier,

$$E_{\text{opt}}(t) = \frac{E_{\text{laser}}}{2}\sum_{m=-\infty}^{\infty} j^m \Big[\eta_1 J_m(v_1 V_{\text{in}}) + \eta_2 J_m(v_2 V_{\text{in}})\exp(j\psi)\Big]\exp\Big\{jm[\omega_0 t + \phi(t)]\Big\}. \quad (4)$$

B. Laser phase and amplitude noise

A likely source of length dependent flicker noise comes from the laser noise converted to RF phase noise by some process in the fiber. It is therefore important to take the laser frequency and amplitude noise into account in any noise model of the OEO. The laser frequency and amplitude noise in an OEO was recently measured by Volyanskiy et al. [2]. Their measured spectra showed the laser frequency noise with a $1/f$ slope at frequencies below 1 kHz and RIN with a slope of $1/f$ to $1/f^{1.5}$ at lower frequencies. In this paper we use laser frequency noise and RIN noise power spectra that are within the range of their experimentally measured results. The experimental results also depended strongly upon the power of the laser; in the simulations we do not change the laser noise so that the effects of fiber nonlinearity can be isolated. We model the $1/f$ noise using a spectral filtering algorithm as described in Levy et al. [5].

The laser output including RIN and laser phase noise is given by,

$$E_{\text{laser}}(t) = E_0\big[1 + \alpha_{\text{RIN}}(t)\big]\exp\left[j\omega_c t + j\int_0^t \Delta\omega(t')dt'\right], \quad (5)$$

where E_0 is the field amplitude of the laser, ω_c is the optical carrier frequency, $\alpha_{\text{RIN}}(t)$ is the laser amplitude noise, and $\Delta\omega(t)$ is the laser frequency noise.

C. The optical fiber

The signal from the modulator is directly coupled into an optical fiber. We model the propagation of the optical signal through the fiber including the effects of loss, dispersion, third-order dispersion, and Kerr nonlinearity using the following equation [7],

$$\frac{\partial E}{\partial z} = -\frac{\alpha}{2}E - \beta_1\frac{\partial E}{\partial t} - j\frac{\beta_2}{2}\frac{\partial^2 E}{\partial t^2} + \frac{\beta_3}{6}\frac{\partial^3 E}{\partial t^3}, + j\gamma|E|^2 E \quad (6)$$

where α is the fiber loss, $\beta_1 = 1/v_g$ with v_g being the group velocity, $\beta_2 = \beta''(\omega_c)$ the dispersion, $\beta_3 = \beta'''(\omega_c)$ is the third-order dispersion, and γ is the nonlinear coefficient. Here we take typical parameters for the Corning® SMF-28 fiber of $\alpha = 0.16$ dB/km, $\beta_2 = -20$ ps^2/km, $\beta_3 = 0.1$ ps^3/km, $\gamma = 0.0015$ (W m)$^{-1}$.

The laser frequency noise is inherently large at optical frequencies due to the large operating frequency of the laser. The optical phase noise is therefore extremely large, which greatly restricts the time discretization of the numerical simulations if implemented directly. For efficient simulations we do not explicitly calculate with the laser phase noise, instead we make the substitution $E(t,z) = E_{\text{laser}}(t)A(t - z/v_g, z)$; where $E_{\text{laser}}(t)$ is given by Eq. 5 and $A(t,z)$ is the propagating

envelope initially given by the modulator response, delayed by the group velocity. This leads to an equation in $A(t,z)$

$$\frac{\partial A}{\partial z} \simeq -\frac{\alpha}{2}A - j\frac{\beta_2}{2}\left[\partial_t + j\Delta\omega(t)\right]^2 A + \frac{\beta_3}{6}\left[\partial_t + j\Delta\omega(t)\right]^3 A + j\gamma P_0\left[1+\alpha_{\mathrm{RIN}}(t)\right]^2 |A|^2 A, \quad (7)$$

where we no longer need to directly model the large laser phase noise.

Furthermore, to model the frequencies close to the RF harmonics we can expand the field $A(z,t)$ near the harmonics of the RF oscillation frequency, w_0. Namely, we write

$$A(z,t) = \sum_{m=-M}^{M} a_m(z,t)\exp(jm\omega_0 t), \quad (8)$$

where M is the number of harmonics that are modeled in the optical domain. This assumption is equivalent to assuming the noise spectrum is slowly varying compared to the RF oscillation frequency. Substituting Eq. 8 into Eq. 7 we arrive at a set of coupled PDEs

$$\frac{\partial a_m}{\partial z} = -\frac{\alpha}{2}a_m - j\frac{\beta_2}{2}\left[\partial_t + j\Delta\omega(t)\right]^2 a_m + \frac{\beta_3}{6}\left[\partial_t + j\Delta\omega(t)\right]^3 a_m + j\gamma \sum_{k=-M}^{M}\sum_{l=-M}^{M} a_j a_k a^*_{j+k-m}. \quad (9)$$

The nonlinear term contains all cross-phase modulation and four wave mixing terms. The numerical solution of these coupled equations allows the noise signals close-in to the carrier to be propagated with full nonlinear dynamics.

D. Detection

The detector completes the optical path and converts the optical signal to the electronic domain. Using the notation of Eq. 8 the detected signal at the fundamental RF frequency is given by the following equation

$$V_{\mathrm{RF}}(t) = \rho R \sum_{m=-\infty}^{\infty} a_m(L,t)a^*_{m-1}(L,t)\exp(j\omega_0 t)$$

All other harmonics will be filtered in the electronic domain, so we need only consider in this fundamental RF frequency.

If the optical fiber is modeled as a perfect delay with no other effects then the RF signal reduces to the equation given by Yao and Maleki [6]

$$V_{\mathrm{RF}}^{(\mathrm{ideal})}(t) = \frac{P_0}{2}R\rho\eta\cos\left(\frac{\pi V_B}{V_\pi}\right)J_1\left(\frac{\pi V_{\mathrm{in}}}{V_\pi}\right)\cos\left[\omega_0 t + \phi(t)\right]$$

where R is the impedence. We use this ideal response of the optical path as a comparison for the results of the different optical effects.

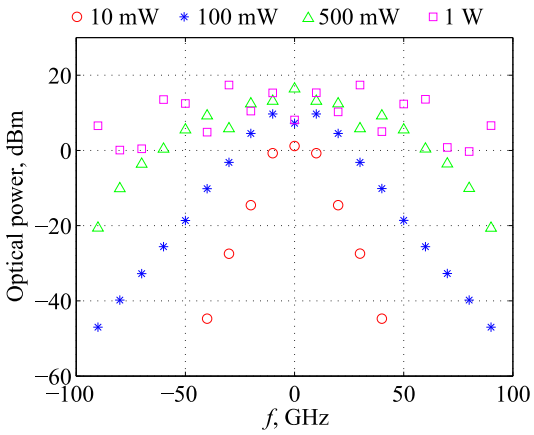

Fig. 3. Theoretical optical power in the harmonics for a 10 GHz OEO after 6 km of transmission through SMF-28 for different input laser powers.

III. The Large Signal Behavior

As a first step, it is necessary to find the stationary state of the system. Once the steady state is identified, it is possible to calculate the impact of the laser, photodetector, and RF amplifier noise on the OEO's phase noise.

In general there will be two main effects on the evolving harmonics in the optical domain: Firstly, increasing the nonlinearity will increase the power transferred to the harmonics further from the carrier in the optical domain due to spectral broadening. Secondly, the phase of the harmonics will rotate due to both dispersion and nonlinear effects leading to reduction of the detected signal, if a perfect modulator is considered.

The calculated power in the optical harmonics at the end of a 6 km optical fiber is shown in Fig. 3. As expected as the optical power is increased the power in the signal broadens in the frequency domain. For power levels below 100 mW the majority of the power is in the three lowest order harmonics; however, above this cutoff power in the higher-order harmonics increases quickly.

The phase of the harmonics is changed by dispersion and nonlinearity, if we neglect the amplitude changes just described, which is approximately valid for laser powers less than 100 mW, we can write the phasor at the end of the fiber as the input phasor rotated by a phase θ_m

$$a_m(L) = a_m(0)\exp\left[-\frac{1}{2}\alpha z + j\theta_m\right]$$

Assuming that the majority of the signal comes from the three lowest order harmonics ($m=-1,0,1$) the relative depahsing factor between the beating harmonics is given by

$$\delta = \frac{\theta_1(L)+\theta_{-1}(L)}{2} - \theta_0(L)$$

For dispersion alone this dephasing factor would be given by $\delta = \frac{\beta_2}{2}\omega_0 L$; however, in the presence of nonlinearity it must be calculated numerically. Assuming an ideal modulator any

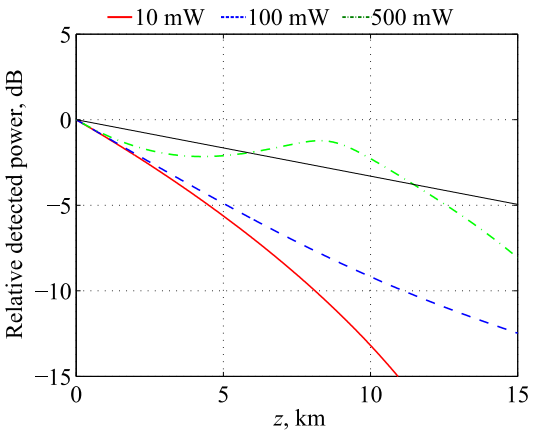

Fig. 4. Calculated detected power for a 10 GHz OEO for a modulator with zero chirp, $\eta = 0.7$, $V_\pi = 5.1$ V and $V_B = 2.6$ V. The solid black line is the expected detector power if only fiber loss was considered.

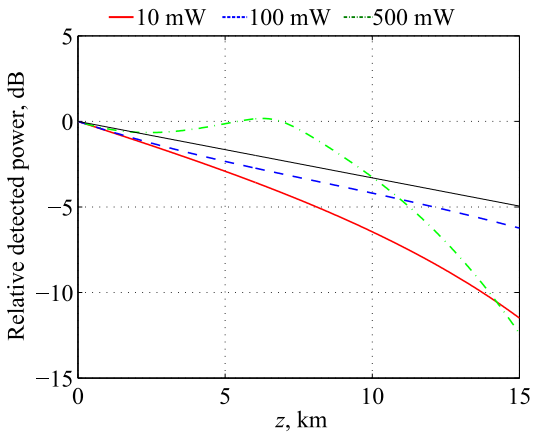

Fig. 5. Calculated detected power for a 10 GHz OEO for a modulator with a chirp of $\alpha = 0.6$, $\eta = 0.7$, $V_\pi = 5.1$ V and $V_B = 2.6$ V. The solid black line is the expected detector power if only fiber loss was considered.

dephasing would cause a decrease in the detected signal that is given by

$$V_{\mathrm{RF}}(t) = \exp(-\alpha L)\cos(\delta)V_{\mathrm{RF}}^{(\mathrm{ideal})}(t)$$

This is shown in Fig. 4 where the detected power for an unchirped modulator for different laser powers is shown. The lower power curve is considerably decreased over the case where there is only fiber loss, and increasing the power causes the Kerr nonlinearity to increasingly oppose the phase rotation due to the dispersion.

For a modulator with non-ideal extinction ratio and chirp the RF harmonics will have different phases immediately after modulation which will be further changed by optical propagation. This can increase or decrease the detected signal depending on the chirp of the modulator. Most commercial modulators have chirps that cancel the effect of anomalous dispersion; therefore having modulator chirp will increase the detected signal in the presence of optical dispersion. This is shown in Fig. 5. The detected power for low laser powers is higher than that in Fig. 4 due to the modulator chirp.

IV. RF and Optical Noise Behavior

A. Dispersion

Expanding Eq. 7 and neglecting third order dispersion, nonlinearity, higher order noise terms and assuming the laser frequency noise is a slow signal compared to the frequencies of interest we obtain

$$\frac{\partial A}{\partial z} - \beta_2 \Delta\omega(t)\frac{\partial A}{\partial t} \simeq -\frac{\alpha}{2}A - j\frac{\beta_2}{2}\frac{\partial^2 A}{\partial t^2} \qquad (10)$$

the left hand side can now be seen as a random timing jitter driven by the laser frequency noise, and the terms on the right-hand side of Eq. 10 give the fiber loss and a phase rotation in the frequency domain. The timing jitter of $\beta_2\Delta\omega(t)z$ can be converted to a phase shift of the RF frequency leading to a RF phase noise due to propagation through a fiber of length L of,

$$\phi_{\mathrm{RF}}(z) = \beta_2\omega_0 L\Delta\omega(t), \qquad (11)$$

which is the same equation given by Volyanskiy et al. [2].

B. Kerr nonlinearity

In recent experimental measurements the RF phase noise in an OEO using standard fiber as well as dispersion shifted fiber (DSF) were compared [4]. The experimental results failed to show the expected decrease in length-dependent flicker noise that would be expected if the conversion of laser frequency noise to RF phase noise discussed in the previous section was dominant. Furthermore, the results were highly power dependent indicating that there is a dominant nonlinear process that drives the length-dependent flicker noise. In this section we investigate the Kerr nonlinearity of the fiber and determine its role in length-dependent noise in the OEO.

Considering Kerr nonlinearity alone the optical signal only experiences a nonlinear phase rotation. After direct detection this has no effect on the noise or large signal dynamics of the OEO. However, the combination of nonlinearity and dispersion can have complex effects. In the previous section these effects were investigated with regards to the large signal behavior. The effect of nonlinearity and dispersion can also affect the noise, specifically it can cause noise mixing of noise between channels through cross-phase modulation and in addition can cause parametric amplification of noise, where power from the pump is transferred via four-wave mixing to the noise.

To investigate their effects on the noise after detection we use numerical simulations of the optical path described in the preceding sections, from modulator input to detector output.

We begin taking a system with a noise-free RF input and adding laser phase noise alone to the simulations. As discussed previously, dispersion directly converts laser frequency noise to RF phase noise after detection. This is shown in Fig. 6 the dashed lines indicate different laser powers, while assuming

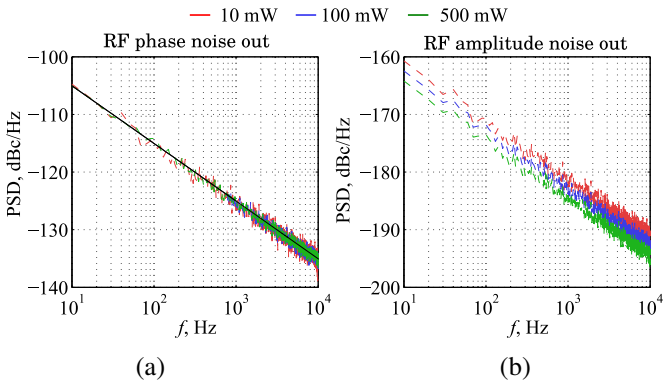

Fig. 6. The theoretical detected RF (a) frequency and (b) amplitude noise converted from a typical laser frequency noise spectrum by dispersion and nonlinearity in a 6 km length of SMF-28 fiber.

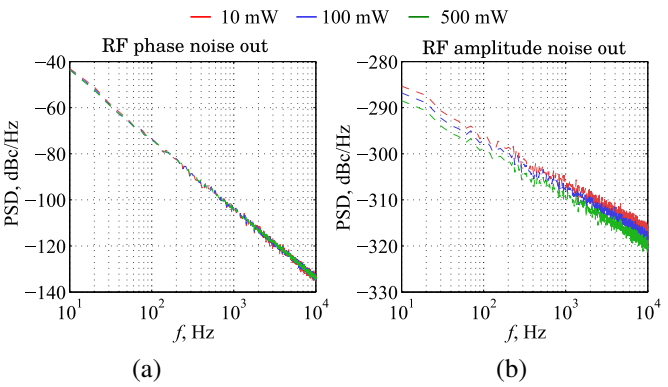

Fig. 8. The theoretical detected RF (a) phase and (b) amplitude noise spectra after optical propagation with an RF phase noise input for a 6 km length of SMF-28 fiber.

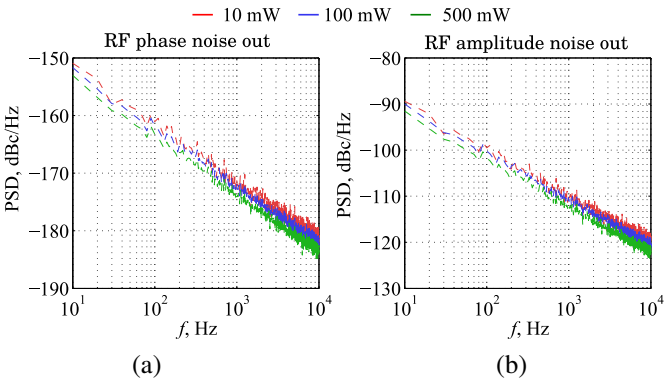

Fig. 9. The theoretical detected RF phase and amplitude noise spectra after optical propagation with an RF amplitude noise input for a 6 km length of SMF-28 fiber.

the same laser frequency noise at each power. We see that the RF phase noise is the same independent of power, and has excellent agreement with the linear calculation of Eq. 11 shown as the solid line.

Figure 7 shows the results of similar numerical experiments where in this case the only noise in the simulations is the laser RIN noise. The RIN converts directly to RF amplitude noise as expected, and is also parametrically amplified through propagation in the fiber, but only at powers which are considerably higher than that used in experimental OEOs and only by a small amount. Kerr nonlinearity and third order dispersion can also convert RIN to RF phase noise as seen in Fig. 7a; however, this is expected to be negligible — it is well below the white noise floor of the system.

With zero laser noise the conversion of a typical RF phase noise on the input signal before the modulator to RF phase and amplitude noise at the detector output is shown in Fig. 8. The RF phase noise out is not affected by Kerr nonlinearity and remains constant at different powers. Similarly, with zero laser noise the conversion of a typical RF amplitude noise on the input signal before the modulator to RF phase and amplitude noise at the detector output is shown in Fig. 9. The RF amplitude noise marginally decreases with increasing laser power, due to nonlinear squeezing effects. Third order dispersion converts RF amplitude noise to RF phase noise, which is less than other sources of RF phase noise in the system, and as the amplitude noise is gain clamped by the saturable gain of the loop, is not expected to be large at low frequencies.

V. Conclusion

We are conducting a systematic investigation of the optical domain portion of OEOs with a view to modeling major optical processes that contribute to length-dependent RF phase noise. To date we have investigated the effects of dispersion and nonlinearity on both the large signal and noise in the OEO optical path. As has been previously demonstrated, dispersion converts laser frequency noise to RF phase noise; however, experiments have indicated that this is not the only source of length-dependent noise and the noise increases nonlinearly with the optical power. We have found that the Kerr nonlinearity of the fiber was not the cause of this observed nonlinear length-dependent RF phase noise. In the future we plan to theoretically investigate other possible nonlinear amplification processes in the fiber, in particular Brillouin and Rayleigh effects.

***Abstract*— We report on a study of hyper-parametric oscillation in high-Q calcium fluoride and magnesium fluoride optical microresonators, and show that, magnesium fluoride microresonators generate wider Raman-free Kerr frequency combs at telecom wavelengths, in contrast with calcium fluoride ones. We observed 30 nm wide frequency combs in magnesium fluoride microresonators pumped with only 2 mW of continuous wave 1543 nm light.**

I. Introduction

Optically pumped solid state microresonators allow generating optical frequency combs resulting from four-wave mixing (FWM) in the resonator host material (frequently dubbed as Kerr combs) [1]-[11]. The efficiency of the FWM process depends on group velocity dispersion (GVD) and the thermo-refractive properties of the resonator modes. Anomalous GVD as well as small thermo-refractivity is desirable for generation of octave-spanning Kerr combs [8]. On the other hand, stable frequency combs are also produced in resonators possessing normal GVD [2], [3], [12]. In this work we discuss results of our recent efforts on optimization of the resonator morphology and host material selection for generation of stable Kerr combs at telecom wavelengths. We have compared optical combs generated in calcium (CaF_2) and magnesium (MgF_2) fluoride whispering gallery mode (WGM) resonators. The resonators are characterized with the opposite signs of GVD at 1543 nm. We found that the Kerr comb generation in magnesium fluoride resonators suffer less from the stimulated Raman [13], [14] as well as Brillouin [15], [16] scattering, compared to the comb generation in calcium fluoride WGM resonators. The power efficiency of the comb generation in MgF_2 WGM resonators is also superior.

II. Kerr combs in MgF_2 resonators

Generation of Kerr frequency combs usually starts with so called hyper-parametric oscillation resulting from conversion of two pump photons into two Stokes and anti-Stokes photons [12]. Having competing hyper-parametric oscillation [17], [18] and Raman lasing [13], [14] is an undesirable feature in the Kerr comb generators. Usage of a resonator host material possessing anomalous GVD is one of the ways for suppressing Raman lasing, since the anomalous GVD relaxes phase matching conditions required for the efficient comb generation, and the threshold of the hyper-parametric oscillation becomes lower than that of Raman lasing. The resonator host material also should have a low thermo-refractive constant to reduce related low frequency instabilities. We found that magnesium fluoride possesses both of these properties. In addition, crystalline MgF_2 features an excellent mechanical stability, hardness, and optical transparency, making it promising for production of very high-Q WGM microresonators [19], [20], [21], [22], [23]. Resonators made with MgF_2 are attractive because they allow dual mode thermal stabilization that can lead to stable and power efficient RF oscillators without any atomic frequency references involved [24].

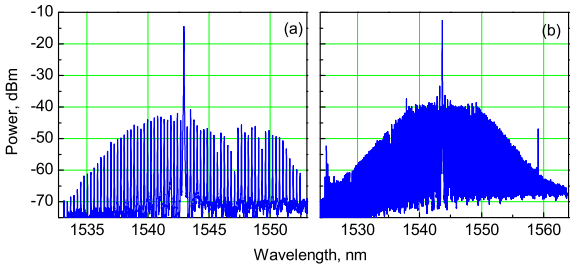

Fig. 1. (a) and (b) Spectra of optical frequency combs generated in two different MgF_2 whispering gallery mode microresonators pumped with approximately 2 mW of continuous wave light. The combs have 34.7 GHz (a) and 27 GHz (b) repetition rates corresponding to the FSR of the resonators. No SRS is observed.

We have demonstrated an optical frequency comb generated in MgF_2 WGM resonators characterized with 34.7 GHz and 27 GHz FSRs, and loaded Q-factor of about 10^9. The resonators were fabricated from a commercially available z-cut MgF_2 optical window by mechanical polishing. The shape of the resonators in the vicinity of mode localization was that of an oblate spheroid (with removed polar cups). One of the resonators (see Fig. (3)) was characterized with radius $a = 1$ mm, corresponding to 34.67 GHz free spectral range (FSR) of the fundamental mode family. The other resonator was characterized with radius $a = 1.27$ mm, corresponding to 27 GHz FSR of the fundamental mode family. The resonators were pumped optically using identical 1543 nm distributed feedback diode lasers self-injection locked [25] to WGM modes of the resonators. The locking occurred due to the intrinsic Rayleigh scattering in the resonators host material. The optical power emitted by the lasers was approximately 4 mW. The coupling efficiency of the pump light to the corresponding resonator mode was approximately 30%, while

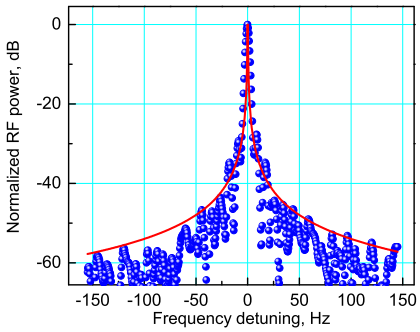

Fig. 2. Frequency spectrum of the RF signal produced by the 27 GHz frequency comb impinging (Fig. 1b) on a fast photodiode, and recorded using an RF spectrum analyzer (blue circles). The resolution bandwidth of the measurement and the span are 300 Hz. The instantaneous linewidth determined by fitting the skirts of the RF spectrum with a Lorentzian line (red solid line) is 0.4 Hz. The center frequency of the RF line is drifting in time determining the long term (in)stability of the signal resulting from the thermal drifts in the setup, while the instantaneous linewidth is a measure of the short term stability intrinsically determined by the oscillation process (see [25] and references therein). The measured RF carrier frequency is 27 GHz, and the corresponding frequency detuning is calculated from this frequency.

50% of the light exiting the resonators is collected into a multimode fiber coupled to an optical spectrum analyzer. An example of the observed frequency spectra of the generated combs is shown in Fig. 2. No stimulated Raman scattering (SRS) was observed with the resonators.

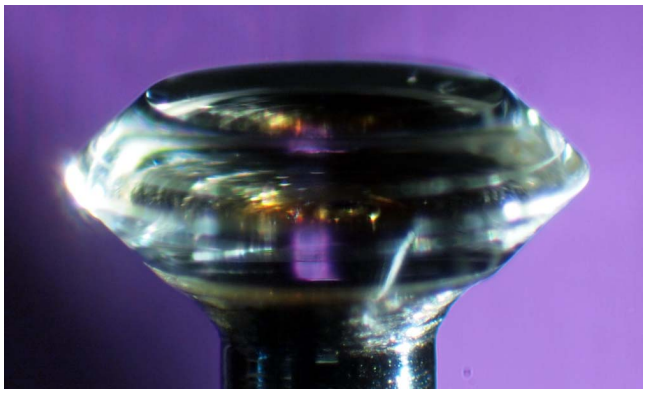

Fig. 3. A picture of MgF_2 resonator characterized with 34.7 GHz free spectral range on the manufacture post.

To our knowledge this is the most power-efficient, in terms of spectral width and pump power ratio, frequency comb generator reported so far (see Table I).

This is also the first demonstration of Kerr comb generation in an anisotropic crystalline material [29]. Our previous attempts to produce frequency combs in crystalline SiO_2, $LiNbO_3$, and $LiTaO_3$ WGM resonators were unsuccessful, even though those materials are characterized with large values of cubic nonlinearity and low values of optical attenuation that facilitate generation of Kerr combs. Fast cubic nonlinearity is approximately the same in transparent dielectrics

Material	Pump, mW,	Width, THz	Repetition, GHz
Silica [1]	130	63	895

TABLE I

PARAMETERS OF VARIOUS KERR COMBS.

with several exceptions. Nonlinear refractive index n_2 and corresponding XPM/SPM interaction constant g for various transparent materials is shown in Table II. Coupling parameter characterizing comb generation $g = \hbar\omega_0^2 n_2 c/(\mathcal{V} n_0^2)$ (where ω_0 is the frequency of the cw pumping light, n_0 is the linear refractive index of the material; see also [30]) is found for a resonator with mode volume $\mathcal{V} = 2 \times 10^{-7}$ cm^3 (1 mm mode radius, 3 μm radial mode depth, 10 μm mode height) pumped at 1,550 nm. Notations "o" and "e" stay for ordinary and extraordinary polarization of light. The results vary from research to research within 20% margin.

Data presented in Table 1 suggests that the four-wave mixing should have similar efficiency in the dielectrics provided that losses and phase matching conditions are identical. Some materials, like chalcogenide glasses and semiconductors have much larger nonlinearity. However, this nonlinearity is usually accompanied by nonlinear absorption that reduces the efficiency of the four-wave mixing.

TABLE II

CUBIC NONLINEARITY OF OPTICAL MATERIALS

We see the reason for this in the interplay of the not optimal GVD, leading to increase of the comb generation threshold, and the low enough threshold of the SRS, competing with the Kerr comb generation, in the materials. SRS results in the pump depletion suppressing Kerr comb generation. Kerr combs always have lower threshold compared with SRS in the MgF_2 WGM resonator we studied.

We studied the dependence of the comb optical spectrum on resonator loading, while keeping the laser current constant (Fig. 4). The detuning of the frequency of the pumping light from the corresponding optical resonance was kept as small as possible, though we did not control this parameter directly.

As expected, no comb was observed when the coupling prism touched the resonator surface and the loaded Q-factor became too small to support the comb generation. The loading was then decreased until hyper-parametric oscillation started and several spectral lines of the comb separated by almost a THz appeared. A further decrease of the resonator loading resulted in the reduction of the repetition rate and creation of higher density combs. After stabilization of the resonator loading, adjustment of the laser current produced stable Kerr frequency combs with desirable repetition rates and spectral shapes.

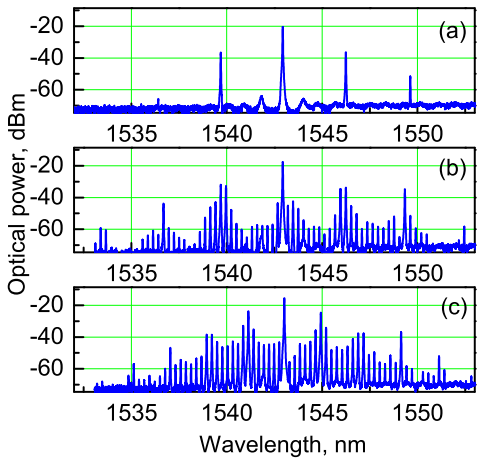

Fig. 4. Growth of the frequency comb generated in the MgF_2 resonator (FSR=34.67 GHz) pumped with cw light. The loading of the resonator decreases (the Q-factor increases) from (a) to (c). The comb with higher repetition rate is generated in the overloaded resonator. Increase of the loaded Q-factor results in filling the gaps between the modes. Finally the comb transforms to that in Fig. (1a).

III. Dynamics of the comb growth and its analysis

According to our experiments with WGM resonators characterized with anomalous GVD, Kerr frequency combs with higher frequency repetition rates have lower threshold compared with smaller repetition rate combs. To explain the observation and to find the dependence of the threshold conditions on the repetition rate we consider the case of two sidebands only and the pump (a model of a hyper-parametric oscillator [30]), and assume the power of generated sidebands is much smaller than the pump power. The set of equations linearized with respect to sidebands can be written as follows

$$\left[\Gamma_0 - ig|A|^2\right]A = F_0, \tag{1}$$

$$\dot{B}_+ = -\Gamma_+ B_+ + 2ig|A|^2 B_+ + igB_-^* A^2, \tag{2}$$

$$\dot{B}_-^* = -\Gamma_-^* B_-^* - 2ig|A|^2 B_-^* - igB_+(A^*)^2, \tag{3}$$

where $\Gamma_0 = i(\omega_0 - \omega) + \gamma_0$, $\Gamma_\pm = i(\omega_\pm - \tilde{\omega}_\pm) + \gamma_\pm$, F_0 stands for the cw pump amplitude; ω_0, ω_+, and ω_- are the eigenfrequencies of the modes; ω is the frequency of the pump, $\tilde{\omega}_+$ and $\tilde{\omega}_-$ are the frequencies of the generated sidebands. Decay rates γ_0, γ_+, and γ_- represent both coupling and internal losses. Due to the energy and photon number conservation we find $\tilde{\omega}_- + \tilde{\omega}_- = 2\omega$.

We introduce dimensionless variables $\xi = g|A|^2/\gamma_0$ where $A = |A|\exp i\phi_0$; $\mathcal{B}_+ = |B_+|/|A|$ where $B_+ = |B_+|\exp i\phi_+$; $\mathcal{B}_- = |B_-|/|A|$ where $B_- = |B_-|\exp i\phi_-$; $\psi = \phi_{F_0} - \phi_0$ where $F_0 = |F_0|\exp i\phi_{F_0}$; $\phi = 2\phi_0 - \phi_+ - \phi_-$; $\Delta_+ = (\omega_+ - \tilde{\omega}_+)/\gamma_0$; and $\Delta_- = (\omega_- - \tilde{\omega}_-)/\gamma_0$. Furthermore, we introduce $f = (g/\gamma_0)^{1/2}|F_0|/\gamma_0$, $\Delta_0 = (\omega_0 - \omega)/\gamma_0$, and $D = (2\omega_0 - \omega_+ - \omega_-)/\gamma_0$. For the sake of simplicity we assume $\gamma_\pm = \gamma_0$.

The characteristic equation for Eqs. (2) and (3) is

$$\begin{vmatrix} \lambda + 1 + i(\Delta_+ - 2\xi) & -i\xi e^{i\phi} \\ i\xi e^{-i\phi} & \lambda + 1 - i(\Delta_- - 2\xi) \end{vmatrix} = 0. \tag{4}$$

which has two solutions

$$\lambda_\pm = -1 \pm \frac{1}{2}\sqrt{4\xi^2 - (2\Delta_0 - D - 4\xi)^2} - \frac{i}{2}(\Delta_+ - \Delta_-). \tag{5}$$

The instability condition for the sidebands (oscillation condition) is

$$4(\xi^2 - 1) - (2\Delta_0 - D - 4\xi)^2 > 0 \tag{6}$$

where ξ is given by steady state solution of Eq. (1)

$$\xi\left[1 + (\Delta_0 - \xi)^2\right] = f^2. \tag{7}$$

Eq. (6) results in the threshold condition for the normalized amplitude of the pump field inside the resonator

$$\xi_\pm = \frac{1}{3}\left(2\Delta_0 - D \pm \sqrt{\frac{1}{4}(2\Delta_0 - D)^2 - 3}\right). \tag{8}$$

Since, by definition $\xi \geq 0$, we find $2\Delta_0 - D > 2\sqrt{3}$. In the case of anomalous GVD the pump mode can be dynamically stable (no bistability observed) and modulationally unstable [39]. The conditions are: $1 < f^2 < 8/(3\sqrt{3})$ and $\lambda_+ > 0$.

This analysis allows us to find the dependence of the preferred repetition rate of the comb on the loaded bandwidth of the resonator. In the experiment we kept the optical pump at the corresponding resonance, selecting $\Delta_0 = \xi$, and $\xi = f^2$ (Eq. (7)). The maximal gain (5) ($\lambda_+ = \xi - 1$) occurs when $D = -2\xi$. The value of D depends on the comb repetition rate and is a free parameter in our case. Since the oscillation threshold power corresponds to $\xi = f^2 = 1$ ($\lambda_+ > 0$), the hyper-parametric oscillation that eventually leads to Kerr frequency comb generation starts in the mode pair for which $D = -2$, or

$$\nu_{i+j} + \nu_{i-j} - 2\nu_i \simeq \gamma_{FWHM}. \tag{9}$$

where ν_i is the frequency of ith mode, and $\gamma_{FWHM} = 2\gamma_0$ is the full width at half maximum (FWHM) of the loaded resonance.

The condition (9) is valid for resonant tuning of the external pump and can be fulfilled only in the case of anomalous GVD [4]. The resonant tuning here is determined in terms of the optically pumped, not the "cold", resonator. Because the

modes are nonlinear, the SPM results in a shift of the optically pumped resonance when the optical pump power increases. To stay resonant, i.e. to maintain the maximal optical power within the resonator for a fixed power of the external pump, the pump frequency should be properly adjusted such that the condition $\Delta_0 = \xi$ is preserved.

The simplest theoretical model of the Kerr comb growth can be built based on the model described above of three-mode hyper-parametric oscillator [30]. Increase of the optical pump power above the oscillation threshold results in generation of the two preferable optical sidebands. Those sidebands beat with themselves and the pump light and produce higher order sidebands via the XPM effect. The threshold of the comb generation is determined by the threshold of the hyper-parametric oscillation, and the higher order sidebands are always phase locked to the lower order sidebands [12].

The comb repetition rate depends on the switching dynamics of the system. The hyper-parametric oscillations have the pump-power-dependent gain maximum. Generation of a higher frequency repetition rate comb is expected at the higher pump power [9]. This is a result based on the notion of compensation of the nonlinear phase shift by the anomalous GVD [4]. On the other hand, an adiabatic increase of the pump power results in broadening of the lower repetition rate frequency comb started at lower pump power. This process is stable if growth of the higher-order optical sidebands properly reduce the power of light confined within the optical mode.

Since the power level of the optical pumping used in our experiment is limited, the comb generation starts only when the Q-factor of the mode exceeds a certain level. The corresponding FWHM of the maximally overloaded mode is approximately 2 MHz. Calculating the GVD of the fundamental mode sequence using Sellmeier equation for MgF_2 (Fig. 5) we find that, according to (9), the lowest threshold is reached for the modes being at 0.6 THz from the carrier, which approximately corresponds to the comb observed in Fig. (4a) for the case of highest loading of the resonator. Reduction of the loading results in the reduction of the preferred comb repetition rate and to the growth of the comb at a single FSR as in Fig. (4b and 4c). The simplest three mode analysis [30] cannot explain this process, and numerical methods [39] should be applied.

We did not observe nonlinear processes other than four-wave mixing in MgF_2 resonators. It does not mean that the processes are absent there. The most probable reason is that the four wave mixing dominates at the wavelength and power levels of the pumping light as well as the WGM resonator size and shape we utilized. The spectrum of the observed nonlinear phenomena is much broader in the case of CaF_2 resonators. In what follows we discuss two cases of competition of the comb generation process with SRS and SBS processes.

IV. Competition of Kerr combs and SRS in CaF_2 resonators

GVD depends on the size of the resonator and the wavelength of the pumping light, so there is an optimal combination

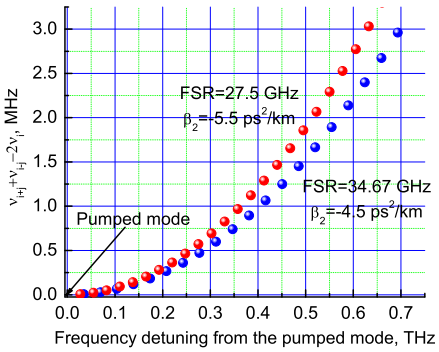

Fig. 5. GVD of the WGM spectrum found in terms of frequency difference $\nu_{i+j} + \nu_{i-j} - 2\nu_i$, where i is the azimuthal number of the pumped mode ($i = 5,548$ in the case of the resonator with 36.67 GHz FSR). The FSR of the resonator is defined as $\nu_{FSR} = \nu_i - \nu_{i-1} = 34.67$ GHz. The optical pump is extraordinarily polarized with respect to the crystalline axis (electric filed vector is collinear with the resonator axis and the symmetry axis of the crystal). The estimated value of GVD of the modes of the resonator with 36.67 GHz FSR is $\beta_2 = -(\nu_{i-1} + \nu_{i+1} - 2\nu_i)(n_e/2\pi c\nu^2_{FSR}) = -4.5$ ps^2/km, where $n_e = 1.38$ is the extraordinary index of refraction of the material, c is the speed of light in the vacuum. Similar calculations can be done for the resonator with 27 GHz FSR.

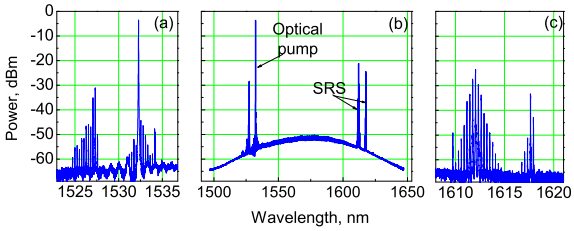

Fig. 6. Competition of stimulated Raman scattering (SRS) and hyper-parametric oscillation in a fluorite microresonator. (b) Optical spectrum generated in a CaF_2 resonator having 34.6 GHz FSR, and pumped with 1 mW of continuous wave 1532 nm light. (a) and (c) show details of the spectrum. The observed SRS is more efficient than the hyperparametric oscillation process. Nonlinear interaction of the Stokes Raman comb with the carrier results in generation of "anti-Stokes" sidebands in the vicinity of the carrier as well as the second lower frequency manifold of the Raman comb. It worth noting that the manifold also experiences Raman gain since the Raman line is broad enough.

of those parameters for Kerr comb generation. For instance, CaF_2 WGM resonators demonstrate generation of Raman-free, stable, and wide enough Kerr fundamental combs with repetition rates around 10 GHz and centered at 1550 nm, in the vicinity of zero GVD point of the material [12]. On the other hand, SRS [13] becomes preferable in smaller CaF_2 resonators (35 GHz FSR) pumped at 1532 nm, and phase locked Raman frequency combs are readily observed there [14]. One of the reasons is that the GVD of CaF_2 is normal in the resonators at 1532 nm, while it is nearly zero at the Raman wavelength. The resonator prefers to oscillate at smaller normal FSR.

An example of competition of the FWM and SRS processes in those resonators is illustrated by Fig. (6). Raman Stokes line is generated as a dual frequency comb around 1611 nm.

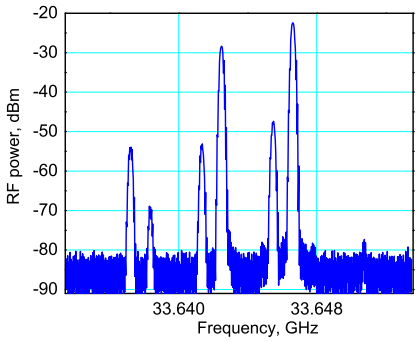

Fig. 7. Microwave spectrum generated by the optical signal shown in Figure 6 on a fast photodiode. The existence of the RF lines possessing different frequencies can be explained by the different values of the FSR at different optical wavelengths. FSR is about 4 MHz smaller at the carrier wavelength (1532 nm) than at the Raman wavelength (1611 nm). This is verified by using an optical high-pass filter. The repetition rates of the combs are determined by the different FSR values.

At the same time the Kerr comb is generated around the optical pump line (1532 nm). FWM of the Raman combs and pumping light results in generation of an anti-Stokes frequency comb in the vicinity of the pump line, as in dual-pump fiber-optic parametric amplifiers [40]. To verify the phase locking feature of the generated optical combs we sent them to a fast photodiode and found that the combs produce several narrow RF signals separated by several MHz, Fig. (7).

V. Competition of Kerr combs and SBS in CaF_2 resonators

Stimulated Brillouin scattering (SBS) is usually forbidden in solid state ring microresonators with high quality factors. The reason for this is the phase mismatch between the optical phonons and light. If the pump light is resonant with a mode of the resonator, the scattered light has no optical mode to interact with. Moreover, if occasionally such a mode is present, the overlap integral between the acoustic mode as well as the pump and Stokes optical modes tends to be zero. The absence of SBS in optical microresonators is used as an advantage in studies of weaker nonlinear effects such as four wave mixing and stimulated Raman scattering. On the other hand, it is interesting to understand for which morphology as well as dimensions of the microresonators the SBS is not forbidden. An SBS laser based on a microresonator should possess a low threshold as well as narrow linewidth.

A triply-resonant SBS was demonstrated recently in over-moded WGM resonators [15], [16]. Since the enhanced SBS uses bulk, not surface, acoustic modes, the observed SBS frequency was given by the properties of the resonator host material, and shape of the resonator was less important. Due to the high absorption of the hypersound waves the finesse of the acoustic "mode" can be less than one, which simplified phase matching of the process.

We observed interplay between SBS and four-wave mixing in an overmoded CaF_2 resonator pumped with 1550 nm light (Figure 8a). Because we studied only the light scattered in the forward direction, we have observed pronounced second order SBS harmonic. The first order harmonic was visible due to Rayleigh scattering within the resonator modes. The Anti-Stokes line was generated due to four-wave mixing process. All three generated harmonics are phase locked with the pump light, since they produce single RF tone at the fast photodiode (Figure 8b). The locking occurs due to four-wave mixing.

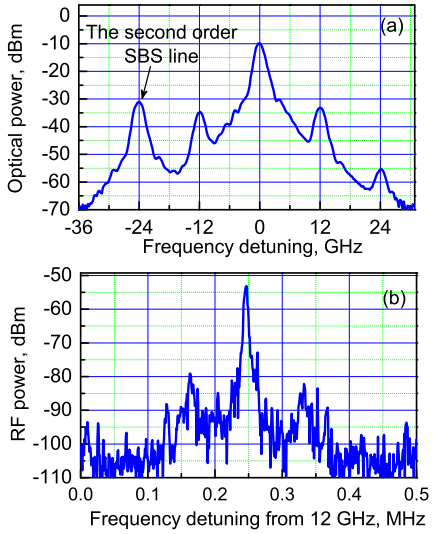

Fig. 8. (a) Optical signal resulting from the competing stimulated Brillouin scattering (SBS) and four wave mixing in a CaF_2 WGM resonator. The resonator is pumped at 1550 nm. The frequency of the SBS Stokes line is 12.1 GHz. (b) RF signal produced by the optical signal on a fast photodiode.

The Brillouin frequency shift for the case of backscattering along the axis of a cubic crystal can be found approximately as

$$\Delta\nu_B = \frac{2n_0}{\lambda_0}\sqrt{\frac{C_{11}+C_{12}+2C_{44}}{2\rho}}. \qquad (10)$$

where $n_0 = 1.424$ is the refractive index of the material at $\lambda_0 = 1550$ nm, $\rho = 3.18$ g/cm^3 is the density of the material. Calcium fluoride is a cubic crystal described by three independent elastic constants: $C_{11} = 1.6420$, $C_{12} = 0.4398$, $C_{44} = 0.3370$ [$\times 10^{11}$ Pa]. Substituting these values into Eq. (10) we find $\Delta\nu_B \simeq$ 12.1GHz. Further analysis shows that the polarization of the phonons is nearly collinear with their wave vector in the case of the highest–frequency branch. Hence, the observed SBS process results from the interaction of light and longitudinal hypersound wave.

VI. Conclusion

We have observed very efficient generation of Kerr frequency combs in optically pumped magnesium fluoride whispering gallery mode resonators and found that the resonators are free from the undesirable competition of the four-wave

mixing and Raman as well as Brillouin stimulated scattering observed in calcium fluoride resonators under similar conditions. The MgF_2 kerr comb generators are useful for spectroscopy, production of spectrally pure RF signals, and for generation of nonclassical states of light.

***Abstract*— Atom interferometers allow the measurement of the acceleration of freely falling atoms with respect to an experimental platform at rest on Earth's surface. Such experiments have been used to test the universality of free fall by comparing the acceleration of the atoms to that of a classical freely falling object. In a recent paper, Müller, Peters and Chu [Nature 463, 926-929 (2010)] argued that atom interferometers also provide a very accurate test of the gravitational redshift (or universality of clock rates). Considering the atom as a clock operating at the Compton frequency associated with the rest mass, they claimed that the interferometer measures the gravitational redshift between the atom-clocks in the two paths of the interferometer at different values of gravitational potentials. In the present paper we analyze this claim in the frame of general relativity and of different alternative theories, and conclude that the interpretation of atom interferometers as testing the gravitational redshift at the Compton frequency is unsound. The present work is a summary of our extensive paper [Wolf *et al.*, arXiv:1012.1194, Class. Quant. Grav. in press], to which the reader is referred for more details.**

I. Introduction

The gravitational redshift, considered as one of the "classical tests" of general relativity (GR), is actually a test of one facet of the Einstein equivalence principle (EEP). The weak version of the equivalence principle has been verified with high precision using torsion balances [1] and Lunar laser ranging [2]. The gravitational redshift was predicted by Einstein but not observed for a long time. It became observable with the advent of high precision quantum spectroscopy and was first measured in 1960 by Pound and Rebka [3], who used gamma ray spectroscopy of the radiation emitted and absorbed by ^{57}Fe nuclei. The emitter and absorber were placed at the top and bottom of a $22.5\,\mathrm{m}$ high tower at Harvard and the frequency difference predicted by GR was measured with about 1% uncertainty.

In a test of the gravitational redshift using clocks, one checks that the clock rates are universal — i.e. the relative rates depend only on the difference of gravitational potentials (as determined by the trajectories of massive test bodies) but not on the nature and internal structure of the clocks. In 1976 a hydrogen-maser clock was launched on a rocket to an altitude of $10,000\,\mathrm{km}$ and its frequency compared to a similar clock on ground. This yielded a test of the gravitational redshift with about 10^{-4} accuracy [4]. The European Space Agency will fly in 2013 the Atomic Clock Ensemble in Space (ACES) [5], including a highly stable laser-cooled atomic clock, which will test (in addition to many other applications in fundamental physics and metrology) the gravitational redshift to a precision of about 10^{-6}. The gravitational redshift is also tested in null redshift experiments in which the rates of different clocks (based on different physical processes or different atoms) are compared to each other [6].

Quite generally in a modern context, tests of GR measure the difference between the predictions of GR and of some generalized alternative theory or theoretical framework (see [7] for a review). It has to be kept in mind that the classification and inter-comparison of different tests have then to be defined with respect to the framework used.

Atom interferometers have reached high sensitivities in the measurement of the gravitational acceleration [8], [9]. This yields very important tests of the weak equivalence principle (WEP) or universality of free fall (UFF) when comparing the free fall of atoms with that of classical macroscopic matter (in practice a nearby freely falling corner cube whose trajectory is monitored by lasers). The relative precision of such tests of the UFF is currently 7×10^{-9}, using Cs [8], [10] or Rb [9] atoms. Although it remains less sensitive than tests using macroscopic bodies of different composition [2], [1] which have reached a precision of 2×10^{-13}, this UFF test is interesting as it is the most sensitive one comparing the free fall of quantum objects (namely Cæsium atoms) with that of a classical test mass (the corner cube). In this contribution, which summarizes the extensive paper [11], we investigate whether such experiments can also be interpreted as tests of the gravitational redshift.

II. Overview of our extensive paper [11]

In a recent paper, Müller, Peters and Chu [10] (hereafter abbreviated as MPC) proposed a new interpretation of atom interferometry experiments as testing the gravitational redshift, that is also the universality of clock rates (UCR), with a precision 7×10^{-9}, which is several orders of magnitude better than the best present [4] and near future [5] clock tests.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

A. Analogy with clock experiments

The main argument of MPC (see also the more detailed papers [12], [13]) is based on an analogy between atom interferometry experiments and classical clock experiments. The idea of clock experiments is to synchronize a pair of clocks when they are located closely to one another, and move them to different elevations in a gravitational field. The gravitational redshift will decrease the oscillation frequency of the lower clock relative to the higher one, yielding a measurable phase shift between them. There are two methods for measuring the effect. Either we bring the clocks back together and compare the number of elapsed oscillations, or we measure the redshift by means of continuous exchanges of electromagnetic signals between the two clocks. In both methods one has to monitor carefully the trajectories of the two clocks. For example, in the second method one has to remove the Doppler shifts necessarily appearing in the exchanges of electromagnetic signals.

In the first method, the phase difference between the two clocks when they are recombined together, can be written as a difference of integrals over proper time,

$$\Delta\varphi_{\rm clock} = \omega \left[\int_{\rm I} {\rm d}\tau - \int_{\rm II} {\rm d}\tau \right] \equiv \omega \oint {\rm d}\tau \,. \qquad (1)$$

The two clocks have identical proper frequency ω. We denote by I and II the two paths (with say I being at a higher altitude, i.e. a lower gravitational potential) and use the notation $\oint {\rm d}\tau$ to mean the difference of proper times between the two paths, assumed to form a close contour. The integrals in (1) are evaluated along the paths of the clocks, and we may use the Schwarzschild metric to obtain an explicit expression of the measured phase shift in the gravitational field of the Earth.

The phase shift measured by an atom interferometer contains a contribution which is similar to the clock phase shift (1), so it is tempting to draw an analogy with clock experiments. In this analogy, the role of the clock's proper frequency is played by the atom's (de Broglie-)Compton frequency $\omega_{\rm C} = mc^2/\hbar$, where m denotes the rest mass of the atom. However the phase shift includes also another contribution $\Delta\varphi_\ell$ coming from the interaction of the laser light used in the beam-splitting process with the atoms. Thus,

$$\Delta\varphi = \omega_{\rm C} \oint {\rm d}\tau + \Delta\varphi_\ell \,. \qquad (2)$$

Here we are assuming that the two paths close up at the entry and exit of the interferometer; otherwise, additional terms have to be added to (2). The schematic view of the atom interferometer showing the two interferometer paths I and II is given by Fig. 1. The first term in (2) is proportional to the atom's mass through the Compton frequency and represents the difference of Compton phases along the two classical paths. In contrast, the second term $\Delta\varphi_\ell$ does not depend on the mass of the atoms.

At first sight, the first term in (2) could be used for a test of the gravitational redshift, in analogy with classical clock experiments, and the precision of the test could be very good,

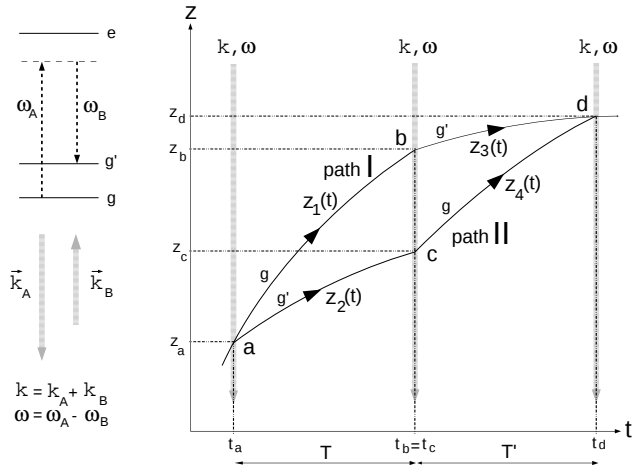

Fig. 1. Space-time trajectories followed by the atoms in the interferometer. Laser pulses occur at times t_a, $t_b = t_c$ and t_d, separated by time intervals T and T' (we have $T' = T$ when gravity gradients are neglected). The two-photon Raman transitions are between two hyperfine levels g and g' of the ground state of an alkali atom.

because the Compton frequency of the Cæsium atom is very high, $\omega_{\rm C} \approx 2\pi \times 3.0 \times 10^{25}\,$Hz. However, as shown in a previous brief comment [14] and the detailed paper [11], this re-interpretion of the atom interferometer as testing the UCR is fundamentally incorrect.[1]

At this point, we want to mention other crucial differences between atom interferometry and clock experiments, which reinforce our conclusions. In clock experiments the trajectories of the clocks are continuously controlled for instance by continuous exchange of electromagnetic signals. In atom interferometry in contrast, the trajectories of the atoms are not measured independently but theoretically derived from the Lagrangian and initial conditions. Furthermore, we expect that it is impossible to determine independently the trajectories of the wave packets without destroying the interference pattern at the exit of the interferometer.

Another important difference lies in the very notion of a clock. Atomic clocks use the extremely stable energy difference between two internal states. By varying the frequency of an interrogation signal (e.g. microwave or optical), one obtains a resonant signal when the frequency is tuned to the frequency of the atomic transition. In their re-interpretation, MPC view the entire atom as a clock ticking at the Compton frequency associated with its rest mass. But the "atom-clock" is not a real clock in the previous sense, since it does not deliver a physical signal at Compton frequency, as also recently emphasized in the same context in [16].

Note also that the phase shift (1) for clocks is valid in any gravitational field, with any gravity gradients, since it is simply the proper time elapsed along the trajectories of the clocks in

[1] See also the reply of MPC [15] to our brief comment. After completion of our work [14], [11], several independent analysis have appeared [16], [17] supporting our views and consistent with our conclusions.

a gravitational field. By contrast, the phase shift (2) is known only for quadratic Lagrangians [18] and cannot be applied in a gravitational field with large gravity gradients, or more generally with any Lagrangian that is of higher order.

B. Analysis in general relativity

The clear-cut argument showing that the atom interferometer does not measure the redshift is that the "atom-clock" contribution, i.e. the first term in (2), is in fact *zero* for a closed total path [18], [19]. As a specific example, let us consider the prediction from GR, which has been extensively treated in [20]; here we only present a very basic analysis sufficient for our purposes. The appropriate Lagrangian is given by the proper time $\mathrm{d}\tau = (-g_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu/c^2)^{1/2}$, i.e. $L_{\text{GR}} = -mc^2\mathrm{d}\tau/\mathrm{d}t$, and is derived to sufficient accuracy using the Schwarzschild metric generated by the Earth,

$$L_{\text{GR}}(z,\dot{z}) = -mc^2 + \frac{GMm}{r_\oplus} - mgz + \frac{1}{2}m\dot{z}^2\,, \qquad (3)$$

where $r_\oplus$ is the Earth's radius, $g = GM/r_\oplus^2$ is the Newtonian gravitational acceleration, G is Newton's gravitational constant, M is the mass of the Earth, m the mass of the atom, c the speed of light in vacuum, z is defined by $r = r_\oplus + z$ with r the radial coordinate, and we neglect the post-Newtonian corrections. For simplicity we restrict ourselves to only radial motion, which is sufficient for the arguments in this paper.

The equations of motion are deduced from (3) using the principle of least action or the Euler-Lagrange equations, and read evidently $\ddot{z} = -g$. Then, when integrating (3) along the resulting paths, and calculating the difference of action integrals $\Delta\varphi_S$ as defined by the first term in (2), one finds

$$\Delta\varphi_S = 0\,. \qquad (4)$$

The key point about the result (4) is a consistent calculation of the two paths in the atom interferometer and of the phases along these paths, both derived from the same classical action, using in a standard way the principle of least action. At the deepest level, the principle of least action and its use in atom interferometry comes from the Feynman path integral formulation of quantum mechanics or equivalently the Schrödinger equation [18]. Thus only the second term $\Delta\varphi_\ell$ remains in (2). The final phase shift,

$$\Delta\varphi = \Delta\varphi_\ell = k\,g\,T^2\,, \qquad (5)$$

depends on the wavevector k of the lasers, on the interrogation time T and on the local gravity g. This shows that the atom interferometer is a gravimeter or accelerometer. The phase shift (5) arises entirely from the interactions with the lasers and the fact that the atoms are falling with respect to the laboratory in which the experiment is performed. The atom's Compton frequency is irrelevant.

C. Analysis in the modified Lagrangian formalism

This framework, which we call the "modified Lagrangian formalism", is an adaptation for our purpose of a powerful formalism for analyzing tests of the EEP and its various facets: the WEP, the local Lorentz invariance (LLI) and the local position invariance (LPI) [21], [22], [7]. This formalism allows deviations from general relativity and metric theories of gravity, with violations of the UFF and UCR, and permits a coherent analysis of atom interferometry experiments.

The formalism is defined by a single Lagrangian, that is however different from the GR Lagrangian. For our purposes it is sufficient to use a strongly simplified "toy" Lagrangian chosen as a particular case within the "energy conservation formalism" of Nordtvedt and Haugan [21], [22] (see [7] for a review). To keep in line with MPC we choose an expression similar to the Lagrangian of GR given by (3), namely

$$L_{\text{modified}} = -m_0\,c^2 + \frac{GMm_0}{r_\oplus} - \left(1+\beta_X^{(a)}\right) m_0\,g\,z + \frac{1}{2}m_0\,\dot{z}^2\,, \qquad (6)$$

where $\beta_X^{(a)}$ denotes a dimensionless parameter characterizing the violation of LPI, and depending on the particular type X of mass-energy or interaction under consideration; e.g. $\beta_X^{(a)}$ would be different for the electromagnetic or the nuclear interactions, with possible variations as a function of spin or the other internal properties of the atom, here labelled by the superscript (a). Thus $\beta_X^{(a)}$ would depend not only on the type of internal energy X but also on the type of atom (a).

The Lagrangian (6) describes the Newtonian limit of a large class of non-metric theories, in a way consistent with Schiff's conjecture and fundamental principles of quantum mechanics. Most alternative theories commonly considered belong to this class which encompasses a large number of models and frameworks (see [7] and references therein), like most non-metric theories (e.g. the Belinfante-Swihart theory [23]), some models motivated by string theory [24], some general parameterized frameworks like the energy conservation formalism [21], [22], the TH$\varepsilon\mu$ formalism [25], and the Lorentz violating standard model extension (SME) [26], [27].

Within this general formalism there is no fundamental distinction between UFF and UCR tests, as violation of one implies violation of the other, thus testing one implies testing the other. Depending on the theory used, different experiments test different parameters or parameter combinations at differing accuracies, so they may be complementary or redundant depending on the context. By varying (6) we obtain the equations of motion of the atom as

$$\ddot{z} = -\left(1+\beta_X^{(a)}\right) g\,, \qquad (7)$$

which shows that the trajectory of the atom is affected by the violation of LPI and is not universal. In fact we see that $\beta_X^{(a)}$ measures the non-universality of the ratio between the atom's passive gravitational mass and inertial mass. Thus, in the modified Lagrangian framework the violation of LPI implies a violation of WEP and the UFF, and $\beta_X^{(a)}$ appears to be the UFF-violating parameter. This is a classic example [21], [22] of the validity of Schiff's conjecture, namely that it is impossible in any consistent theory of gravity to violate LPI (or LLI) without also violating WEP.

The violation of LPI is best reflected in classical redshift experiments with clocks which can be analysed using a cyclic

gedanken experiment based on energy conservation [21], [22], [7]. The result for the frequency shift in a Pound-Rebka type experiment is

$$Z = \left(1 + \alpha_X^{(a)}\right) \frac{g\,\Delta z}{c^2}\,, \tag{8}$$

where the redshift violating (or UCR violating) parameter $\alpha_X^{(a)}$ is again non-universal. The important point, proven in [21], [22], [7], is that the UCR-violating parameter $\alpha_X^{(a)}$ is related in a precise way to the UFF-violating parameter $\beta_X^{(a)}$, namely

$$\beta_X^{(a)} = \alpha_X^{(a)}\, \frac{\overline{E}_X}{\overline{m}\, c^2}\,, \tag{9}$$

where $\overline{E}_X$ is the internal energy responsible for the violation of LPI, and $\overline{m}$ is the sum of the rest masses of the particles constituting the atom. Therefore we can compare the different qualitative meaning of tests of UCR and UFF. For a given set of UFF and UCR tests their relative merit is given by (9) and is dependent on the model used, i.e. the type of anomalous energy $\overline{E}_X$ and its dependence on the used materials or atoms.

We now consider the application to atom interferometry. In the experiment of [8], [10] the "atom-clock" that accumulates a phase is of identical composition to the falling object (the same atom), hence one has to consistently use the same value of $\beta_X^{(a)}$ when calculating the trajectories and the phase difference using the Lagrangian (6). It is then easy to show that $\Delta\varphi_S = 0$ with the above Lagrangian [18], [20], [28]. The vanishing of $\Delta\varphi_S$ in this case is a general property of all quadratic Lagrangians and comes from consistently using the same Lagrangian for the calculation of the trajectories and the phase shift. It is related to the cancellation between the kinetic term and the gravitational potential energy term in the Lagrangian (6).

Then the total phase shift of the atom interferometer is again given by the light interactions only, which are obtained from the phases at the interaction points evaluated using the trajectory given by (6). One then obtains

$$\Delta\varphi = \Delta\varphi_\ell = \left(1 + \beta_X^{(a)}\right) k\, g\, T^2\,. \tag{10}$$

We first note that in this class of theories the Compton frequency plays no role, as $\Delta\varphi_S = 0$. Second, we note that although $\beta_X^{(a)}$ appears in the final phase shift, this is entirely related to the light phase shift coming from the trajectory of the atoms, and thus is a measurement of the effective free fall acceleration $(1+\beta_X^{(a)})g$ of the atoms, which is given by (7). In [8], [10] the resulting phase shift is compared to $k\,\tilde{g}\,T^2$ where $\tilde{g}$ is the measured free fall acceleration of a falling macroscopic corner cube, i.e. $\tilde{g} = \left[1 + \beta_X^{(\text{corner cube})}\right] g$, also deduced from (7). In this class of theories the experiment is thus a test of the UFF, as it measures the differential gravitational acceleration of two test masses (Cæsium atom and corner cube) of different internal composition, with precision

$$\left|\beta_X^{(\text{Cs})} - \beta_X^{(\text{corner cube})}\right| \lesssim 7 \times 10^{-9}\,. \tag{11}$$

Note that this expression is equivalent to the one obtained by MPC in their recent paper [13] (p. 4), but different from the one obtained in the same paper (p. 3) for UCR tests.[2]

D. Analysis in the multiple Lagrangian formalism

In the second framework, which we call the "multiple Lagrangian formalism", the *motion* of test particles (atoms or macroscopic bodies) obeys the standard GR Lagrangian in a gravitational field, whereas the *phase* of the corresponding matter waves obeys a *different* Lagrangian. The MPC analysis in [10] belongs to this framework,[3] which raises extremely difficult problems.

The WEP is assumed to be valid for the motion of massive classical particles which thus obeys the standard Lagrangian of general relativity, $L_{\text{particle}} = L_{\text{GR}}$, i.e. to first order

$$L_{\text{particle}} = -m\,c^2 + \frac{GMm}{r_\oplus} - m\,g\,z + \frac{1}{2} m \dot{z}^2\,. \tag{12}$$

On the other hand the action integral to be used for the computation of the phase shift of the quantum matter wave is assumed to be calculated from the different Lagrangian

$$L_{\text{wave}} = -m\,c^2 + \frac{GMm}{r_\oplus} - (1+\beta) m\,g\,z + \frac{1}{2} m \dot{z}^2\,, \tag{13}$$

where the parameter β that measures the deviation from GR (i.e. $\beta = 0$ in GR) enters as a correction in the atom's gravitational potential energy. Integrating the Lagrangian (13) along the paths given by the Lagrangian (12) shows that $\Delta\varphi_S = \beta\, k\, g\, T^2$, where β takes the meaning of a redshift-violation parameter. In particular we notice that β could be "universal", in contrast with the parameter $\beta_X^{(a)}$ in (6) which depends on the type of atom (a) and on some internal energy X violating LPI. In the multiple Lagrangian formalism, because WEP is valid we can always test the value of β by comparing g as obtained from the free-fall of test bodies, to the phase difference cumulated by matter waves (as proposed by MPC [10]).

The most important problem of this formalism is that it is inconsistent to use a different Lagrangian (or metric) for the calculation of the trajectories and for the phases of the atoms or clocks. More precisely, it supposes that the fundamental Feynman path integral formulation of quantum mechanics, which is at the basis of the derivation of the phase shift in an atom interferometer [18], has to be altered in the presence of a gravitational field or could be wrong. Physically it amounts to making the distinction between the atoms when calculating their trajectories and the same atoms when calculating their phases, which is inconsistent as it

[2] In [13] atom interferometer tests set limits on the same parameter combination as classical UFF tests, namely $\beta_1 + \xi_1^{\text{bind}} - \beta_2 - \xi_2^{\text{bind}}$ ([13], p. 4), where the subscripts refer to test masses 1 and 2 (e.g. $1 =$ Cs and $2 =$ falling corner cube in [8] whilst $1 =$ Ti and $2 =$ Be in [1]), and ξ^{bind} refers to the nuclear binding energy of the test masses. On the other hand UCR tests in [13] set limits on either $\beta_1 - \xi_2^{\text{trans}}$ or $\xi_1^{\text{trans}} - \xi_2^{\text{trans}}$ ([13], p. 3), where ξ^{trans} is related to the atomic transition of the atom used in the clock and not to its nuclear binding energy.

[3] See "Methods" in [10], where they consider two scenarios. The first one clearly states that the trajectories are not modified whilst the atomic phases are. The second uses g' for the trajectories and $g(1+\beta)$ for the phases, which again corresponds to two different Lagrangians.

is the same fundamental matter field in both cases. Even more, the basis for the derivation of the atom interferometry phase shifts is unjustified because the Feynman formalism is violated. To remain coherent some alternative formalism for the atomic phase shift calculations (presumably modifying quantum mechanics) should be developed and used. More generally the multiple Lagrangian formalism supposes that the duality between particles and waves in quantum mechanics gets somehow violated in a gravitational field.

The above violation of the "particle-wave duality", implied by the multiple Lagrangian formalism, is very different from a violation of the equivalence principle in the ordinary sense. In this formalism a single physical object, the atom, is assumed to be described by two different Lagrangians, L_{wave} applying to its phase shift, and L_{particle} applying to its trajectory. By contrast, in tests of the equivalence principle, one looks for the modification of the free fall trajectories or clock rates as a function of composition or clock type. Thus, different bodies or clocks are described by different Lagrangians, but of course for any single type of body we always have $L_{\text{wave}} = L_{\text{particle}}$. The pertinent test-bed for equivalence principle violations is the modified Lagrangian formalism reviewed in Section II-C, which does not imply any particle-wave duality violation.

The second problem of theories in the multiple Lagrangian formalism and of the interpretation of MPC is the violation of Schiff's conjecture [29]. Indeed, we have assumed in this Section that the LPI aspect of the equivalence principle is violated but that for instance the WEP aspect remains satisfied. In a complete and self-consistent theory of gravitation one expects that the three aspects of the Einstein equivalence principle (WEP, LLI and LPI) are sufficiently entangled together by the mathematical formalism of the theory that it is impossible to violate one without violating all of them. The Schiff conjecture has been proved using general arguments based upon the assumption of energy conservation [21], [22]; it is satisfied, for instance, in the TH$\varepsilon\mu$ formalism [25]. A contrario, we expect that violating the conjecture leads to some breakdown of energy conservation. In the present case this translates into postulating two Lagrangians (12) and (13) for the same physical object. Explicit theories that are logically and mathematically consistent but still violate Schiff's conjecture are very uncommon (see [7] and references therein).

We conclude that the general statement of MPC according to which the atom interferometer measures or tests the gravitational redshift at the Compton frequency is incorrect. Instead, the interpretation of the experiment needs to be considered in the light of alternative theories or frameworks. Although one can consider particular alternative frameworks in which the statement of MPC could make sense, such frameworks raise unacceptable conceptual problems which are not at the moment treated in a satisfactory manner. In particular, they break the fundamental principles of quantum mechanics which are used for calculating matter wave phases. In most common and plausible theoretical frameworks the atom interferometry experiment tests the universality of free fall with the Compton frequency being irrelevant.

***Abstract*— We present our cold atom interferometer using ^{87}Rb developed to perform absolute g measurement similar to the Stanford experiment [1] which used Cs. The device and the measurement protocol are described and an example of 12 days continuous measurement is presented. This measurement shows the capabilities of the instrument in the frame of a watt balance experiment, avoiding the use of environmental models to extrapolate the accurate value of g needed to link the Planck constant to the kilogram [2]. Limits in terms of sensitivity and accuracy are finally presented.**

I. Introduction

Based on techniques used on atomic clocks at LNE-SYRTE, we use atom interferometry to perform an absolute measurement of the gravitational acceleration g with ^{87}Rb free falling atoms [3]. Mainly used by geophysicists, absolute gravimeters allow geodesists to determine the distance between the geoid and the referential ellipsoid. Since the end of 80's and the proposition of Brian Kibble [4], absolute gravimeters are involved in fundamental metrology in the frame of watt balance experiments, participating in the kilogram redefinition and in which an absolute g determination is needed [5]. The most widely used absolute gravimeters measure the free fall of a corner cube using an optical interferometer [6]. The aging of the mobile part of these devices depends directly of the number of drops of the test mass. To preserve the instrument, most operators use a relatively low repetition rate and include dead time periods in g determinations which degrade the sensitivity of the measurement. In contrast, our instrument allows performing continuous g measurement at a large cycling rate of 3 Hz. It has recently participated in several comparisons with corner cube gravimeters [7], [8], [9].

We present here the device and the algorithm we use to perform continuous g measurement rejecting most of the systematic phase shifts. A measurement of 12 days is presented and the efficiency of the algorithm is discussed.

II. Atomic gravimeter CAG

The cold atom gravimeter (CAG) developed at LNE-SYRTE uses atom interferometry to perform a cyclic absolute measurement of g. At each cycle, a new cold cloud of Rb atoms is prepared in a UHV chamber, to be used as a test mass. During their free fall, these atoms undergo three stimulated Raman transitions that respectively separate, redirect, and recombine the atomic wave function, resulting in an atomic interferometer. The total phase shift between the two paths of this atomic interferometer depends on g, and scales with the square of the time interval between two consecutive Raman pulses. The phase difference is given by $\Delta\Phi_g = \vec{k}_{\text{eff}} \cdot \vec{g} T^2$ [10], where $\vec{k}_{\text{eff}} = \vec{k}_1 - \vec{k}_2$ is the effective wave vector with $|\vec{k}_{\text{eff}}| = |\vec{k}_1| + |\vec{k}_2|$ for counter-propagating beams.

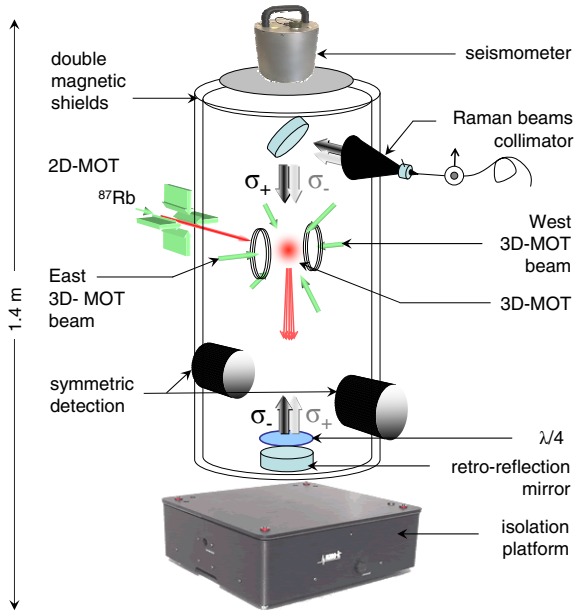

Fig. 1. Schematic of the cold atom gravimeter (CAG). A cold ^{87}Rb atomic sample is prepared by 2D- and 3D-magneto-optical trapping. After a short sub-Doppler cooling phase, where the atoms reach a temperature of $\sim 2\mu$K, the trapping beams are switched off and the atoms start their free fall in the vacuum chamber. During the free fall, a sequence of three stimulated Raman transitions is used to realize the atomic interferometer. These transitions are performed with two vertical, counter-propagating, circularly polarized laser beams, addressing the hyperfine transition of rubidium at 6.834 GHz via two-photon excitation. The phase shift at the output of the interferometer is deduced from a symmetric fluorescence measurement of the atomic state at the bottom of the vacuum chamber [11].

A more complete description of the CAG is given in Figure 1. The vacuum chamber lies on top of a passive isolation platform. The non-filtered vibration noise is measured with a Guralp seismometer rigidly attached to the vacuum chamber,

and is used to post-correct the atomic signal [3]. We use a mirror to retro-reflect the Raman beams, which is placed inside the chamber, leading to reduced optical wavefront aberrations. Furthermore, the fluorescence detection is performed with a double set of detectors placed symmetrically at opposite sides of the atomic cloud [12].

III. Measurement and protocol

The Raman lasers come from two extended cavity diode lasers based on the design described in [13], and amplified by two independent tapered amplifiers. They are phase-locked onto a low phase noise microwave reference source, which is swept according to $\omega_2 - \omega_1 = \omega_2(0) - \omega_1(0) + \alpha t$ in order to compensate for the Doppler shift induced by gravity. This adds a αT^2 term to the interferometer phase, which is eventually cancelled it for a perfect Doppler compensation. The central fringe of the interferometer thus corresponds to $\alpha_0 = \vec{k}_{\text{eff}} \cdot \vec{g}$. The value of g is therefore derived from the frequency chirp and from the mean effective wave-vector. We use a positive (resp. negative) frequency chirp to build an interferometer with $k_\downarrow$ (resp. $k_\uparrow$).

A maximal sensitivity to phase fluctuations is achieved when operating the interferometer at half fringe, which corresponds to $\Delta\Phi = \pm\pi/2$. The Raman phase is modulated by $\pm\pi/2$ so that the measurement is always performed at half fringe height, alternately on both sides to the central fringe as in an atomic fountain clock. From two consecutive measurements of the transition probability P_i and P_{i+1}, the phase error can be estimated. In practice, a correction $G\times(P_i - P_{i+1})$ is added at each cycle to α, in order to stir the chirp rate onto the central fringe. This realizes an integrator, whose time constant can be set to a few cycles by adjusting the gain G. This locking technique has the advantage of rejecting offset and contrast fluctuations, while preserving maximal sensitivity to phase fluctuations.

The measurement of g is shifted by many systematic effects. These systematic phase shifts can be sorted into two classes of error sources, either dependent ($\Delta\Phi_{dep}$) or independent ($\Delta\Phi_{indep}$) on the direction of $\vec{k}_{\text{eff}}$ pointing upwards or downwards ($\uparrow$ / $\downarrow$). The difference of the atomic phases accumulated along the two paths of the interferometer can thus be expressed as $\Delta\Phi_{\uparrow/\downarrow} = \pm\vec{k}_{\text{eff}} \cdot \vec{g}T^2 \pm \Delta\Phi_{dep} + \Delta\Phi_{indep}$. Taking that into account, the measurement procedure we use interleaves g measurements with $k_\uparrow$ and $k_\downarrow$:

Half difference and half sum of successive $\Delta\Phi_\uparrow$ and $\Delta\Phi_\downarrow$ measurements allow to separate $\Delta\Phi_{indep}$ from $k_{\text{eff}}gT^2 + \Delta\Phi_{dep}$. $\Delta\Phi_{indep}$ originates from effects related to perturbations of the internal degrees of freedom of the atoms (such as magnetic field gradient, one-photon light shift) and from radio-frequency phase shifts [14]. $\Delta\Phi_{dep} = \Delta\Phi_C + \Delta\Phi_{WF} + \Delta\Phi_{LS2}$ with $\Delta\Phi_C$ the Coriolis phase shift, $\Delta\Phi_{WF}$ the wavefront aberration phase shift and $\Delta\Phi_{LS2}$ the two-photon light shift. $\Delta\Phi_{LS2}$ is due to off-resonant Raman transitions which shift the atomic levels and therefore modify the hyperfine transition frequency [15]. As it scales linearly with the Rabi frequency of the Raman lasers Ω_{eff}, additional measurements realized with half Rabi frequency allow correcting for this effect by extrapolating to zero. Finally, the algorithm contains four configurations measuring respectively $\Delta\Phi_{\uparrow,\Omega_{\text{eff}}}$, $\Delta\Phi_{\downarrow,\Omega_{\text{eff}}}$, $\Delta\Phi_{\uparrow,\Omega_{\text{eff}}/2}$ and $\Delta\Phi_{\downarrow,\Omega_{\text{eff}}/2}$. They allow to determine $\Delta\Phi_g = k_{\text{eff}}gT^2$ only affected by the Coriolis and the wavefront distortion biases.

$$\begin{aligned}\Delta\Phi_g + \Delta\Phi_C + \Delta\Phi_{WF} &= \Delta\Phi_{\uparrow,\Omega_{\text{eff}}/2} - \Delta\Phi_{\downarrow,\Omega_{\text{eff}}/2} \\ &\quad - \frac{\Delta\Phi_{\uparrow,\Omega_{\text{eff}}} - \Delta\Phi_{\downarrow,\Omega_{\text{eff}}}}{2}\end{aligned}$$

While alternating $k_\uparrow$ and $k_\downarrow$ configurations does not degrade the sensitivity in the g measurement, the arithmetic involved when canceling the two photon light shift leads to a degradation in the short term sensitivity by a factor $\sqrt{10}$ with respect to a single configuration measurement. Indeed, as the sensitivity of a single configuration measurement $\sigma_{\Delta\Phi_g}$ is independent of the pointing direction of $\vec{k}_{\text{eff}}$ and of the Rabi frequency Ω_{eff}, summing quadratically the uncorrelated sensitivities $\sigma_{\Delta\Phi}$ of the right terms in the previous equation leads to a sensitivity on $\Delta\Phi_g$ of $\sqrt{5/2}\times\sigma_{\Delta\Phi}$. As each $\Delta\Phi_g$ is obtained with four measurement points, it corresponds to an effective cycle time of $4T_c$, where T_c is the cycle time of the experiment. This leads to a global degradation of the sensitivity of $\sqrt{5/2}\times\sqrt{4} = \sqrt{10}$ with respect to a single configuration measurement.

IV. Results

Figure 2 shows a continuous g measurement during 12 days in November 2010. It was performed in our laboratory dedicated to gravity measurements [2] close to the LNE watt balance project [5] nearby Paris. The points represented on this figure are obtained switching from one configuration to the next one every 100 shots. Each point thus represents 400 drops (about 170 s). Only three outliers out of 6 000 points over the 12 days measurement have been withdrawn from the figure. The measurements have been corrected from atmospheric pressure and polar motion effect on g [16] but not from tides, which they follow in very good agreement with a local tidal model [2]. The residuals obtained by correcting the data from tides are represented at the bottom of the figure for bins of 170 and 10 000 s. We see resolved temporal changes in the noise which we attribute to variations in human activity over nights and days or week-ends.

The Allan standard deviation of the residual signal is represented as black dots in Figure 3. It averages down as white noise in $\tau^{-1/2}$ and corresponds to an equivalent sensitivity at 1 s of $\sigma_g = 70$ μGal[1]. The sensitivity remains lower than 1 μGal after 5 000 s and flickers at the level of $0.7 - 0.8$ μGal, which is comparable to the accuracy of our local tidal model [2]. It is thus difficult to assess whether the long term stability is limited by our instrument or by the tidal model itself. On the same figure, the blue squares

[1] 1 μGal = 10^{-8} m.s^{-2}

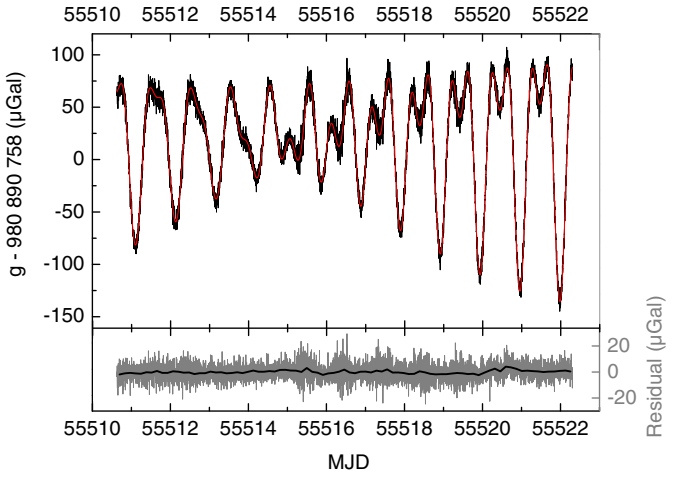

Fig. 2. Top, continuous g measurement from November 10^{th} to November 22^{nd} 2010 uncorrected from tides (bins of 400 drops). (Red solid line) Tide model. Bottom, residuals, in gray for bins of 400 drops (170 s), in black for bins of 10 000 s.

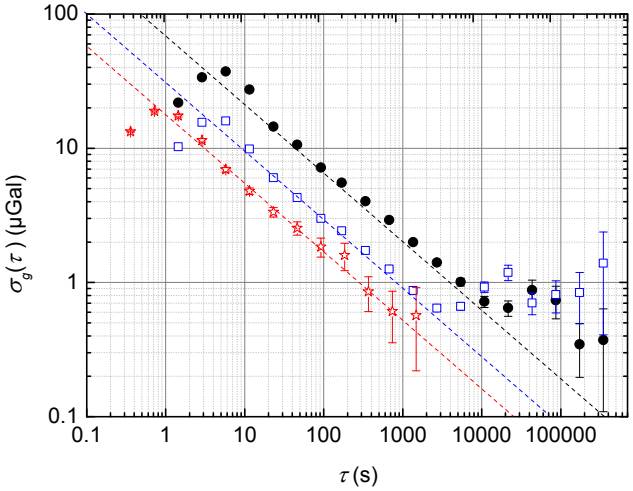

Fig. 3. Allan standard deviation of corrected g signals. Black dots: using the four configurations algorithm to reject the LS2. Blue squares: half difference of only two configurations alternating $k_\uparrow$ and $k_\downarrow$. It corresponds to a blue slope $\sqrt{5/2}$ lower than the black one. Red stars: using a single configuration measurement taken as continuous during about 3 h.

represents the Allan standard deviation of the half difference when alternating only two configurations $k_\uparrow$ and $k_\downarrow$. Note that for this plot we selected data only at full intensity, which amounts to taking only half of the data points, keeping the same effective cycle time of $4\ T_c$. The algorithm suppresses the fluctuations of $\Delta\Phi_{indep}$ and allows to obtain a sensitivity of $0.6\ \mu$Gal after $3\ 000$ s. Nevertheless the measurement is still sensitive to the two-photon light shift fluctuations represented by the bump on the red plot at about $20\ 000$ s. Finally the improvement of stability for long term measurement with four interleaved configurations clearly illustrates the efficiency of the two photon light shift rejection. We also represent as red stars the Allan standard deviation of the corrected signal obtained with a single configuration during three hours, considered here as continuous. The corresponding red slope representing the white noise should be $\sqrt{10}$ lower than the black one and the sensitivity as explained previously but it is even better as the data computed only include three hours of g measurements obtained during a night. Then the sensitivity at 1 s is $1.5\ \mu$Gal instead of $2.2\ \mu$Gal.

The total accuracy of the instrument is $5.2\ \mu$Gal, mostly due to the wave-front distortion bias [12]. It could be reduced if we limit the transverse motion of the cloud. Three comparisons with different free fall corner cube gravimeter [6], [17], [18], [19] performed from October 2009 to April 2010 [7], [8], [9] showed good agreements ($4.3 \pm 6.4\ \mu$Gal) and differences up to $15\ \mu$Gal.

V. Conclusion

We presented the LNE-SYRTE absolute atomic gravimeter, developed in the frame of the LNE watt balance experiment. It allows performing continuous g measurement at a high cycling rate of 3 Hz, avoiding the use of environmental models for the watt balance measurement sessions. The algorithm we use allows to suppress most of the phase shifts. The sensitivity of the instrument is $1\ \mu$Gal after $5\ 000$ s time measurement and flicker at $0.7\ \mu$Gal level that corresponds to the accuracy of our tidal model. The accuracy is 5 times bigger than the targeted accuracy we expect to reach when improving the uncertainty associated to the wave-front distortion correction which is the limiting effect of such a device. For that purpose, the next step consists in limiting the transverse motion of the cloud by cooling the atoms further down in a dipole trap or using horizontal Raman beams to limit the cloud expansion.

***Abstract*— The properties of a new class of electromechanical resonators based on GaN are presented. By using the flexural modes of a doubly clamped beam, the two-dimensional electron gas (2-DEG) present at the AlGaN/GaN interface can be modulated by a field effect arising from the GaN buffer piezoelectricity. This leads to active piezoelectric transducers for which we show experimental results with detailed bias condition studies up to 10 MHz. Associated with modeling of the transduction physics, this allows explaining how the 2-DEG properties lead to the transconductance effect in the electromechanical domain.**

I. INTRODUCTION

Gallium nitride is the second most used semiconductor material after silicon, with applications driven by optoelectronics, RF devices and DC power converters. All these devices benefits from GaN-on-silicon increasing material quality [1, 2]. Moreover, GaN combines piezoelectric properties to a high sound velocity, which could make possible the co-integration of SAW devices with HEMTs amplifiers [3, 4]. Among high frequency devices, SAWS [5, 6] and bulk acoustic filters [7] have already been studied. Quasi-static MEMS devices have been investigated for studying the gauge factor, which points out the importance of transport interaction with piezoelectric effects [8-10]. Moreover, GaN is able to withstand high electric fields and high temperatures, thus being a very interesting material for sensors operating in harsh environments [11, 12]. With the advances in RF power electronics, GaN heterostructures have reached high electron mobility in two dimensional electron gas (2-DEG) that makes them attractive for exploring active piezoelectric devices for high frequency resonant sensors [13]. The concept of small signal amplification coupled to transduction of motion in resonators dates back to Nathanson [14]. Recently, this approach has been revisited in silicon, with active devices exploiting the piezoresistive effect inside transistors [15]. Here we present an overview of a new class of electromechanical resonators based on GaN. The main idea is to use the 2-DEG at the AlGaN/GaN interface and the piezoelectric properties of the heterostructure in order to convert piezoelectric polarization generated in the bulk into an amplified current. Active piezoelectric transducers with experimental results are demonstrated with detailed bias condition studies up to 80 MHz. In particular, the importance of the 2-DEG properties is emphasized for the understanding of the electromechanical transconductance.

II. MATERIAL AND PROCESS

A. Development of MEMS compatible epilayers

Today, electronic grade GaN material is obtained by heteroepitaxy on silicon carbide, sapphire, or silicon substrates. Typical epilayers stacks consist in a nucleation layer, followed by a GaN buffer where the dislocation density lowers from its bottom to the top. Given the temperature growth range (800-1000°C) and the substrate properties, large thermal stresses develops at cooling, thus preventing to grow more than 2-3 µm of high quality GaN onto silicon or silicon carbide. As far as MEMS applications are concerned, ilicon is the prominent choice for the substrate material since it allows taking advantage of existing high aspect ratio machining techniques such as deep reactive ion etching (DRIE). In addition, silicon when patterned by fluorinated plasma or by wet etching techniques exhibits a high selectivity over GaN. Moreover, GaN-on-silicon has been demonstrated on 200 mm wafers using MOCVD technique [17]. In MBE growth on silicon substrates, 2µm thick GaN can be obtained provided that the large thermal mismatch (115%) effect is mitigated by using AlN/GaN/AlN layers, thus reducing induced stress. Here, buried cracks appear in this region and a compressive mean stress is obtained in the thick GaN layer [18]. In order

This work was supported by the French National Agency (ANR) in the frame of its programme in Nanosciences and Nanotechnologies (MEMSGAN project n°ANR-08-NANO-023).

to overcome the stress issues due to the use of standard HEMT wafers,1 µm thick AlN/GaN buffer epilayers have been engineered for MEMS applications. Using *in situ* wafer curvature measurement [19] as well a systematic processing of test structures, the growth process was optimized. Epilayers with a mean tensile stress in the range 250-400 MPa with no buried cracks have been obtained (Figure 1).

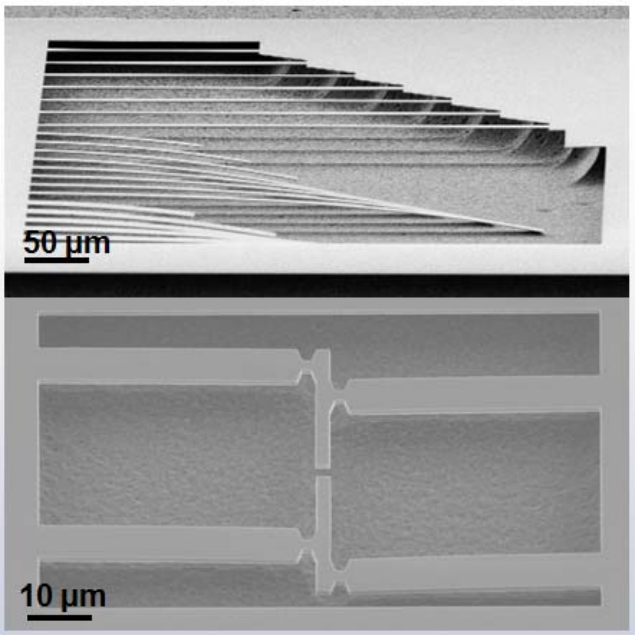

Figure 1. Micromechanical test structures of released AlGaN/GaN. The optimized growth conditions of the buffer allows to reach a tensile stress lower than 400 MPa.

B. *Simultaneous fabrication of HEMTs and R-HEMT transducers*

The fabrication of GaN resonators consists in processing HEMTs and R-HEMTs transducers first, and then defining mechanical parts. In our fabrication runs, we used two GaN epilayers: both are terminated by a 22 nm AlGaN barrier, the first one has a thickness 2.3 µm and a -2.3 V pinch-off voltage, the second is 1.8 µm thick and a -4.5 V pinch-off voltage. To make transistors and transducers ohmic contacts, we deposit a 350 nm Ti/Al/Ni/Au stack which is annealed during 30s at 850°C. Then a damage implant is used to define the 2-DEG electrical path for the R-HEMT channel extension and the actuator bottom electrode. A Mo/Au gate is formed by lift-off and 150 nm SiO_2 is deposited to passivate the devices. This layer is etched to make bridged connections to source and drain contacts as shown on Figure 2. This architecture allows using all the beam width as the R-HEMT drain extension, thus maximizing the signal. After the passivation step, a hard mask is deposited and patterned, followed by the etching of the entire GaN stack down to the silicon substrate. Then the resonators are released by isotropic etching of silicon using xenon difluoride process. Figure 3 shows a 50 µm long flexural resonator after release.

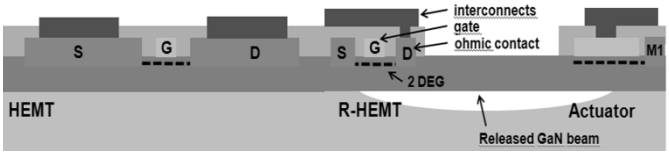

Figure 2. Architecture of the processed devices. Together with AlGaN/GaN/ HEMTs with large sizes (leftmost part), R-HEMTs transducers are fabricated. The Schottky gate and the actuator electrode are defined simultaneously. After passivation and metal pads deposition, micromechanical beams are etched in the GaN epilayer. Then, the resonators are released by Si substrate etching.

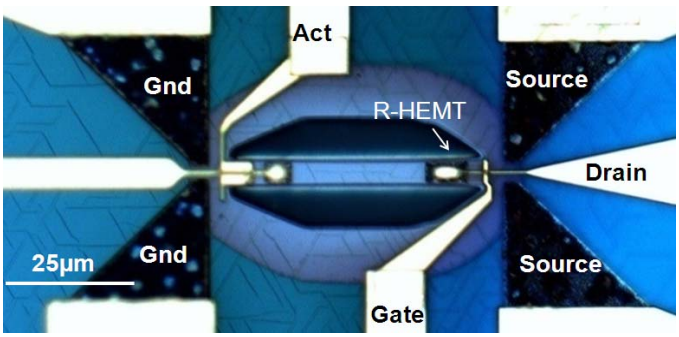

Figure 3. Optical image of a 50 µm long flexural GaN MEMS resonator with fully integrated transducers. The actuator is here the Schottky gate at left side of the beam. At right, a Resonant High Electron Mobility Transistor (R-HEMT) enables active mechanical detection.

III. ELECTRICAL AND MECHANICAL CHARACTERIZATION

A. *Transducers properties*

The testing of GaN MEMS devices involves optical, DC, and AC electrical measurements. The setup is based a vacuum testing chamber with coplanar probes enabling measurements from 77K to 330K. Three different bias tees are used at the actuator, drain, and source ports. The actuator is reverse biased in order to maintain the Schottky in the reverse regime, and the AC voltage is provided by port 1 of a network analyzer (Agilent 8753). The main effect observed in these resonators is shown on Figure 4. It consists of the increase of the motional current with applied drain bias, each maximum having first a linear dependence before 2V, and then followed by saturation (in practical, due to the high current density of 0.8A/mm enabled by the heterostructure, the small interconnecting metal bridge collecting the drain current withstands only voltages up to 4V).

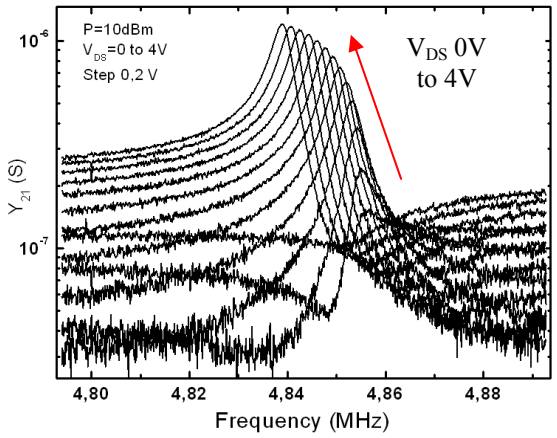

Figure 4. Optical GaN resonator response versus DC voltage applied on the drain at 0V on the gate. The amplification provided by the transducer enables motion detection with a ~20dB improvement as compared to a passive piezoelectric of similar size. The shift of the resonance frequency is attributed to the static piezoelectric strain due to the drain-source field, in addition to the portion of source lying inside released area.

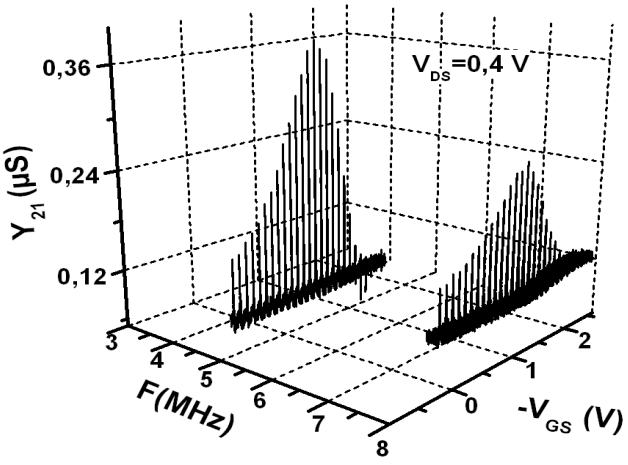

Figure 5. GaN resonator response versus the gate DC voltage (77K). The vibration modes are the 2nd and 3rd flexural of a 100 µm long doubly clamped beam. They evidence a variation of the resonator admittance that clearly denotes transconductance in the electromechanical domain.

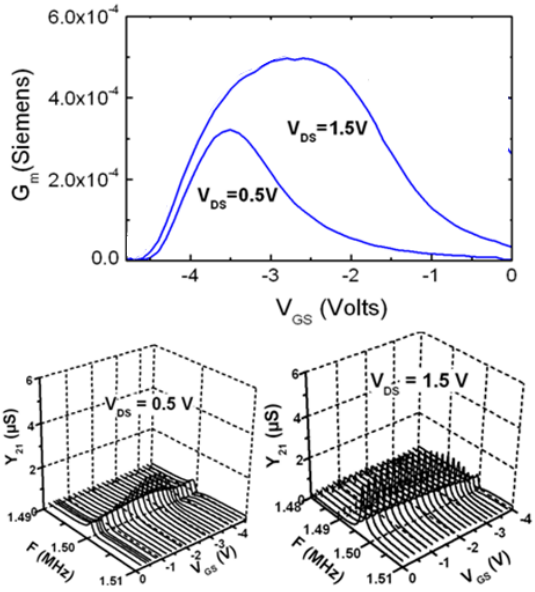

Figure 6. DC transconductance characteristics and electromechanical response versus gate in the linear and saturated regime (300K). A strong analogy is observed, evidencing the importance of 2-DEG mobility in the amplification-detection mechanism. The DC transconductance with other test structures allows to extract local and mean mobility, which are necessary to understand the response to the 2-DEG to additional carrier concentration originated by the piezoelectric buffer

The observation of amplification raises questions about the amplification mechanism and the physical effect occurring under the R-HEMT channel. A first calculation of the current in the linear regime shows that the corresponding sheet carrier density in the 2-DEG agrees with the order of magnitude of equivalent fixed piezoelectric charge generated in the GaN buffer and the heterostructure. A detailed study of the response, at cryogenic temperatures and on various resonators/vibration modes was performed. in Figure 5, we show at 77K the vibration spectra of a 100µm long resonator versus gate voltage. For both flexural modes of order 2 and 3, we observe that the R-HEMT response follows dependence very similar to the well known transconductance in AlGaN/GaN HEMTs. In particular, the gate completely switches-off the response near the pinch-off voltage (-2.4V), and a maximum is reached in the linear regime at a -1.8V value. This confirms that the electromechanical response occurs in the 2-DEG and not across parasitic conduction. On a different epilayer ($V_{pinch-off}$=-4.7V), the transconductance recorded under DC conditions confirms the analogy with the electromechanical admittance (Figure 6).

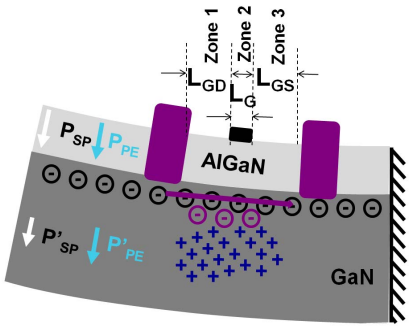

Figure 7. Extrinsic model of the R-HEMT. The active transducer includes 3 zones where the 2DEG can be influenced by the piezoelectric properties of the GaN buffer. Zones 1 and 3 are the access region with carriers having a mobility different from the 2-DEG located in the zone 2. With the gate bias, the carrier number and thus the local mobility can be tuned, resulting in a modulation of piezo-amplified transduction.

The HEMT DC transconductance (G_m) is known to display a pronounced maximum, since the main effect of the gate voltage is to control the mean carrier number in the channel. The mean carrier concentration turns in modifying the local mobility of the carriers, which is reflected in the extrinsic transconductance. The systematic observation of such maxima in the resonator response points towards the fact that the change of carrier concentration is the dominant mechanism in our case. We developed a quantitative approach based on 3 different zones in the R-HEMT showed in Figure 7. The idea is to take into account the response of the 2-DEG in the different zones, the zone 2 being the only one with mobilities controlled by the gate.

B. Minimum detectable amplitude with the R-HEMT transducer

Given the previous observation, we can bias the R-HEMT close to its maximal electromechanical transconductance and look for the minimum detectable signal in the saturation regime of the transistor. Figure 8. shows typical resolution reached with a 1.5 MHz resonator. Using laser Doppler vibrometry, the amplitude was calibrated so that the 2 mV excitation voltage corresponds to a floor of 1.2×10^{-13} m.Hz^{½}. Given that the stiffness constant is 15 N/m, this first result is promising for force measurements applications.

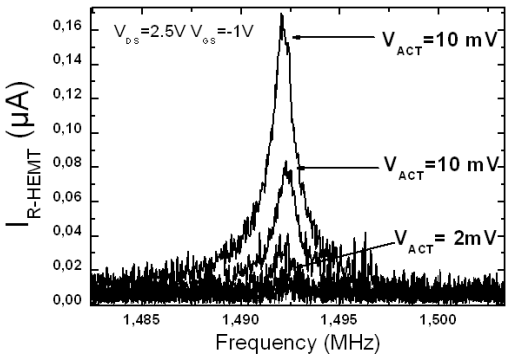

Figure 8. Performance of amplitude detection with the R-HEMT biased at saturation. The beam length is 100µm and a stiffness of 15 N/m. A resolution of 1.2×10^{-13} m. Hz ½ is reached.

IV. RESONATOR RESPONSE UP TO 100 MHZ

In order to evaluate the capability of R-HEMT transducers to detect motion at higher frequency, we acquired vibration spectra up to 100 MHz. First, a comparison between optical measurements and electrical response was performed (Figure 9). Together with FEM simulation, the conclusion is that R-HEMT senses all the flexural modes with out-of-plane motion.

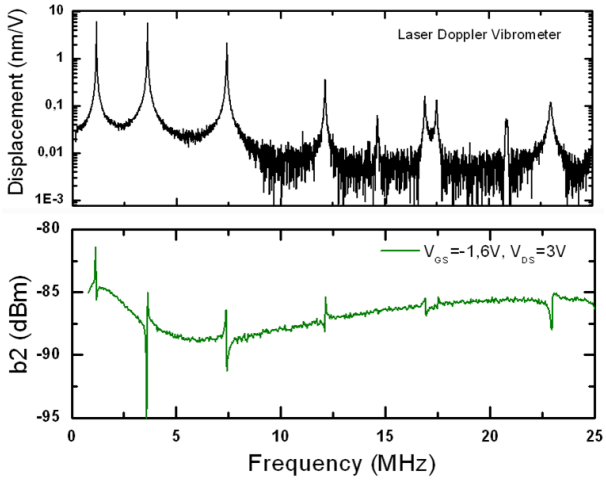

Figure 9. 1-25 MHz study of a 100µm long GaN resonator. The top curve represents the vibration amplitude recorded by a Laser Doppler Vibrometer, with the excitation provided by the piezoelectric 2-DEG actuator. The bottom curve is the power transmitted by the resonator measured at the R-HEMT drain. All the flexural out-of-plane modes are detected,.

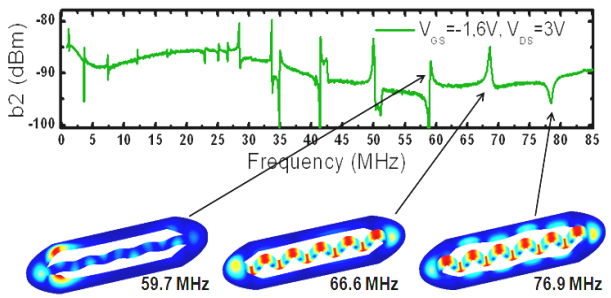

Figure 10. Electrical response up to 85 MHz. FEM simulations including the epitaxial stack and the exact dimensions of the released areas of the measured resonator allows to identify high order flexural modes, as well membrane-like modes involving peripheral motion.

At frequencies beyond the laser Doppler Vibrometer bandwidth, the transduction still evidences vibration modes. Finite Element Modeling allows identifying several high order flexural modes (Figure 10), and also confirms that in plane flexural modes are not detected by the R-HEMT. This is consistent with the interpretation that the 2-DEG screens the piezoelectric polarization, which leads to a charge density in the GaN buffer only when it has a non vanishing divergence.

V. Conclusion

We have presented the development of Gallium nitride MEMS resonators based on AlGaN/GaN heterostructures grown on silicon substrates. The use of piezoelectricity and 2-DEG in the R-HEMT device allows providing active transduction that evidences harmonic response up to 77 MHz on flexural beams.

Hot Filament CVD Conductive Microcrystalline Diamond for High *Q*, High Acoustic Velocity Micromechanical Resonators

Mehmet Akgul, Robert Schneider, Zeying Ren, Gerry Chandler*, Victor Yeh, and Clark T.-C. Nguyen
Department of EECS, University of California, Berkeley, CA, USA
*sp3 Inc., Santa Clara, CA, USA

***Abstract*—A capacitively transduced micromechanical resonator constructed in hot filament CVD boron-doped microcrystalline diamond (MCD) structural material has posted a measured *Q* of 146,580 at 232.441 kHz, which is 3× higher than the previous high for *conductive* polydiamond. Moreover, radial-contour mode disk resonators fabricated in the same MCD film and using material mismatched stems, cf., Figure 1, exhibit a *Q* of 71,400 at 299.86 MHz, which is the highest *series-resonant Q* yet measured for any on-chip resonator at this frequency. The material used here further exhibits an acoustic velocity of 18,516 m/s, which is now the highest to date among available surface micromachinable materials. For many potential applications, the hot filament CVD method demonstrated in this work is quite enabling, since it provides a much less expensive method than microwave CVD based alternatives for depositing doped CVD diamond over large wafers (e.g., 8") for batch fabrication.**

I. Introduction

Frequency-selective resonators with on-chip *Q*'s >30,000 at GHz frequencies, if possible, would offer a paradigm shift in transceiver design by enabling narrow band low insertion loss RF channel-select filters capable of suppressing adjacent-channel interferers directly after the antenna in the receive chain, thereby significantly improving robustness and power consumption. Unfortunately, no existing room temperature on-chip resonator can yet achieve such *Q*'s at GHz frequencies.

Nevertheless, recent advances in capacitively transduced micromechanical resonator technology have yielded devices that draw ever closer to this goal, with *Q*'s reaching past 200,000 at HF [1], 160,000 at VHF [2] and 14,600 at 1.2 GHz [3]. Among structural material options for capacitive resonators, polydiamond is among the most compelling, since its acoustic velocity is considerably higher than that of other popular surface-micromachinable materials, surpassing polysilicon by 2.3× and SiC by 1.6× and allowing polydiamond resonators to achieve GHz frequency with larger, more easily definable dimensions. Furthermore, phonon-phonon interaction based loss theory predicts polydiamond to achieve the highest $f \times Q$ product at GHz frequencies among alternative materials, such as silicon, quartz, SiC and AlN [4][5]. Indeed, contour mode micromechanical disk resonators fabricated in polydiamond with (material-mismatched) polysilicon stems have already demonstrated very impressive *Q's* of 11,555 at 1.14 GHz and 55,300 at 498 MHz [6]. However, most previous work on high *Q* diamond resonators [6][7] employ microwave plasma CVD (MPCVD) tools [8] that are often constrained to deposit films over small areas, due to the high cost of generating a uniform plasma over large wafers. Hot filament CVD (HFCVD) [9] presents an alternative deposition technique that can uniformly deposit polydiamond over large area wafers at much lower cost. Unfortunately, previous attempts to employ HFCVD diamond material for micromechanical resonators have so far yielded vastly inferior performance, causing some to dismiss HFCVD as a viable option for MEMS-based resonators.

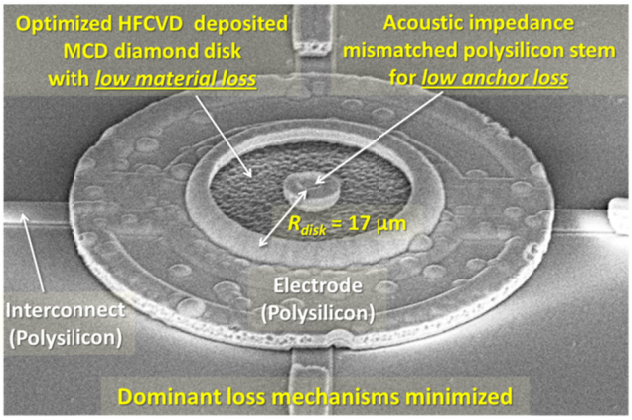

Figure 1: SEM image of a 300-MHz contour mode disk resonator with fully surrounding electrode used for high frequency HFCVD polydiamond resonator evaluation.

This work dispels such doubts by demonstrating HFCVD diamond MEMS resonators with unprecedented performance. Specifically, it presents a capacitive-comb transduced micromechanical resonator constructed in HFCVD boron-doped microcrystalline diamond (MCD) structural material with a measured *Q* of 146,580 at 232.441 kHz, which is 3× higher than the previous mark for MPCVD-based devices [7]. Furthermore, contour mode disk resonators fabricated in the same HFCVD film and using material-mismatched stems demonstrate a *Q* of 71,400 at 299.8 MHz, which is the highest series resonant *Q* measured at this frequency for an on-chip room temperature micromechanical resonator, recording an $f \times Q$ product of 2.13×10^{13} Hz that is on par with similar resonators fabricated using MPCVD diamond [6]. The material used here further exhibits an acoustic velocity of 18,516 m/s, which is now the highest to date among available surface micromachinable materials. It is very possible that this new polydiamond recipe can eventually enable an increase beyond the *Q*>30,000 at GHz frequencies required for next-generation

The authors would like to thank DARPA for supporting this work.

TABLE I. COMPARISON OF ACOUSTIC VELOCITIES AND THEORETICALLY PREDICTED QUALITY FACTORS AT 1GHZ AND 3GHZ

Material	v_a (m/s)	Q_{Theory} @ 1GHz[4]	Q_{Theory} @ 3GHz[4]
Diamond	18,500	380,000	380,000
SiC	13,300	320,000	116,000
Quartz	5,720	39,000	13,000
Si	8,500	36,000	36,000
AlN	10,970	8,700	3,400

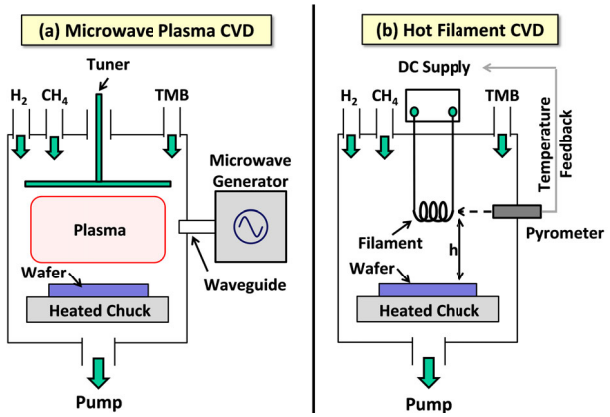

Figure 2: Schematic descriptions of (a) a microwave plasma CVD (MPCVD) system; and (b) a hot filament CVD (HFCVD) polydiamond deposition system.

RF channel-selecting transceiver front-ends [10].

For this and other potentially high volume applications, the hot filament CVD method demonstrated in this work is quite enabling, since it provides a much less expensive method than microwave CVD based alternatives for depositing doped CVD diamond over large wafers (e.g., 8").

II. THE DIAMOND FREQUENCY & QUALITY FACTOR ADVANTAGE

Anchor loss and intrinsic material loss due to phonon-phonon interactions are the two major Q limiting mechanisms for room temperature GHz frequency micromechanical resonators operated under vacuum. To alleviate the former, various anchor design practices, from the use of Bragg reflectors to quarter-wavelength support design, are commonly used to minimize energy lost to the substrate via anchors. Once anchor losses are sufficiently removed (if ever), intrinsic material losses remain to set the Q. While a complete understanding of intrinsic dissipation mechanisms in micromechanical resonators remains elusive, recent studies predict an $f \times Q$ product that is linear with frequency [4][5]—a prediction that deviates significantly from earlier belief in a frequency independent upper limit. Table I presents a comparison of predicted material Q's based on phonon-phonon energy dissipation calculations [4] at 1-3 GHz for common MEMS resonator materials, together with measured acoustic velocities. Polydiamond clearly stands out among materials in this table, having more than 3× the predicted Q and 1.4× the acoustic velocity of its closest competitors, perhaps making it the material of choice for high Q, high frequency micromechanical resonators.

III. POLYDIAMOND DEPOSITION TECHNIQUES

Figure 2 describes the two most common methods for thin-film deposition of polydiamond: microwave plasma CVD (MPCVD) [8] and hot filament CVD (HFCVD) [9]. As shown in the figure, an MPCVD tool supplies energy for CVD via microwave plasma, which must be uniform over the receiving wafer to ensure diamond film uniformity. Despite their previously mentioned prowess in attaining high Q at high frequency, the high cost of the technology needed to generate uniform microwave plasmas over large substrates often constrains MPCVD diamond tools to small area film depositions, making them less suitable for high volume batch production.

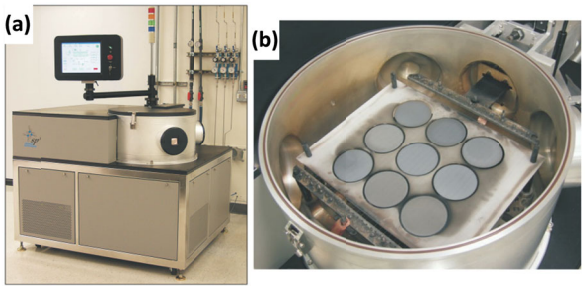

Figure 3: (a) Photo of the sp3 Model 650 HFCVD diamond deposition reactor used in this work. (b) Uniform film deposition over nine 4" wafers in a single batch.

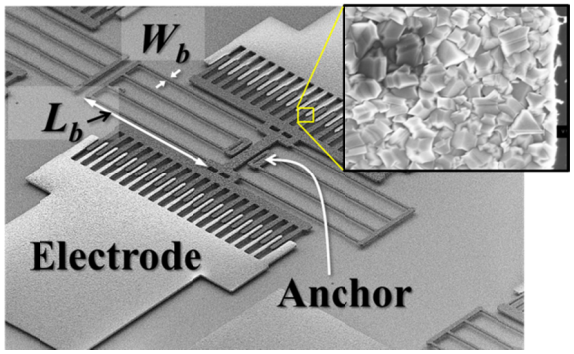

Figure 4: SEM of a fabricated comb-driven folded-beam resonator used to evaluate different HFCVD diamond deposition recipes.

In contrast, a hot filament CVD tool supplies energy for reaction via direct heat delivered by filaments long enough to extend over several wafer-sized substrates. The filaments are simple and easy to replace, and the tool is much simpler to build and operate, hence its much lower cost. Before this work, HFCVD had not been able to produce diamond micromechanical resonators with Q and acoustic velocity performance equaling that of the more expensive MPCVD, causing many would-be-adopters to shy away from the former.

This work uses an sp3 Model 650 HFCVD diamond deposition reactor, pictured in Figure 3, to explore more fully the efficacy of the hot filament approach and perhaps dispel prevailing biases against it. Since vibrating resonators for RF applications are of main interest, Q and acoustic velocity are the main metrics used to gauge performance in this work. Since the mechanisms for Q-limiting loss are often frequency and device geometry dependent, evaluations are done at both low and high frequencies, as is now described.

IV. HOT FILAMENT CVD POLYDIAMOND FOR HIGH Q LOW FREQUENCY MICROMECHANICAL RESONATORS

To evaluate the low frequency material Q as a function of HFCVD polydiamond deposition recipe, folded-beam electrostatic comb-driven resonators [11], such as depicted in Figure 4, were used. As amply covered in the literature, these devices

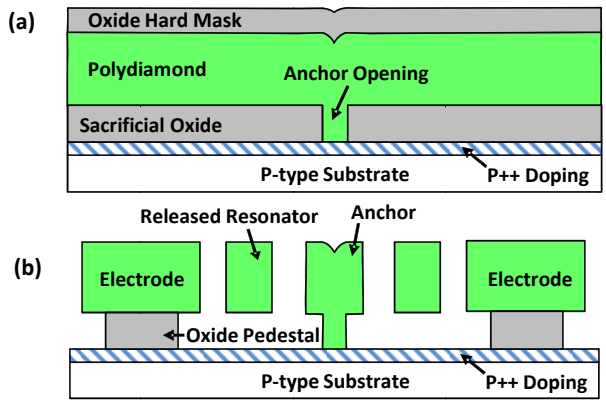

Figure 5: Two-mask comb-driven folded-beam resonator process flow cross-sections after: (a) diamond and hard mask deposition; and (b) diamond etch and HF release.

employ capacitive-comb transducers to linearize the ac voltage-to-force transfer function, as well as compliant folded-beam suspensions that alleviate the effects of residual stress. Such devices make for excellent gauges of intrinsic material Q at low frequencies, since their stiffnesses on the order of 1 N/m are quite low, making energy losses to the substrate through anchors quite small. If anchor losses can be made significantly smaller than the intrinsic material Q, then the measured Q more accurately gauges the intrinsic material Q.

A. Two-Mask HFCVD Polydiamond Fabrication Process

Figure 5 summarizes the quick two-mask fabrication process used to achieve folded-beam comb-driven resonators. The process starts with p++ doping of substrates via boron solid-source (to form a blanket ground plane), followed by a 2 µm LPCVD deposition of sacrificial oxide at 450°C. Anchors to the substrate are then lithographically defined and etched into the oxide, followed by HFCVD deposition of boron-doped polydiamond via recipes (one for each wafer) summarized in Table II. Here, an array of recipes is used with the intent of finding optimal conditions that maximize the material Q. For each recipe, the diamond deposition process consists of:

1. Seeding of nano-diamond particles by spin coating onto the wafers a liquid loaded with hydrocarbon nano-particles, prepared via ultrasonic agitation of fine diamond powder in DI water [12].
2. Flowing CH_4, which provides hydrocarbon radicals as the source of carbon for diamond deposition; and H_2, which dissociates into atomic hydrogen via thermal energy from the heating filaments and promotes the formation of sp3 diamond bonds over the undesired sp2 graphite phase.

After diamond deposition, a blanket LPCVD oxide is deposited to serve as a hard mask during etching of diamond. The diamond resonator structure and electrodes are defined by a second lithography step, then etched in an RIE chamber with 50 sccm O_2 and 2 sccm CF_4 flow at 50 mTorr pressure and 750W power. This recipe, with the help of the aforementioned oxide hard mask, creates vertical sidewalls. Finally, the wafer is diced, and individual dies are released in 49 wt. % HF via a timed etch that releases the resonator structures, but leaves their electrodes on oxide pedestals, firmly attached to the substrate. Figure 4 already presented the SEM image of a fabricated and released HFCVD diamond resonator, with a zoom in showing the 700 nm grain size achieved by recipe MCD^2.

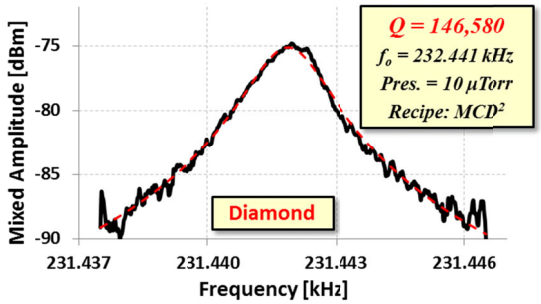

Figure 6: Measured frequency response for the polydiamond resonator using the best HFCVD recipe, showing a measured Q of 146,580 at 232.441 kHz.

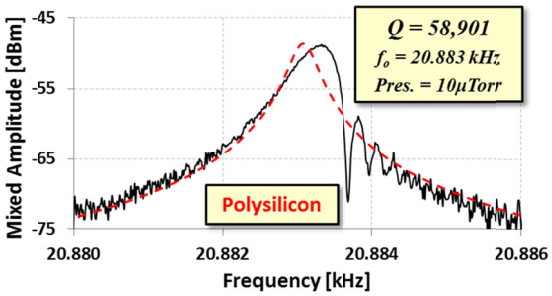

Figure 7: Measured frequency response (and Lorentzian fit with dashed lines) for a polysilicon resonator with identical geometry to that of Figure 6, showing a 3× lower Q of 58,901.

B. Measurement Results

Fabricated folded-beam resonators were measured using a two-port mixing measurement setup, as described in [13], at room temperature and under 10 µTorr vacuum to eliminate air damping. Figure 6 presents the measured frequency response for the resonator fabricated using the best HFCVD polydiamond recipe, achieving a measured Q of 146,580 at 232.441 kHz, which surpasses the previous high for conductive polydiamond [7] by 3×.

For comparison, polysilicon folded-beam resonators with geometries similar to those of the polydiamond versions were also fabricated using phosphorus-doped polysilicon structural material deposited via LPCVD at 615°C. Figure 7 presents the measurement for one such polysilicon resonator in a design nearly identical to that of Figure 4, exhibiting a measured Q of 58,901 at 20.883 kHz. The diamond version not only posts an 11.1× higher resonance frequency than the polysilicon one, but also bests its Q by 2.4×. Since anchor losses are higher for the stiffer diamond resonator, and if one assumes that other loss mechanisms (e.g., surface contamination) are comparatively negligible, these measurements suggest that the intrinsic material Q of HFCVD polydiamond structural material is at least 2.4× that of polysilicon in the kHz frequency range. Given that the previous mark for Q in conductive MPCVD diamond material is 47,900 [7], this measurement further indicates that it is possible to deposit lower loss materials using HFCVD than MPCVD, with the additional benefits of higher throughput and lower tool cost.

C. HFCVD Diamond Recipe Optimization

To determine the optimum HFCVD polydiamond deposi-

TABLE II. HOT FILAMENT DEPOSITED CVD DIAMOND PROPERTIES VS. DEPOSITION CONDITIONS

Parameter	NCD^1	NCD^2	MCD^1	MCD^2	Unit
CH_4 Concentration	2.7	1.5	1.5	1.0	%
Dopant TMB:CH_4	7500	1350	2250	675	ppm
Wafer Temp.	720	720	710	730	°C
Filament Temp.	2285	2200	1975	2010	°C
Quality Factor, Q	12,171	18,246	25,580	146,580	–
Acoustic Velocity	16,767	14,442	16,886	18,516	m/s
Resonance Freq., f_o	41.840	36.035	210.650	232.441	kHz
Young's Modulus	984	730	998	1198	GPa
Density, ρ	3500	3500	3500	3500	kg/m^3

tion conditions that maximize Q, resonators using variants of the deposition recipe were measured and compared. Table II compares the recipes and resulting measurements, showing a 12× improvement in Q between the initial (NCD^1) and final (MCD^2) optimized recipes. Each recipe shown in the table minimizes residual stress via proper adjustment of the filament and wafer temperature during deposition, and this makes possible the non-curled folded resonator beams shown in Figure 4. The column denoted as MCD^2 indicates the best deposition conditions for microcrystalline polydiamond, marked by the highest measured Q of 146,580 and acoustic velocity of 18,516 m/s for conductive polydiamond.

From the table, three important strategies for raising Q can be inferred:

1. Reduce the TMB:CH_4 ratio, which reduces the boron doping level.
2. Reduce the CH_4 flow, which reduces non-diamond carbon formation, thereby yielding a lower loss film.
3. Target microcrystalline polydiamond (MCD) films instead of nanocrystalline diamond (NCD), since the former seems to be able to attain higher Q, despite its surface roughness.

V. HOT FILAMENT CVD POLYDIAMOND FOR HIGH Q HIGH FREQUENCY MICROMECHANICAL RESONATORS

Because they have historically achieved the highest Q's among resonator designs operating past VHF, this work employs radial-contour mode disk resonators, such as shown in Figure 1, to evaluate the high frequency Q achievable by HFCVD diamond material. As shown in Figure 1 and in the cross section of Figure 9-(b), this device consists of a polydiamond disk suspended 700 nm above a polysilicon ground plane and anchored to the substrate by a polysilicon stem at its very center. Polysilicon electrodes surround the disk with an electrode-to-disk gap spacing of only 80 nm. All structural and interconnect materials are boron-doped, so are conductive.

The disk device operates similarly to the previous folded-beam resonators, where a combination of a dc-bias and ac excitation voltages are applied across the resonator-to-input electrode gap to excite resonance vibration; and currents flowing through the resulting time-varying dc-biased resonator-to-output electrode capacitive gap are sensed as a measure of the resonance displacement against frequency. As detailed in [6], the resonance frequency of a radial-contour mode disk is inversely proportional to radius and directly proportional to acoustic velocity, the latter of course being one of the major advantages of diamond.

The prospects of attaining Q's at high frequencies as high as seen for the low frequency folded-beam devices of the previous section are mediocre, at best. Indeed, the results of the previous section, although very impressive, only apply to low frequency resonators for which anchor losses are small and the intrinsic material Q is set primarily by TED [14]. At the much higher frequencies needed for RF applications, Landau-Rumer regime phonon-phonon interactions supplant TED as the dominant intrinsic material loss mechanism [4], and this changes the value of the theoretical maximum attainable Q. Perhaps more importantly, the higher stiffnesses needed to attain high frequency greatly accentuate the role of supports and anchors as conduits for energy loss, to the point where anchors generally dominate over other loss mechanisms when a high frequency resonator is operated under vacuum. Indeed, anchor losses have historically prevented measurement of intrinsic material Q at UHF frequencies.

Needless to say, the key to attaining a best estimate of the Q set by intrinsic HFCVD polydiamond material loss mechanisms at high frequency is to eliminate anchor losses.

A. Material-Mismatched Stem forMinimal Anchor Loss

Anchor loss has long been recognized as an important Q limiter on the micro-scale, from the very first MEMS-based resonators to reach VHF frequencies with high Q [15], to more recent rings [3], disks [6], and lamb wave structures [16] operating at GHz frequencies. Indeed, VHF free-free beam micromechanical resonators [15] were the first to employ quarter-wavelength supports attached at nodal points in the resonator mode shape to minimize support-derived energy losses—a technique still very much used in the latest generation of GHz devices [3], and still among the most effective at reducing anchor loss. To be sure, other strategies for reducing support losses have also been explored, including the use of Bragg reflectors [17] or photonic bandgap structures [18] between the resonator and substrate, but these have so far not been as effective as quarter-wavelength supports attached at nodal locations, at least from the perspective of maximum Q.

Ultimately, the above strategies to suppress anchor loss all seek to create large acoustic impedance mismatches at the resonator-anchor boundaries in an attempt to confine the acoustic energy within the resonator structure during resonance vibration, thereby preventing energy loss to the surroundings. Knowing this, and further recognizing the very large difference in characteristic acoustic impedance between polydiamond and other common micromachinable materials, the work of [6] used MPCVD polydiamond for the disk structure, but polysilicon for the stem, to effect a material mismatch between the disk and stem that reflects energy back into the disk structure, preventing the energy leakage that would otherwise occur. The degree of reflection can be modeled and designed analogously to electrical transmission lines to generate a non-zero reflection coefficient for acoustic waves at the resonator-anchor boundary, preventing energy from flowing into the stem anchor towards the substrate, as depicted in Figure 8. Figure 8 specifically illustrates how a stem made in the same material as the disk does little to impede energy flow; whereas a mismatched stem made in a material different from that of the disk suppresses energy loss to the substrate. This

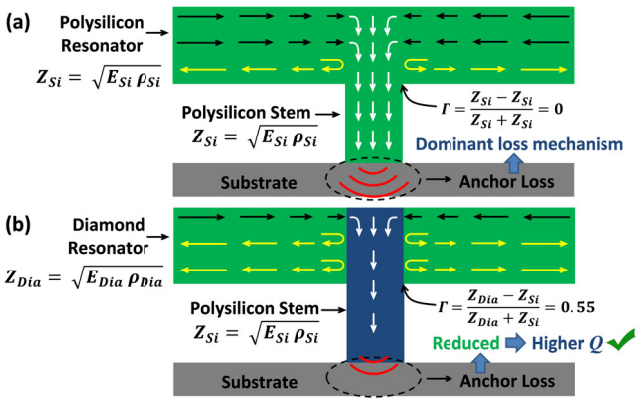

Figure 8: Schematics comparing energy losses to the substrate (indicated by arrows) for (a) a polysilicon disk with an impedance matched polysilicon stem; and (b) a polydiamond disk with a material-mismatched (so impedance-mismatched) polysilicon stem, where (b) loses much less energy.

strategy allowed the device of [6] to achieve measured Q's as high as 55,300 at 498 MHz, which corresponds to a whopping frequency-Q product of 2.75×10^{13}, setting a record for on-chip room temperature resonators at the time of its publication.

To best minimize competing loss mechanisms that might mask the intrinsic structural material Q, the current work borrows from that of [6] in its use of polydiamond for the disk structure, but polysilicon for the stem material.

B. Five-Mask Fabrication Process for High Frequency Contour Mode Disk Resonators

The fabrication process for disk resonators uses five masks and is nearly identical to that of [6], except for the use of an HFCVD diamond tool that allows conformal film deposition over multiple large area wafers at low cost per run, instead of MPCVD diamond, which in [6] was limited to single small area depositions. Figure 9 presents a very brief process flow. The process starts with p++ doping of wafers via boron solid-source, followed by subsequent LPCVD depositions of 2-µm LTO and 500-nm nitride insulation layers. 500 nm of polysilicon is then deposited and boron-doped via solid-source, then patterned and etched to define interconnects and ground planes. A 700-nm LTO layer is deposited as the bottom sacrificial layer, followed by diamond seeding to nucleate a subsequent HFCVD growth of 2-µm structural boron-doped microcrystalline (MCD) polydiamond using recipe MCD^2 from Table II. A 1.2-µm oxide layer is deposited via LPCVD using flow rates of 40 sccm DCS and 100 sccm N_2O at 835°C to serve as a hard mask during the subsequent etch step, and as a vertical spacer for the ensuing polysilicon electrode deposition. The disk resonator structure is then defined and etched to yield the cross-section shown in Figure 9-(a), after which 80 nm of HTO is LPCVD'ed to serve as a sidewall sacrificial oxide that defines the electrode-to-resonator gap spacing. The stem opening and electrode anchors are then lithographically defined and etched, each in separate sequences to allow separate optimization of tiny stems and considerably larger electrode contact vias. A 3-µm-thick boron-doped polysilicon deposition then follows that conformally fills the stem and electrode contact openings to create the aforementioned material-mismatched stems, plus electrodes over the resonator sidewalls. The final lithography and etch step defines the electrodes, and a subsequent liquid HF release frees the resonators,

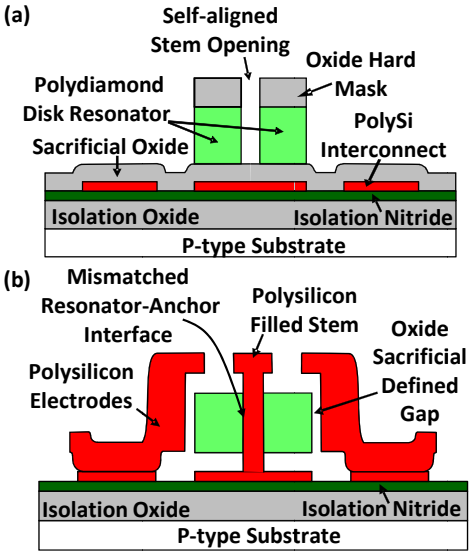

Figure 9: Five-mask disk resonator process flow cross-sections after: (a) diamond deposition and etch (b) electrode etch and HF release.

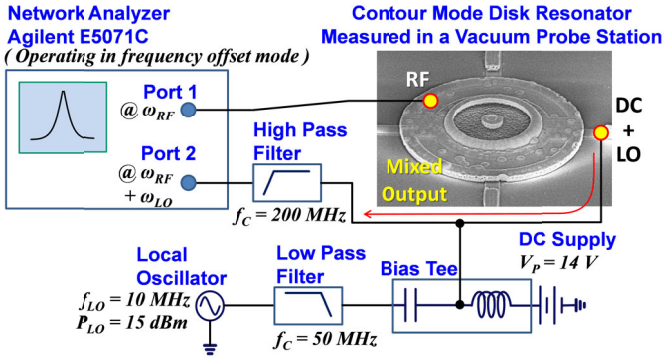

Figure 10: Schematic of the one-port mixing measurement setup used for contour mode disk resonator response measurements.

yielding cross-sections like that of Figure 9-(b).

Figure 1 already presented an SEM image of the resonator measured in this work, which has a disk radius R_{disk} = 17 µm, a 2 µm-diameter acoustic impedance mismatched polysilicon stem, and a fully surrounding electrode with an 80 nm electrode-to-resonator capacitive gap.

VI. Experimental Results

A Lakeshore model FWPX probe station provided 50 µTorr vacuum and probing to allow room temperature frequency characteristic measurements using the mixing measurement setup [13] depicted in Figure 10. Here, a bias tee combines a 10-MHz local oscillator signal with a DC bias voltage to generate the resonator voltage required for mixing measurement; and an Agilent E5071C Network Analyzer sources out of its port 1 an input RF signal that sweeps over a 100 kHz span centered at 10 MHz below the expected resonance frequency. As detailed in [13], the RF and LO signals mix via the square-law voltage-to-force transfer function of the input capacitive transducer, generating a force at their sum frequency, which equals the resonance frequency of the resonator, allowing port 2 of the network analyzer to sense the resonant peak without interference from feedthrough.

Figures 11 and 12 present measured frequency characteristics for HFCVD diamond and polysilicon disks, identically

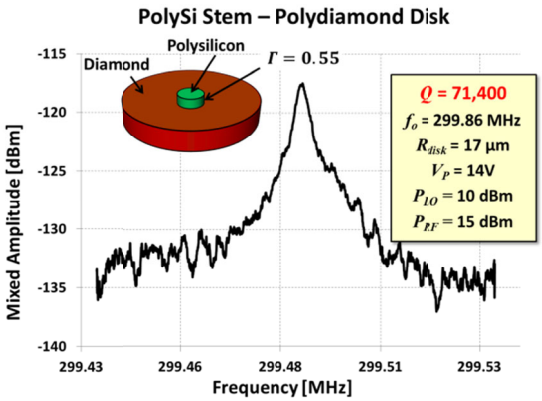

Figure 11: Measured frequency response (using mixing) for a contour mode disk resonator fabricated in HFCVD polydiamond and employing a material-mismatched polysilicon stem.

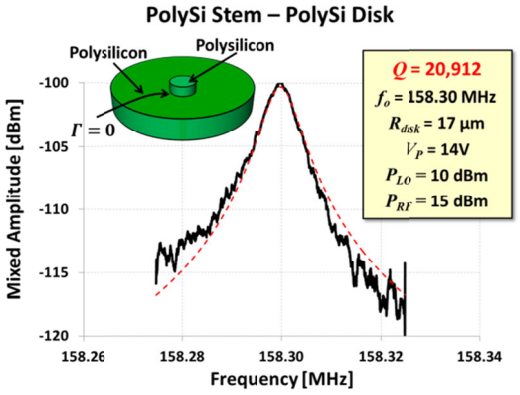

Figure 12: Measured frequency response for a contour mode disk resonator fabricated entirely in polysilicon, with identical geometry as the diamond disk of Figure 11.

dimensioned, both with polysilicon stems. The polydiamond disk with material-mismatched polysilicon stem exhibits a very high Q of 71,400 at 299.86 MHz, which is the highest series resonant Q measured at this frequency for an on-chip micromechanical resonator at room temperature. The polysilicon disk, on the other hand, not only resonates at a much lower frequency of 158.3 MHz, but since it lacks a material-mismatched stem, also posts a much lower Q of only 20,912, which is 3.4× lower than that of the acoustic impedance mismatched diamond device. The measured results clearly confirm the efficacy of stem-to-disk material-mismatching to suppress energy loss to the substrate, and provide resounding testament to the utility of HFCVD polydiamond material for high frequency micromechanical resonators.

VII. Conclusions

The very impressive Q's of 146,580 at 232.4 kHz and 71,400 at 299.86 MHz measured for the folded-beam and disk resonators of this work, respectively, are considerably higher than previously achieved on similar devices constructed using microwave CVD polydiamond (or any other material, for that matter) and now elevate hot filament CVD polydiamond as one of the (if not *the*) most compelling material to use for high frequency on-chip micromechanical resonators. The material used here further exhibits an acoustic velocity of 18,516 m/s, which is now the highest to date among available surface micromachinable materials. It is very possible that this new polydiamond recipe can eventually enable Q >30,000 at GHz frequencies, and work to demonstrate this continues. If achievable with adequately small motional impedance (which will take some work), a paradigm-shift in the design of next generation RF communication transceivers might be possible, such as described in [10], where channel-selecting RF filter banks enabled by Q's this high remove all interferers from the signal directed to demodulation electronics, allowing realization of a fast, low power frequency gating spectrum analyzer that in turn enables true software-defined cognitive radio.

***Abstract*— For the first time, high frequency (~900MHz) lateral-mode thin-film piezoelectric-on-diamond resonators are reported with insertion loss values as low as 2.6dB when terminated by 50Ω impedance. In this work, the surface of the as-deposited ultrananocrystalline diamond (UNCD) is polished to promote the direct growth of highly oriented c-plane AlN which is critical in enhancing the electromechanical coupling and therefore reducing the motional impedance of the resonator. The frequency of resonators fabricated on 3-4um UNCD with a 930GPa Young's modulus is measured to be about 2x higher than similar devices fabricated on 5um of silicon. These resonators exhibit a low temperature coefficient of frequency (TCF) of -9.6 ppm/°C and have a great potential for being utilized in channel-select high frequency filters [1].**

I. INTRODUCTION

There is a growing demand for miniature and low-cost resonators for several applications such as stable and low-power oscillators, multi-channel filters, and sensors. Lateral-extensional piezoelectric resonators exhibit relatively low motional impedance and can operate at atmospheric pressure as opposed to capacitive resonators [2], and they could enable single-chip multi-standard radio frequency front ends and offer smaller footprint compared to FBARs.

One type of such piezoelectric resonators is the class of thin-film piezoelectric-on-substrate (TPoS) devices which are comprised of a piezoelectric layer sandwiched between two metal layers through which an electric field is applied to excite and sense the resonance. These layers are stacked on top of a substrate (Fig. 1). The resonance frequency of a lateral-extensional resonator is defined by its lateral dimension or in the case of higher harmonics by the finger-pitch which is the center-to-center distance of two adjacent electrodes as denoted in Fig. 1. Such resonators usually offer higher quality factors and better power handling relative to purely piezoelectric resonators [3, 4]. Another advantage of having a substrate is the ability to extend the frequency without compromising the ease of fabrication by choosing a substrate with high Young's modulus (E).

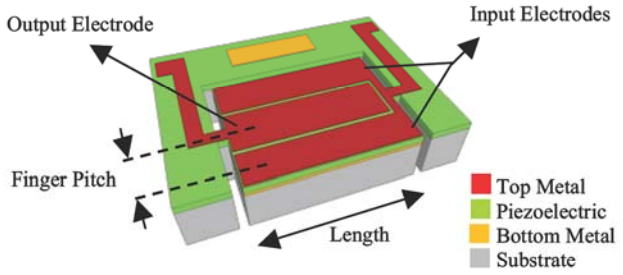

Figure 1. 3D structure of a thin-film piezoelectric-on-substrate resonator.

Diamond has gained much popularity in MEMS community essentially due to its high Young's modulus and low dissipation properties [5]. Thin-film piezoelectric-on-diamond (TPoD) bulk-lateral-mode resonators with 80% higher frequency than the same devices fabricated on silicon have shown much promise in scaling the resonance frequency beyond the limits achievable by silicon [6]. However, the orientation of the piezoelectric film is critical to retain the low insertion loss performance of the resonators. In the earlier work, a polished oxide layer had to be deposited on the nanocrystalline diamond substrate to promote the growth of a highly-oriented piezoelectric film on the rough surface of the substrate. This was the bottleneck for realization of very high frequency resonators since the presence of the oxide would significantly alter the mode shape and lower the quality factor and the frequency [6]. In this work the surface roughness of diamond substrate is substantially reduced by depositing ultrananocrystalline diamond (UNCD) followed by standard chemical mechanical planarization (CMP). Such smooth surfaces allow for direct sputtering of metal/piezoelectric/metal heterostructures with a large coupling coefficient that enable monolithic integration of dispersed-frequency resonators.

This paper describes the work to optimize the properties of UNCD films used to make the TPoD devices as well as the integration of high-quality AlN films on smooth (~1 nm rms roughness) UNCD films achieved via wafer-scale polishing. Next, the design procedure to optimize the performance of the TPoD resonators is discussed and measurement results are presented.

II. FABRICATION

A. Development of UNCD Films

The acoustic velocity is a function of Young's modulus (E) and mass density (ρ) as follows (1):

$$\alpha = \sqrt{E/\rho} \qquad (1)$$

where α symbolizes the acoustic velocity. Since the frequency of a resonator built on a diamond substrate is directly proportional to α of the diamond, it is critical that the Young's modulus of the UNCD be consistently high and uniform across the wafer.

Standard UNCD films have Young's modulus from 650 GPa to 750 GPa, yielding up to 1.6 times increase in frequency compared to silicon-based devices designed with the same lateral dimensions. The challenge in increasing the modulus closer to the largest theoretical value possible (~1200 GPa) is maintaining as small of a grain size as possible to retain the as-deposited smoothness of the material so that CMP-processing is still capable of reducing the rms roughness to about 1 nm.

The UNCD films used for fabricating TPoD devices in this work were produced using hot filament chemical vapor deposition (HFCVD) technique. To increase E, the deposition temperature was increased from about 650 °C to 810 °C by increasing the temperature of the filaments during the deposition step. As depicted in Fig. 2, increasing the deposition temperature yields a clear increase in Young's modulus from 640 GPa (660 °C) to 1028 GPa (810 °C). On the other hand, the residual stress of the as-deposited film is reduced from about 300-400 MPa compressive to about 100 MPa tensile even for films as thick as 5-6 microns. However, increasing the growth temperature also increases the average grain size and the surface roughness. For higher deposition temperatures, films had rms roughness values around 60 nm rms as presented by AFM data in Fig. 3. Such high rms roughness values make the integration of high quality AlN films on the diamond very challenging due to the crystallographic orientation disorder that occurs at the AlN/diamond interface. A highly disordered AlN film results in very poor average piezoelectric coefficient and therefore an inferior insertion loss (IL) for the resonators. For these rougher films a two-stage polishing process was developed in which a more aggressive slurry and greater applied force was used initially to bring the roughness down to about 15 nm,

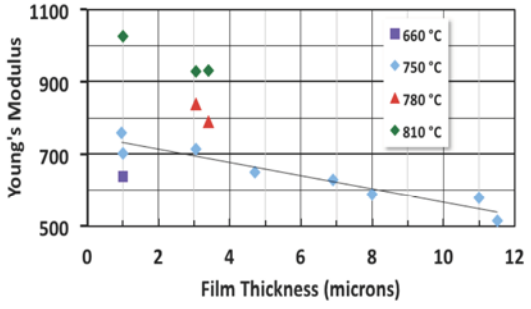

Figure 2. Dependence of UNCD Young's modulus on the deposition temperature.

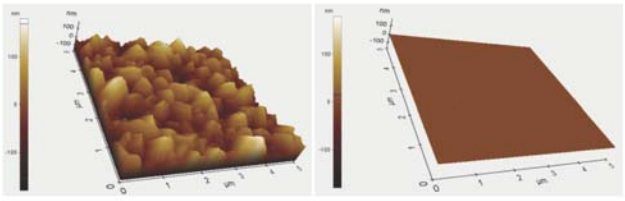

Figure 3. AFM image of high Young's modulus (950 GPa) diamond film surface (a) before and (b) after CMP showing less than 1nm final rms roughness.

after which the CMP process was performed to further reduce the roughness to less than 1nm (Fig. 3).

After UNCD deposition and polishing, the stack of Mo (100 nm)/ AlN (500 nm)/ Mo (100 nm) was sputtered (Fig. 4). AlN is used as the piezoelectric layer due to superior process compatibility, relatively high acoustic velocity and high electrical resistivity. Molybdenum is chosen as the metal layer because of the small lattice and thermal expansion coefficient mismatch with AlN in addition to low acoustic-loss. Fig. 5 represents the X-ray rocking curve of the deposited AlN film with a full-width half maximum (FWHM) of about 3 degrees. The quality of the film was very close to that of the c-axis aligned AlN deposited on polished single crystal silicon substrates for which the typical FWHM is in the range of 2.0-2.5°.

B. Fabrication Process

The schematic flow diagram of the fabrication process is shown in Fig. 6. After depositing UNCD film and the bottom metal layer on the polished surface of the silicon wafer, the bottom metal is patterned by dry-etching to remove the areas underneath the pads and tracks in order to reduce the parasitic capacitances. Then the AlN and the top metal layer are sputtered, and the top metal is patterned. Then the AlN is wet-

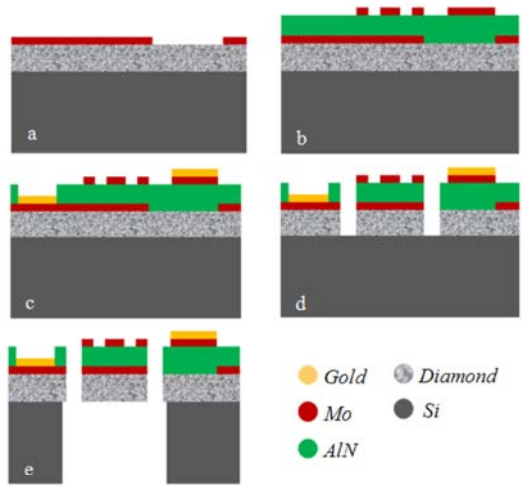

Figure 6. The schematic of the fabrication process flow.

etched in a Tetramethylammonium hydroxide (TMAH) solution to create access to the bottom metal followed by sputtering Au on the electrode areas to reduce ohmic losses. The AlN/Diamond stack is then etched down to the Si substrate in an inductively coupled plasma etcher (AlN in Cl_2 and Diamond in O_2/CF_4 plasma). Finally, devices are released by dry etching silicon from the backside in a deep reactive ion etching chamber.

III. Design Concept

In order to reduce the motional impedance of the resonator or particularly the insertion loss, the actuation area on the resonator should be increased (i.e. resonator's lateral dimensions). This can be obtained either by increasing the number of electrode fingers on the resonator or in other words designing higher order harmonics, or by increasing the length of the resonator. But the drawback in designing a larger resonant structure is that the structure supports a higher number of strong spurious modes that are close to the target frequency. In the simulated frequency response of Fig. 7, examples of such spurs and their corresponding mode-shapes for a 5th order harmonic TPoS resonator are depicted. As established by our group earlier, by adding multiple support tethers to the resonator structure the spurious modes can be effectively suppressed [7]. Here, the same technique was employed to improve the resonator performance.

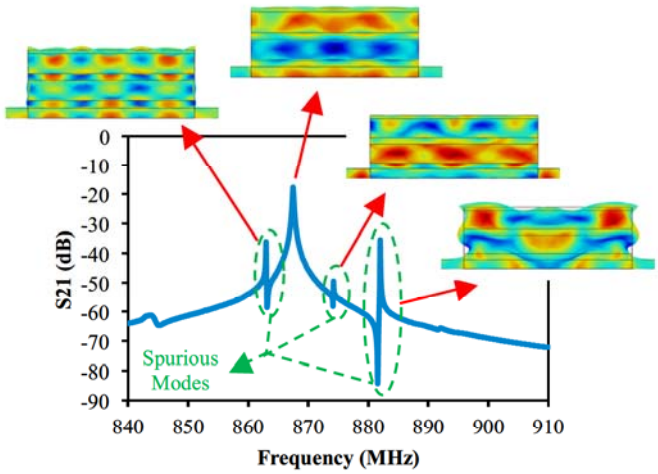

Figure 7. Simulated frequency response for a TPoD resonator designed for excitation of the 5th harmonic mode. The insets show the mode-shapes of the target mode as well as the neighboring spurious modes.

IV. Experimental Results

Frequency response measurements were performed using an Agilent E8358A PNA Network Analyzer and a pair of GSG probes. Prior to measurements, a short-open-load-thru (SOLT) calibration was carried out on a reference substrate.

To evaluate the performance of TPoD resonators, a multi-tethered 21st harmonic resonator was fabricated on two diamond substrates with different Young's modulus (650 and 930GPa) and also on a 5µm thick silicon-on-insulator (SOI) substrate. The typical measured frequency responses are plotted in Fig. 8. The measured frequency of the TPoD resonators is 1.6x (for 650GPa UNCD) and 2x (for 930GPa UNCD) the frequency of the same design on 5µm thick silicon substrate.

Following the discussion in the previous section, a

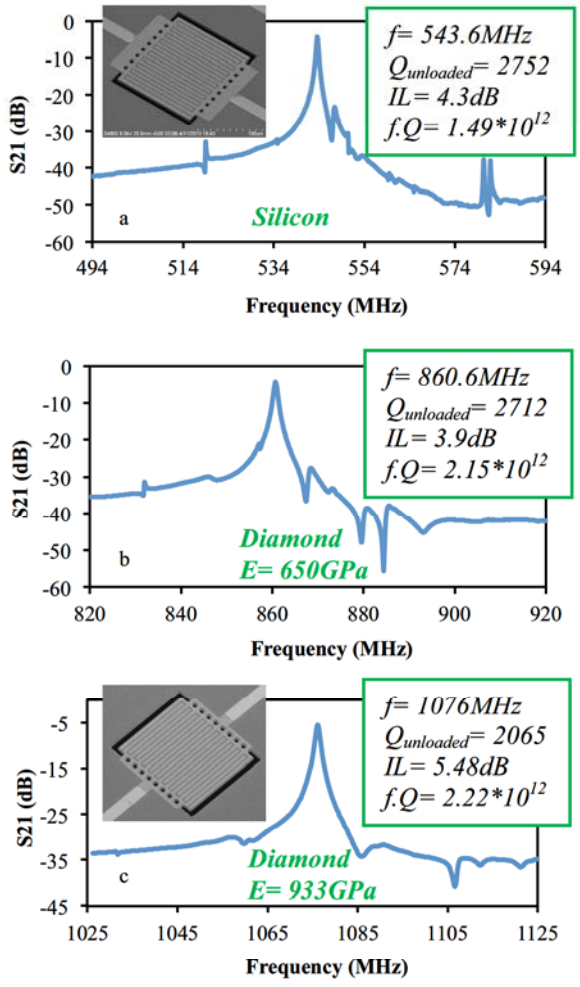

Figure 8. Measured frequency response for a 21st harmonic resonator fabricated on (a) Silicon, (b) Diamond with E=650GPa, (c) Diamond with E=933GPa.

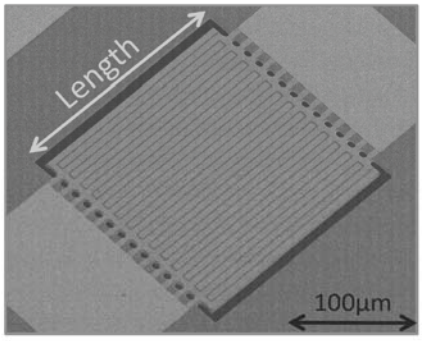

Figure 9. The SEM of the TPoD resonator optimized for excitation of the 29th harmonic.

~205µm long resonator with 7.2µm finger-pitch was designed to excite the 29th harmonic in the lateral dimension. The resonator structure is supported by 13 pairs of support tethers. The SEM of the fabricated device is shown in Fig. 9. This resonator exhibits an unloaded quality factor of ~3000 at 888.6MHz with a **2.6dB** insertion loss (IL) when terminated by standard **50Ω** impedance (Fig. 10). This record low IL corresponds to a 22Ω motional impedance as shown in the equivalent electrical model of the resonator in Fig. 10. The effective electromechanical coupling coefficient ($k^2_{t,eff}$) of this resonator is approximately %0.43 extracted from the equivalent electrical circuit [8]. The lowest IL measured from this device fabricated on three diamond wafers with three different Young's modulus are compared in Table I.

The temperature coefficient of frequency (TCF) for a typical 29th harmonic design described above, was measured in a vacuum chamber to be -9.6 ppm/°C (Fig. 11) which is much lower compared to devices fabricated on silicon for

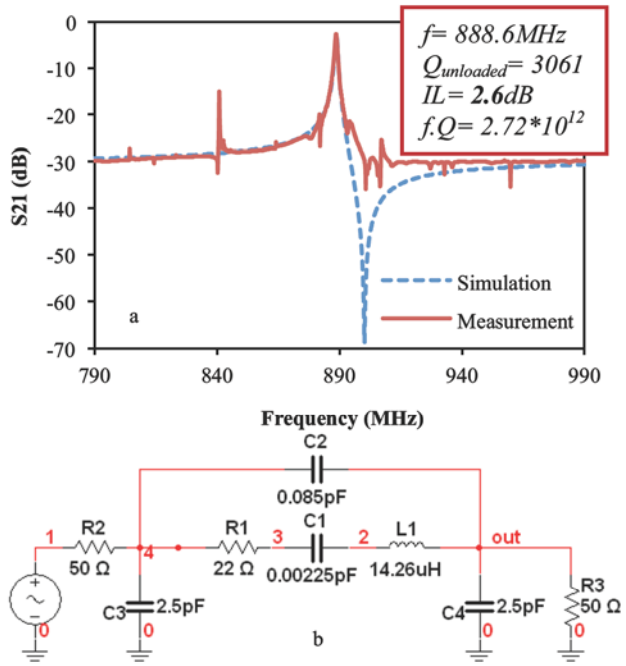

Figure 10. (a) Measured and simulated frequency responses of the 29th harmonic resonator, (b) Equivalent electrical model of the resonator.

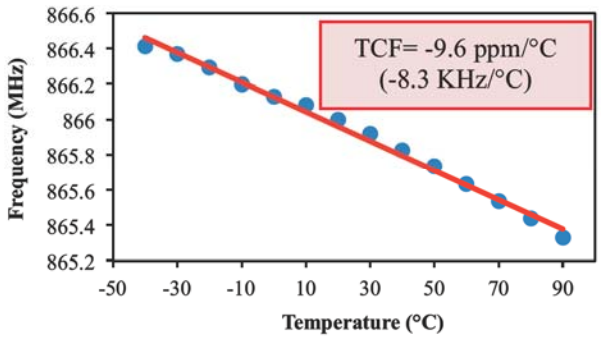

Figure 11. A typical frequency vs. temperature plot measured from a 29th harmonic TPoD resonator.

which the TCF is in the range of -20 to -30 ppm/°C [4, 9]. And also the nonlinearity of the device was examined by varying the input power from -20dBm to 15dBm. The resulted frequency responses are plotted in Fig. 12. The nonlinear behavior is only noticeable from 12dBm input power.

V. CONCLUSIONS

Ultrananocrystalline diamond was deposited using hot filament chemical vapor deposition (HFCVD) technique and further polished to reduce the surface roughness to less than 1nm, therefore promoting the growth of highly oriented c-plane piezoelectric AlN. High frequency and low motional impedance lateral-extensional resonators are fabricated integrating ultrananocrystalline diamond (UNCD) thin films with AlN thin-films. A multi-tethered 29th harmonic TPoD resonator is reported with a motional impedance of 22Ω (insertion loss of 2.6dB) at 888.6MHz. This resonator exhibits

Abstract—**For the first time, fabrication of sub-micron thick single crystal lithium niobate ($LiNbO_3$) membranes on which Film Bulk Acoustic Resonator (FBAR) is reported. The transfer of thin single crystal piezoelectric layers on specific base substrate has been physically and electrically characterized showing to be an innovative and efficient substrate solution for FBAR applications: resonances close to 2.35 GHz with an electromechanical coupling factor of 3.8 % were obtained. Characterized membranes were obtained using the Smart Cut™ technology developed for piezoelectric material such as $LiNbO_3$.**

I. INTRODUCTION

RF filters are a key component in modern front-end circuits, especially when multiband/multimode operations are needed. The use of BAW (Bulk Acoustic Wave) or SAW (Surface Acoustic Wave) technologies enables synthesis of low-loss and compact RF filters. The bandwidth of these filters is primarily defined by the electromechanical coupling factor of each resonators used to build the filter (ladder or lattice topologies). The effective required bandwidth of filter matches at least what is defined by the targeted standard (usually 60 MHz close to 2 GHz). It is however usually increased to account for post-process frequency dispersions and for frequency shifts induced by temperature. Depending on how tightly frequency can be controlled during process and on the thermal sensitivity, these margins can range from a few MHz only up to 15 MHz, increasing the effective bandwidth requirement. As far as BAW filters are concerned, usual designs tend to sacrifice effective electromechanical coupling factor to reach the quality factors required to ensure low losses, pushing even further requirements in terms of piezoelectric material properties. Aluminium Nitride (AlN) is usually sufficient to meet the requirements for most standards (for example PCS and WCDMA) [1], but is hardly sufficient for the most stringent applications such as DCS for example [2]. Thus, the use of materials with larger piezoelectric properties is a possible approach to overcome these limitations.

In order to improve piezoelectric properties, the transfer of thin single crystal piezoelectric layers onto specific base substrates has shown to be an innovative solution [3]. Incorporated into the engineered substrate, buried metallic electrodes enabled the fabrication of HBAR (High Overtone Bulk Acoustic Resonators). Using this approach, we fabricated recently HBARs based on a $LiNbO_3$ thin film transferred onto a $LiNbO_3$ substrate using the Smart Cut™ technology, which allows the transfer of a sub-micron thick monocrystalline layer [4]. To go one step further, we also fabricated Film Bulk Acoustic Resonators (FBAR) using the direct transfer of a $LiNbO_3$ onto a silicon substrate, the grinding and polishing of the piezoelectric substrate to decrease the thickness of the piezoelectric layer, and the forming of free standing membranes through bulk silicon micromachining [5]. Such an approach can only provide films with thicknesses of a few tens of micrometers. Therefore, fabricated resonators exhibited frequencies in the range of 250 MHz. Moreover, the parallelism of the two surfaces of the grinded film proved to be a critical issue with regard to quality factors.

This motivated us to investigate the use of the Smart Cut™ technology to transfer a sub-micron thick $LiNbO_3$ layer to form an FBAR (Film Bulk Acoustic Resonator). In section II we describe the technique used to obtain sub-micron thick single crystal lithium niobate films used in FBAR resonators. We then report on the electrical characterization of the devices in section III.

II. SUBSTRATE REALISATION AND CHARACTERIZATIONS

The Smart Cut™ process is a well known method successfully used by SOITEC for the mass production of SOI (Silicon on Insulator) wafers [6]. This technology has the ability to the transfer of piezoelectric materials (Figure 1), like $LiNbO_3$ [4]. Several articles [5,7] have demonstrated examples of thin $LiNbO_3$ single crystal layer transferred onto silicon substrates. This approach suffers from the large thermal expansion mismatch between silicon and $LiNbO_3$. It causes large strains, which could be detrimental for the self-standing membrane. For this reason, we chose the option of transferring a thin $LiNbO_3$ layer onto a $LiNbO_3$ substrate.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

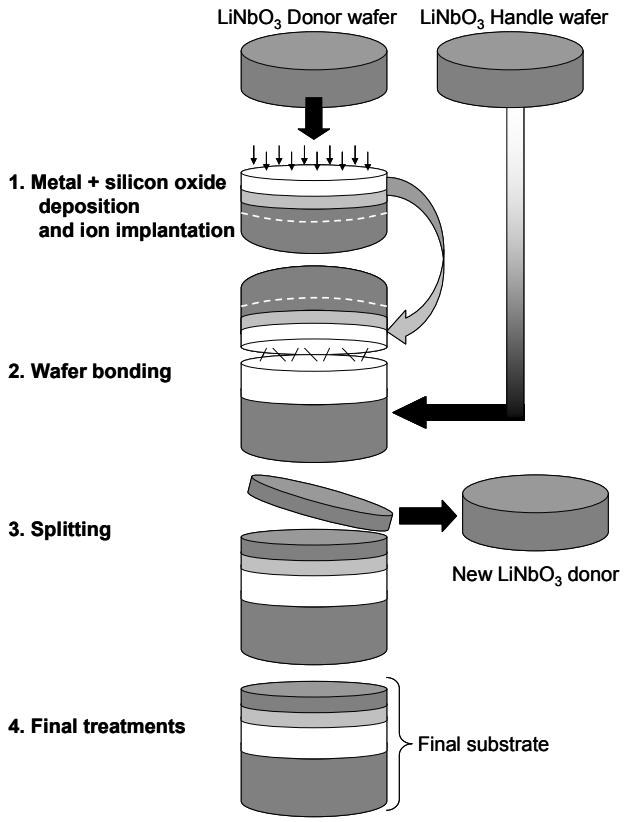

Figure 1. Smart Cut™ technology applied to $LiNbO_3$ thin film fabrication.

A cleaning process has been developed, to obtain a particle free surface without any degradation of the initial roughness, leaving substrates compatible with the bonding technology employed. As required by the final structure, a metallic (low resistivity metal) electrode and PECVD silicon oxide are deposited on the X-cut $LiNbO_3$ bulk donor/handle substrates. The donor structure is then subjected to ion implantation (usually He ions) [8,9]. Top surfaces are then prepared to be bonded at room temperature to a base X-cut, single side polished $LiNbO_3$ substrate thanks to a hydrophilic bonding. Then, a thermal anneal is performed to initiate the splitting of the donor wafer in order to transfer a 1 µm-thick film of $LiNbO_3$. Finishing treatments (annealing and polishing) make $LiNbO_3$ surfaces compatible for device processing. CMP treatment removes the damaged surface layer resulting from implantation and from the splitting. It is also used as a way to control the $LiNbO_3$ layer thickness. After CMP, surface roughness is as smooth as the initial bulk substrate surface and compatible with device fabrication requirements (below 0.6 nm RMS) [10,11]. The donor wafer, from which a thin film has been transferred, can be re-used.

Physical characterizations realized on different samples were used to determine the crystalline quality of the transferred $LiNbO_3$ layer. X-Ray Diffraction (XRD) measurements performed on the as-split transferred layer confirm its single-crystal nature and quality. The $LiNbO_3$ (110) X-ray spectra shown in Figure 2 correspond to measurements of the handle substrate and of the transferred layer performed right after the splitting step. On one hand, the widening of the peak corresponding to the transferred layer can be attributed to implantation sub-surface damages localised in the first 50 nm. On the other hand, the shift observed is the expression of a residual layer strain (about 0.18 %) after transfer. During the final process steps, the remaining damage are completely removed, leaving a bulk-like single crystal material. Furthermore, no extended defects have been observed in the transferred layer by High Resolution TEM (Figure 3).

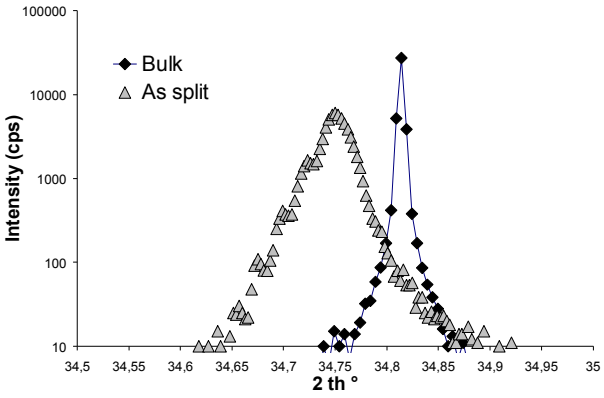

Figure 2. $LiNbO_3$ (110) XRD signals measured right after the Smart Cut™ splitting step for the $LiNbO_3$ layer and for the handle substrate.

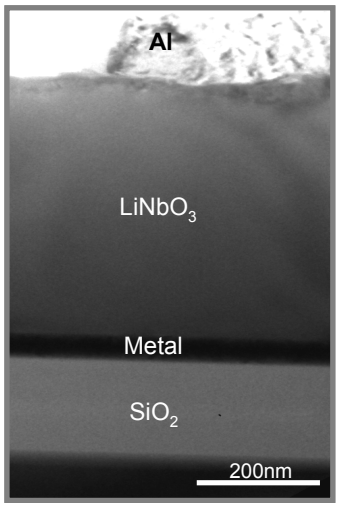

Figure 3. HRTEM cross section of $LiNbO_3$ thin monocrystalline layer with metallic electrode for FBAR devices.

After transfer, the $LiNbO_3$ film is isolated from the bulk substrate (Figure 3) by forming an air-gap between the transferred layer and the handle substrate so as to realize a piezoelectric membrane. Finally, a top aluminium electrode is deposited by evaporation and patterned using wet etch chemistry.

III. SINGLE CRYSTAL FBAR ELECTRICAL CHARACTERIZATION

So as to pattern the only top electrode, we use a set of two resonators connected in series at the level of the bottom electrode. These resonators have been probed on wafer using a vector network analyser. To avoid destruction of the

membrane, probes were positioned on contact pads located outside of the membrane. For this reason, however, we measure both the electrical response of the FBAR located on the free standing membrane and the response of the resonator formed by the contact pads located above the continuous bottom electrode and lying directly in contact with the substrate, as shown in Figure 4.

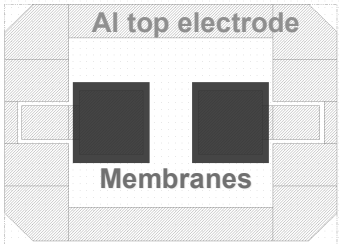

Figure 4. Layout of the resonator indicating the position of the cavity and of contact pads.

As expected from this layout configuration, electrical response of resonators, shown in Figure 5, reveals features associated with both the part of the resonator located over the cavity and the part located at the level of the ground ring and of contact pads. Indeed, two relatively sharp resonances are located at 2.35 GHz for the most coupled mode (fundamental) and at 2.48 GHz for a less coupled one. Their effective electromechanical coupling factors respectively reach 3.8 and 0.7 %, while their quality factors exceed 60. They could correspond to the resonances of the two shear waves piezoelectrically coupled in X-cut $LiNbO_3$. A resonance with a lower quality factor is also visible close to 3 GHz and is likely to correspond to the response of the electrical pads and of the ground ring, where the vibrations in the transferred film radiate in the substrate.

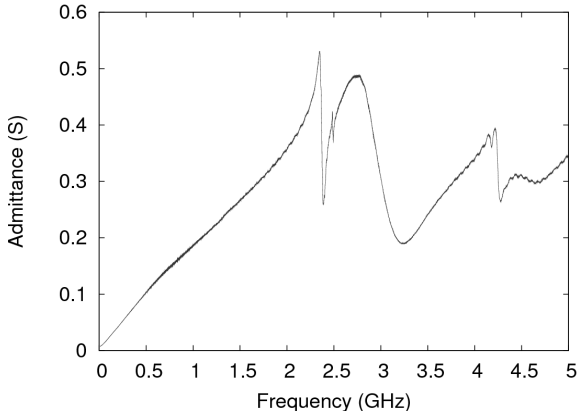

Figure 5. Electrical response of a $LiNbO_3$ FBAR resonator.

To confirm these assumptions, we simulated both parts of the material stack using the scattering matrix method [12] and an estimation of the thicknesses of the various layers obtained from TEM cross sections as shown in Figure 3. The membrane part consists in a SiO_2 / metal / X-cut $LiNbO_3$ 500 nm / Al stack. Its lossless theoretical response (scaled to match the impedance of the complete device) is superimposed with measurements in Figure 6. An excellent agreement is obtained for the position of the fast shear wave resonance, both for the fundamental and for the second order resonance above 4 GHz. The effective electromechanical coupling factor is also well predicted for the second harmonic, suggesting that the discrepancy between the relatively small effective coupling factor of the fundamental (3.8 %) compared to theoretical values (above 45 %) is not related to insufficient piezoelectric properties of the transferred film, but to perturbations brought by the proximity with the low quality factor resonance located at 2.7 GHz.

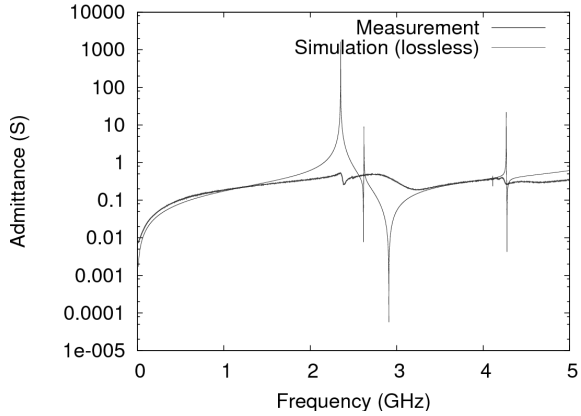

Figure 6. Simulation (light grey curve) of the FBAR part of the device.

We also simulated the same material stack radiating in a semi-infinite X-cut $LiNbO_3$ substrate, representing the behaviour of the single-side polished substrate. As shown in Figure 7, the position of the resonance and antiresonance caused by the piezoelectric film radiating in the semi-infinite substrate corresponds to theoretical predictions. It is to be noted that due to the wide spectrum of these resonances, those caused by the fast shear and by the slow shear wave merge together.

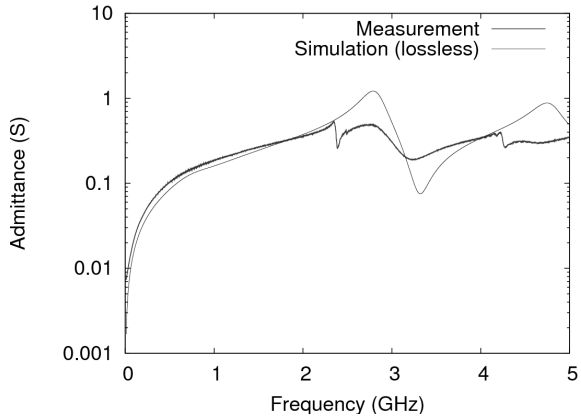

Figure 7. Simulation (light grey curve) of the part of the device located directly on the substrate.

Finally, we merge the two parts of the device by adding their admittances, ponderated by their relative areas. We also add an additional 2 Ω series resistance corresponding to the resistivity of the electrodes and to the length of the electrical path. Response shown in Figure 8, shows that the parallel parasite capacitance brought by the contribution of the part of

the resonator not located above the air-gap dramatically decreases the effective electromechanical coupling factor by a factor close to 10. Therefore, we believe that to the first order, transferred film has kept most of its piezoelectric properties. Quality factors at antiresonance seem higher in simulations than in practice, but it is to be noted that the only sources of losses included in the model are radiation within the substrate and the small series resistance. So, material losses in the stack may account for this phenomenon. Especially, PECVD silicon dioxide used as a bonding layer could explain this result.

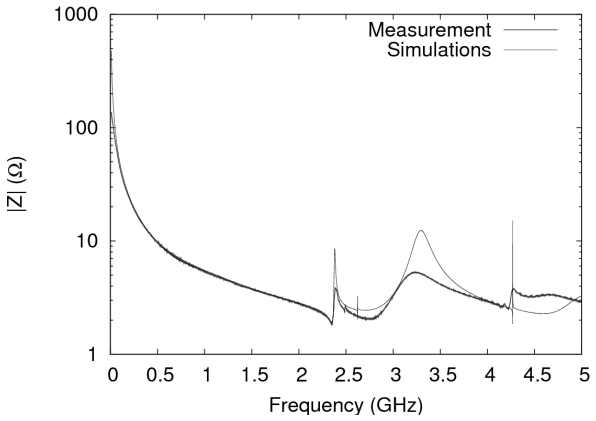

Figure 8. Comparison between measurement (dark grey) and simulation (ligh grey) of the full device.

IV. CONCLUSION

We have reported the first fabrication of sub-micron thick single crystal $LiNbO_3$ membranes in which FBAR resonators were fabricated. Unlike previous works, these membranes were obtained using the Smart Cut™ process and are submicron thick. Furthermore, resonances close to 2.35 GHz were obtained. Although the electromechanical coupling factor is only of 3.8 %, simulations reveal that this relatively low electromechanical coupling factor is largely due to the parallel parasitic capacitance brought by the large part of the resonator located outside of the membrane which is also responsible for the additional resonance damped by radiation within the substrate. Beyond this first study, future work will focus on improving the design of these devices, principally by patterning the bottom electrode to have only the resonators located on the membrane, and substrate optimization to reduce material losses.

***Abstract*— In the last few years the BIPM has started using GNSS phase and code observations and the Precise Point Positioning technique to compute time links for the generation of TAI. The estimated instability of such links for averaging time up to 1 month has been taken as 0.3 ns. In this paper, we investigate methods to estimate this instability, following several approaches.**

I. INTRODUCTION

In the last few years the BIPM has started using GNSS phase and code observations to compute time links. The Precise Point Positioning (PPP) technique has been chosen for its relative simplicity of operation while delivering state of the art results, thanks to the precise satellite orbits and clock products generated by the International GNSS Service. Following earlier studies [1], the uncertainty u_A for PPP links used in TAI is taken as 0.3 ns. As specified in Circular T, this value accounts for measurement noise (which is negligible for PPP due to the low noise of the GNSS phase measurements) but should also account for all effects with typical duration up to one month. In this paper we use different techniques to estimate the time instability of PPP links in the aim of validating the chosen u_A value.

In Section II, some background is given on the use of PPP links in TAI. In Section III, the instability of these operational links is studied through the discontinuities between monthly solutions. Section IV presents results of tests using different processing software and options, including link comparisons to Two Way time transfer. Some implications on the present and future use of this technique in the TAI computation are discussed in Section V.

II. BACKGROUND ON PPP LINKS IN TAI

Among GPS processing techniques, Precise Point Positioning (PPP) appeared as a natural choice for TAI computation needs because it is particularly adapted to a global, but sparse, network of stations and because such processing is flexible and easy to implement [2]. Therefore, to answer the requests from the Consultative Committee for Time and Frequency, the BIPM initiated in 2008 a pilot experiment, named TAIPPP, where time laboratories contribute GPS phase and code data and where the BIPM uses the PPP technique to generate monthly solutions, at first in slightly deferred time after the regular TAI computation. After an initial buid-up, some 30 laboratories have regularly contributed data. Since Circular T 261 (September 2009) PPP has been used for TAI time links and some twenty such links are now regularly used.

All results of the PPP computation are posted on the BIPM web site at ftp://tai.bipm.org/TimeLink/TAIPPP/. In addition, all available link comparisons between PPP and other techniques are included in the link comparisons web page at ftp://tai.bipm.org/TimeLink/LkC.

In March 2011 (the last month in this study), 33 stations sent Rinex data to the BIPM for PPP computation, see the map in Fig. 1. Seven of these stations also participate to the network of the International GNSS Service (IGS) [3] and clock solutions for these stations are also generally available from the IGS.

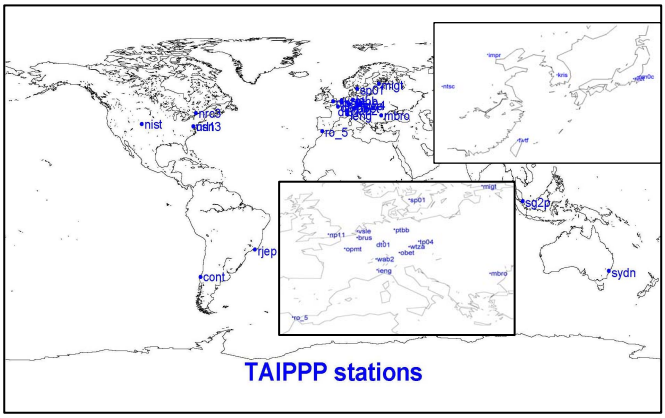

Figure 1. The network of the TAI stations for PPP analysis

The software used in the BIPM operational analysis for TAI is the GPSPPP software developed by Natural Resources Canada [4], presently version 1.04/1087, released in May

2007 and upgraded in July 2008. The software directly uses IGS files for satellite ephemerides and clocks, as well as for the absolute antenna phase center offsets [5]. The BIPM uses the IGS Rapid products, which are available with less than 3 days of delay so are available for the whole month at the date of TAI computation, therefore these same products will be used in this study.

The main operational parameters of the GPSPPP software for the computation of 35-day (or 40-day) batches for TAI are the following: use IGS Rapid SP3 orbits and 5-min satellite clocks referred to the rapid version IGRT of the IGS time scale [6]; ionosphere-free linear combination of code and phase measurements are taken with *a priori* weights of 1 m for code and 1 cm for phase; the elevation cut-off is set to 10°; the observation sampling and clock solution interval are both 5 minutes; the tropospheric zenith delay is modeled as 3mm/√hr random walk, with the GMF [7] mapping function used; ocean loading coefficients are from [8]; station coordinates are estimated on each 1-month batch.

III. Analysis of Discontinuities between Monthly PPP Results

A well-known feature of GPS phase and code solutions based on successive (e.g. daily) batches is the presence of so-called "boundary discontinuities" [9]. The discontinuities are due to the fact that phases are aligned on codes in different manners over the two intervals. They may thus originate either from noise of the code measurements, or from build-up of errors e.g. in the phase ambiguity determination. The effect of code noise would decrease, and thus the discontinuities would also decrease, over long batches only in case of a white noise processes. However, it has been shown that other noise processes are present and sometimes dominant [10], so that discontinuities do not necessarily decrease, and may eventually increase, as the batch duration increases.

We here examine the 1-month discontinuities observed over 35 months of PPP analysis for TAI, i.e. from an ensemble of (at most) 34 discontinuities for 27 stations. Because each monthly batch has a 5-day common period with the preceding, we estimate an average value of the discontinuity over the 5-day period and we also estimate an average rate of the difference between the two results over this period. The determination of discontinuities therefore does not depend on the stability of either the local reference or the IGS reference time scale. Table I shows the statistical information computed from the discontinuity results. We see that the typical discontinuity (median value) is about 170 ps in phase and about 4×10^{-16} in rate. Note that a few of the values may be affected by cases when one of the monthly processing had an undetected error, however the large database and the use of the median should mitigate such effects. Not shown in the Table, the average value of the discontinuity is nearly always statistically consistent with zero, with one notable exception: The equipment designated by nist, operated by the NIST in Boulder (USA) has a very specific behaviour and the average value of the discontinuity (-0.32 ns) is very significantly biased. This equipment is the only one which produces C1/P2 (not P1/P2) data and is also the only one of its brand. However no physical process has yet been proposed to explain the significant bias in discontinuity.

IV. Tests with Different Processing Software and Options

In this section, we first describe tests carried out using two releases of the GPSPPP software. In subsection A, we study the influence on the GPSPPP solutions of the a priori uncertainty assigned to the phase and code measurements, and we compare the two releases in this respect. In subsection B, we form links with the PPP solutions considered in subsection A, and compare these links to Two-Way time transfer (TW).

Finally in subsection C we provide a first comparison of GPSPPP to using the GINS software and the Integer PPP (IPPP) approach which is based on an integer ambiguity resolution scheme.

A. *Tests with the GPSPPP software*

Operational TAI PPP computations are carried out with the NRCan GPSPPP release 1087, hereafter referred to as GPSPPP(2007). Recently NRCan has produced the release 05211 hereafter referred to as GPSPPP(2011). Major changes in release 05211 are (from NRCan release information):

- combined and stand-alone GPS and/or GLONASS processing;
- improved models for GPS yaw/attitude and for station antenna orientation tracking;
- improved processing techniques, such as an adaptive cycle-slip detection and repair, 1ms jumps handling.

One important processing option is the a priori uncertainty for the two types of measurements: Usual default values are u_p = 1 cm for phase and u_c = 1 m for code, representative of the actual measurement uncertainties (such a solution is referred to as "standard"). Here we test the impact of choosing significantly different values for u_c, from 0.5 to 3 m, where low values of u_c tend towards a "code-only" solution while high values tend towards a "code-free" solution. Such expressions are hereafter used to design the two types of solutions.

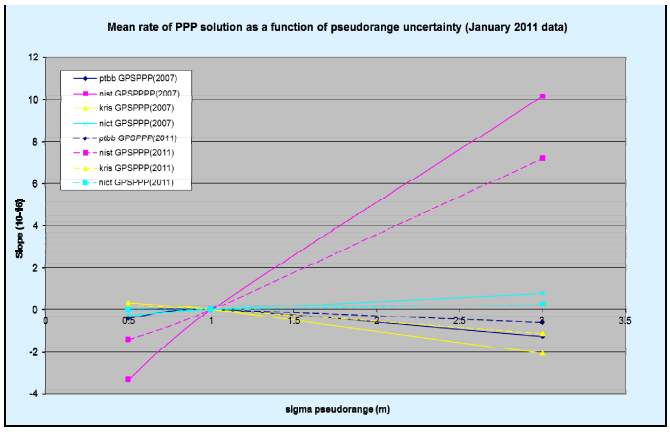

Figure 2. Rate variation of different GPSPPP solutions with respect to the code a priori uncertainty.

We observe that solutions with different u_c values differ essentially by a rate of order a few parts in 10^{16}. This causes somewhat significant differences between the PPP solutions, e.g. the RMS of the difference between two solutions over one month is of order 150 ps for a $2x10^{-16}$ rate difference. As seen in Figure 2, the effect is about similar for all stations, except for nist for which it is much larger. This effect for nist is in relation with the significant bias in the monthly discontinuities, where the net effect of a rate which repeats month after month is to produce a saw-tooth behavior with a discontinuity always of the same sign. Also we note that the effect is significantly reduced using GPSPPP(2011) in all cases, although it is not clear what is the main reason for this change in behavior between the two releases.

B. *Comparisons of GPSPPP links with TW*

Each monthly computation provides the station clock results in the form [Reference – IGRT] with a 5-min interval. Station clock results provide, by simple difference between two stations, link results which can be compared to the TW link results when these are available. Because the quality of several TW links has been somewhat degraded since the change of satellite and set-up in August 2009, all tests are carried out with several stations over July 2009 (noted 0907), and with two specific links (NIST-PTB and KRIS-NICT) over January 2011 (1101). Note that stations are identified either by the name of the TAI laboratory (when upper case in used) or by the name given to the GNSS receiver (lower case).

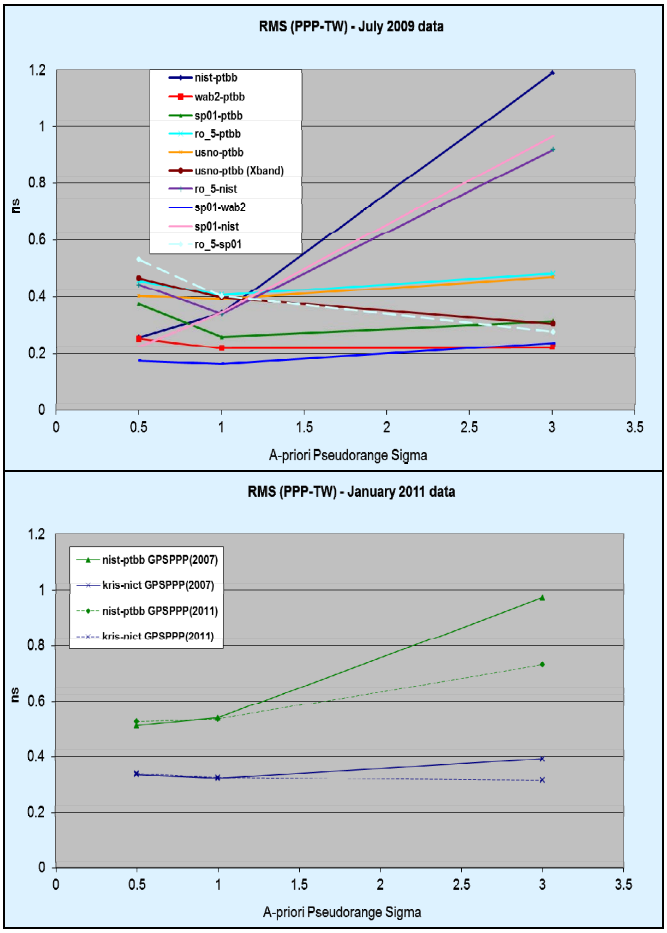

Figure 3. RMS of the difference to TW with respect to the code a priori uncertainty. Top plot: for several links with GPSPPP(2007) for July 2009; Bottom plot: for two links and the two GPSPPP releases for January 2011.

As the magnitude of the effect observed in the previous section is typically of order 150 ps for a given station, the effect on a given link will typically be of order 200 ps or larger, so that it might be possible to discriminate between the different PPP solutions by comparing them to the independently measured TW links. In this aim, for all pairs of stations for which TW is available, PPP links are formed for all types of PPP solution cited in the preceding section and the

RMS of the difference with TW is computed. We observe (Figure 3) that for nist "code-free" solutions (solution with a large code a priori uncertainty) are obviously worse than "code-only" solutions so that the effect must be affecting the phase. We note that, for GPSPPP(2007), there seems to be an "optimal value" of u_c, in the sense that for the best links a minimum can be found in the RMS of the difference to TW. We also observe (case of kris-nict) that GPSPPP(2007) "code-free" solutions seem sub-optimal compared to the "standard" solution which has a better agreement with TW. Using GPSPPP(2011), this feature seems to disappear (all solutions seem equivalent compared to TW), which may be linked to the improved physical model in the GPSPPP(2011) release.

C. *Tests with the GINS-IPPP software*

GINS is a multi-technique geodetic software which is being developed by CNES-GRGS for more than 40 years [11]. In addition to the classical double-difference and PPP GPS data processing strategy, the Integer-PPP (IPPP) technique has recently been implemented into GINS. IPPP is based on the resolution of the phase data integer ambiguities at the un-differenced level, a feature that is expected to greatly improve the solution. This new and alternative approach needs an accurate model of GPS measurements, precise GPS satellite orbit and clock products and the a priori knowledge of individual satellite fractional-cycle biases. The underlying theory is described by several authors [12, 13, 14, 15]. IPPP results presented hereafter are derived from GPS satellite products that are routinely processed by the CNES-CLS IGS Analysis Center (freely available under the acronym GRG). As station clock solutions rely on integer phase observations only, two successive batch series will differ by an integer number of phase cycles. Continuous (phase) receivers clock solutions can easily be generated.

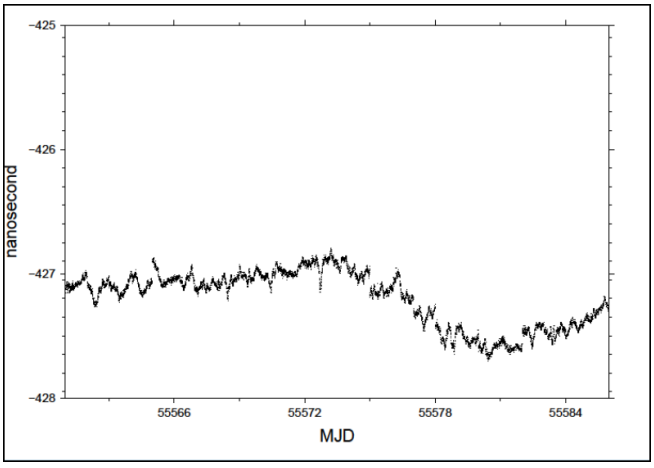

Figure 4. Difference between the IPPP solution and the GPSPPP(2011) "standard" solution for the link nist-ptbb over January 2011 (RMS is 221 ps).

We compute IPPP clock solution difference between NICT and PTBB stations at a 30 second sampling using daily batches and then resolve the integer ambiguities between consecutive days by simple matching. We note that the IPPP and GPSPPP(2011) "standard" solutions differ somewhat (RMS = 221 ps) but do not show significant systematic drift like that observed for the GPSPPP "code free" solution. We infer that IPPP, like TW in the preceding subsection, seems to determine that the GPSPPP "code-free" solution is not optimal. However, with the available data, it is not possible to use TW to determine the preferred solution among them as it seems that the comparison to TW is dominated by noise inherent to TW itself, see Table II.

TABLE II. RMS OF DIFFERENT COMPARISONS FOR THE LINK NIST-PTB OVER JANUARY 2011

Comparison	RMS / ns
GPSPPP (2011) – (2007)	**0.129**
GPSPPP (2011) – IPPP	**0.221**
GPSPPP (2007) – TW	**0.539**
GPSPPP (2011) – TW	**0.534**
IPPP - TW	**0.518**

V. DISCUSSION AND CONCLUSIONS

Time links using PPP solutions have been implemented for TAI computation and now number more than 20, some of them in combination with TW links [16]. The standard uncertainty assigned to these links is 0.3 ns and covers all instability sources with typical duration up to one month. Several studies presented in this paper have shown the following:

- Discontinuities between consecutive monthly PPP solutions have a median value of order 170 ps. Assuming that the results for the two stations of a given link are independent, this indicates that the one-month time instability of a given link is a the level of 250 ps;
- One station shows a significant systematic behavior in discontinuities. Investigations are under way to determine the causes of this effect.
- In the best cases, the comparisons to TW are at the level of 0.2 ns RMS over one month. In other cases, there is no indication that a larger RMS difference is due to the PPP processing.
- Comparisons of PPP links computed with independent software also show a difference of order 0.2 ns RMS. More studies are needed to expand the basis of this comparison.

We therefore conclude that in all typical cases, the value u_A representing the time instability of the link over one month can be taken as 0.3 ns. We expect that further studies involving comparison of different processing software will allow improving on this estimation.

In the present situation, this instability limits the accuracy of frequency comparisons, e.g. for comparing Cs fountains to

TAI, to the level of 1-2x10^{-16} depending on the duration of the comparison (of order 15-30 days). As the best fountains claim an accuracy of order 3x10^{-16} and new frequency standards have already been shown to have an accuracy budget well below 1x10^{-16}, it will shortly be necessary to improve the performances of frequency comparisons.

ACKNOWLEDGMENT

We thank Natural Resources Canada for providing the GPSPPP software, and François Lahaye for his help in maintaining the software and solving run-time problems. The support of all TAI laboratories participating to the TAIPPP experiment is gratefully acknowledged.

Precision and Accuracy of USNO GPS Carrier Phase Time Transfer: Further Studies

Christine Hackman and Demetrios Matsakis
United States Naval Observatory
Washington, DC USA
christine.hackman@usno.navy.mil

Abstract—**The United States Naval Observatory (USNO) produces GPS carrier-phase time-transfer (GPSCPTT) estimates for approximately 100 receiver clocks with 16-hr latency daily in its so-called "rapid" processing. We investigate the uncertainty of these estimates by comparing one year's worth of USNO rapid GPSCPTT estimates to those obtained from two-way satellite time transfer (TWSTT) and from the IGS rapid combined solutions. The time stability of USNO rapid GPSCPTT estimates appears to lie between tens and hundreds of ps for averaging times of 300 s and larger, remaining approximately constant as averaging time increases. The frequency stability of USNO GPSCPTT estimates lies between 10^{-15} and 10^{-14} at an averaging time of one day, decreases as averaging time increases, and could potentially achieve 10^{-16} in 10 d. More work is needed to establish credible frequency-uncertainty estimates at the averaging times (5-20 d) characteristic of the overlap between primary frequency standard evaluations.**

I. INTRODUCTION

The GPS Analysis Division, part of the Earth Orientation Department at the United States Naval Observatory (USNO), produces GPS carrier-phase time-transfer (GPSCPTT) estimates for approximately 100 GPS-receiver clocks daily in its service as an associate analysis center of the International GNSS Service (IGS) [1]. Clock estimates are produced in both "rapid" and "ultra-rapid" operations, each of which creates time-transfer estimates spaced at 5-minute intervals. The processing is conducted using *Bernese 5.0 GPS Analysis Software* [2] in tandem with automation routines developed in-house, with each product set containing estimates of GPS satellite orbits and earth-orientation parameters in addition to GPSCPTT values. While the ultra-rapid clock products are useful for near-real-time applications (they are available with 3-hr latency and provide 24 h of predictions), an initial assessment of their precision was performed in [3] and they are not discussed further here.

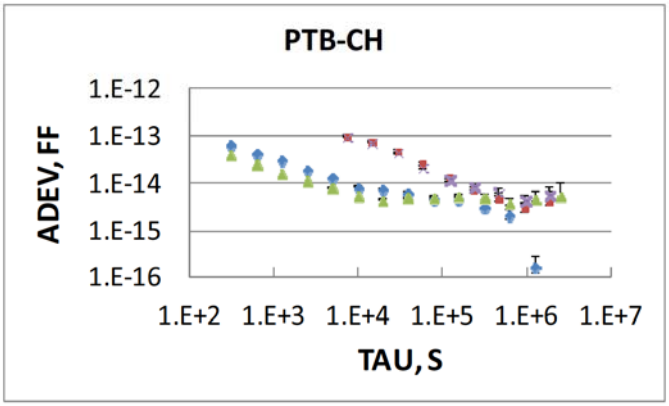
"Rapid" processing is conducted once/day using 24 h of measurements collected the previous UTC day. Solutions for approximately 100 clocks are obtained using either network or precise point positioning (PPP) [4] algorithms and are available with 16-h latency. We evaluate the uncertainty of these estimates by comparing them to those obtained from two-way satellite time transfer (TWSTT) and from the IGS rapid combined solutions [1].

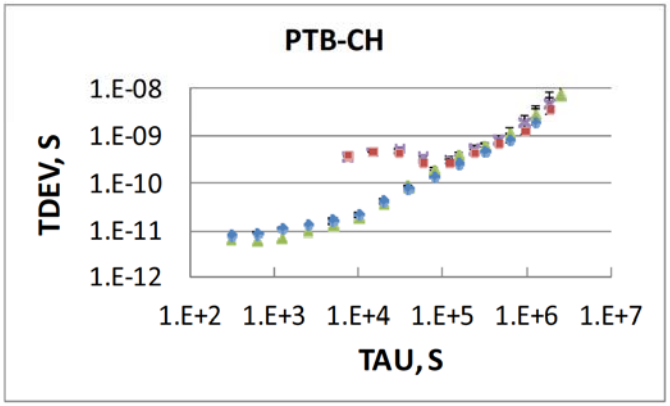
II. METHOD

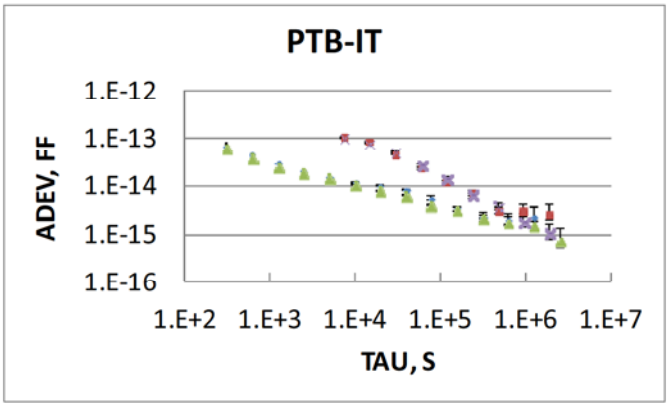
Clock estimates from time-transfer links between three pairs of BIPM timing laboratories were compared. The laboratories are Physikalisch-Technische Bundesanstalt (PTB; Braunschweig, Germany), Istituto Nazionale di Recerca Metrologica (IT; Torino, Italy), (Swiss) Federal Office of Metrology (CH; Wabern, Switzerland) and National Institute of Standards and Technology (NIST; Boulder, Colorado, USA). The links studied were PTB-CH (635 km), PTB-IT (835 km), and PTB-NIST (7532 km). Data from 1 April 2010 – 31 March 2011 (MJDs 55287 – 55651) were analyzed. Both GPSCPTT techniques yield clock values every five minutes, whereas TWSTT yields one value every two hours. Linear interpolation of adjacent GPSCPTT values was used to perform the GPSCPTT – TWSTT subtraction.

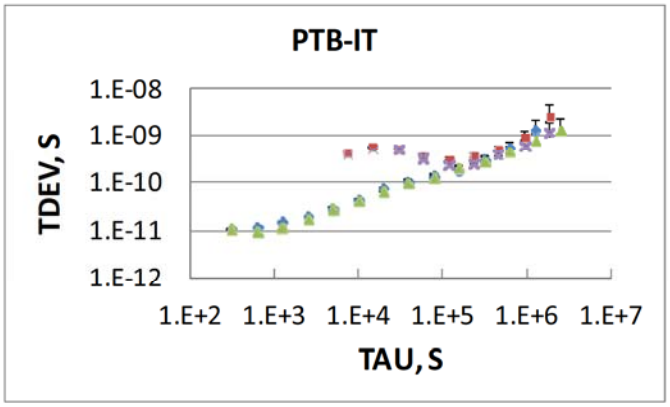
Comparing USNO GPSCPTT values to TWSTT values yields an estimate of the combined uncertainty of the GPSCPTT and TWSTT methods. Equipment and data-analysis uncertainties will be included, as well as uncertainties in models applied to only one of the methods. We use the GPSCPTT-TWSTT values to form an upper bound on our GPSCPTT uncertainties, for reasons that will become apparent in "Results."

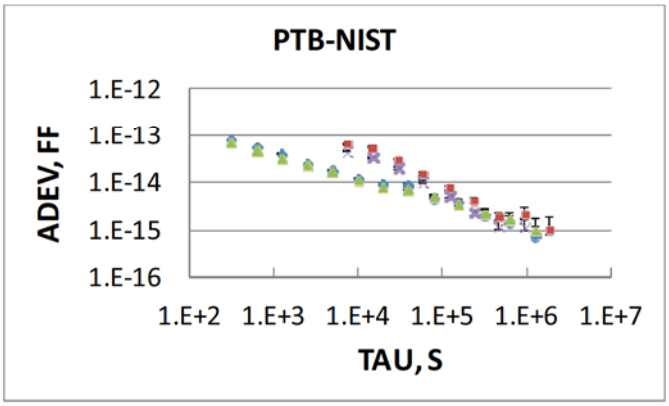
The USNO rapid estimates are not included in the IGS rapid combination (at present). Although USNO GPSCPTT results are thus independent of those obtained by the IGS, both estimate sets are GPSCPTT-based. Therefore, subtracting USNO and IGS GPSCPTT estimates will remove most hardware instabilities, as well as the hardware-and-software-based day-boundary discontinuities, because both estimates will be created using by-and-large the same raw data in which these hardware instabilities are manifest. Therefore, a comparison of these methods yields insight primarily into the uncertainty of processing models and methods: the IGS solution is a combination of analysis-center solutions, and the











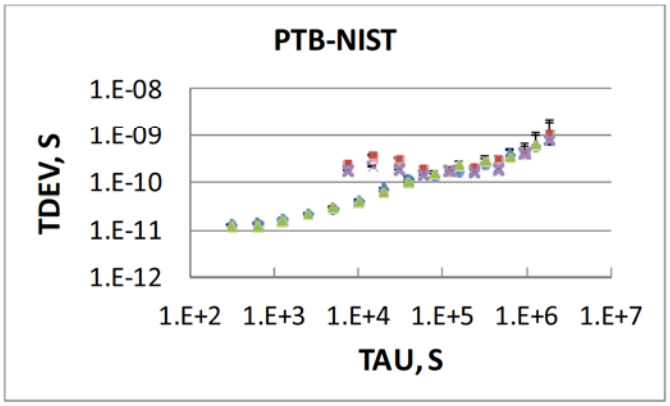


Figure 2. Frequency stability (Allan deviation; ADEV) of the Fig. 1 clock differences. Values shown are for GPSCPTT, Segment 1 and Segment 2, and TWSTT Segment 1 and Segment 2. "FF" = fractional frequency; "TAU" = averaging time. PTB-CH outlier is likely caused by small sample size at tau = $1.2 \cdot 10^6$ s.

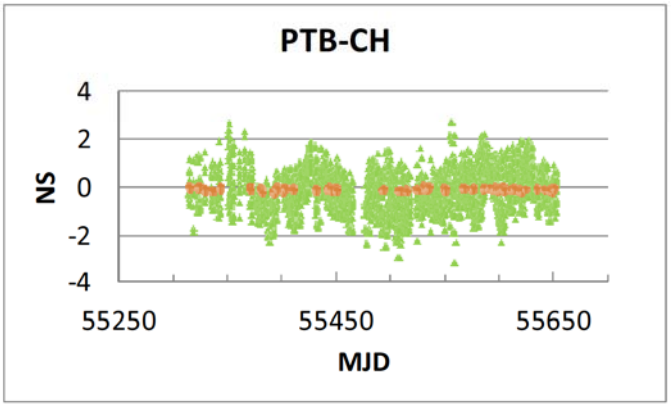
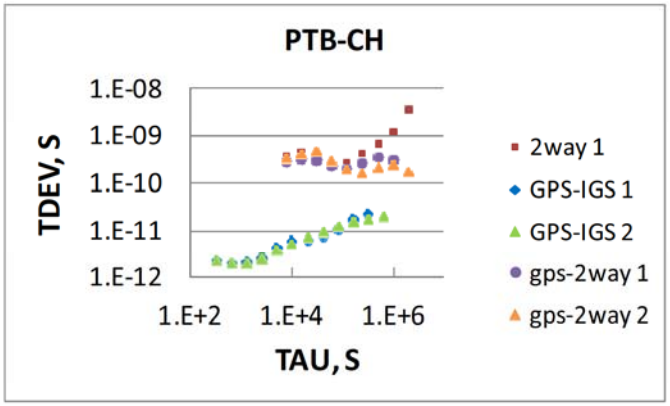
Figure 3. Time stability (time deviation; TDEV) of the Fig. 1 clock differences. Values shown are for GPSCPTT, Segment 1 and Segment 2, and TWSTT Segment 1 and Segment 2.

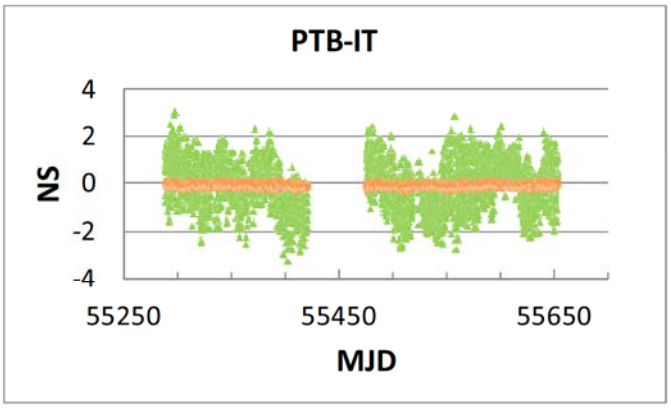
IV. Comparison of Frequency Estimates

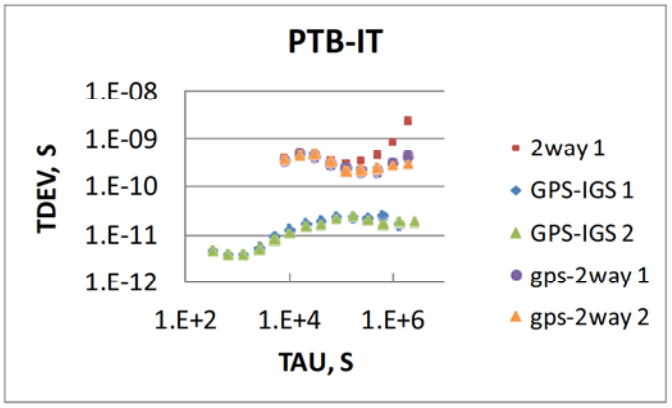
The time stability of USNO GPSCPTT estimates lies between tens and hundreds of ps, as evidenced by the GPSCPTT-IGS and GPSCPTT-TWSTT differences respectively. It remains nearly constant as averaging time increases, implying that longer data averaging yields better frequency stability. The frequency stability of USNO GPSCPTT lies between $1 \cdot 10^{-15}$(GPSCPTT-IGS) and $1 \cdot 10^{-14}$ (GPSCPTT-TWSTT) at tau = 1 d, improves with averaging time, and may reach $1 \cdot 10^{-16}$ in 10 d, based on the comparison with IGS values.

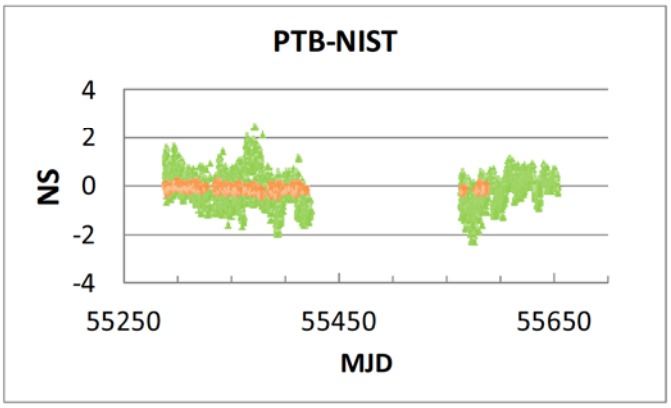
PTB, NIST and IT have cesium fountain primary frequency standards (CFPFSs) whose evaluation values and uncertainties are published in *BIPM Circular T* [5]. Table 1 shows the periods during MJD 55287 – 55651 in which a PTB CFPFS evaluation coincided with a CFPFS evaluation occurring at NIST or IT, along with the uncertainties of each











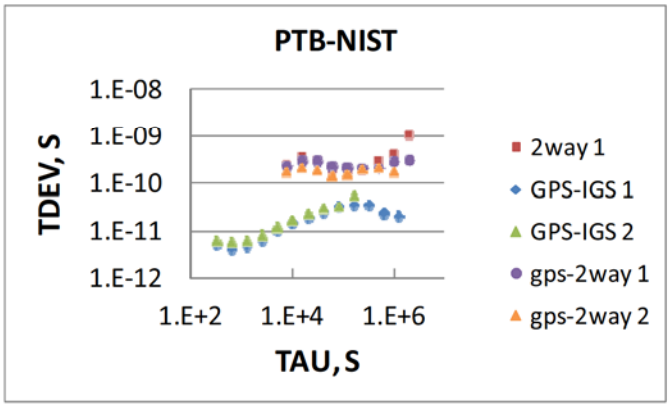


Figure 4. Time differences between solutions for clock pairs: USNO GPSCPTT – TWSTT, USNO GPSCPTT – IGS.

Figure 5. Time stability of the subtraction of solutions (Fig. 4): USNO GPSCPTT - IGS Segment 1, Segment 2; USNO GPSCPTT - TWSTT Segment 1 and Segment 2. Time stability of clock pair obtained from non-subtracted TWSTT measurements shown in red.

evaluation and the RSS combination of the two uncertainties. The uncertainties listed pertain to the entire period over which each CFPFS was evaluated – not just to the overlap time shown in Table 1 – and include the uncertainties of transfers into TAI. Thus, the RSS values of Table 1 show the least-stringent frequency uncertainty requirements GPSCPTT would have to meet to contribute new information to a joint CFPFS evaluation. A detailed treatment of frequency standard evaluation uncertainties is given in [6].

We computed frequencies from GPSCPTT, TWSTT and *BIPM Circular T* for the clock pairs and time periods shown in Table 1, assigning error bars based on the Allan deviation (ADEV) values shown in Fig. 6 or from values given in *Circular T*. We then checked if the frequency values from the three sources agreed within their uncertainties. Frequency values were computed using endpoints, i.e.,

$$y_{A\text{-}B}(t_2 - t_1) = [x_{A\text{-}B}(t_2) - x_{A\text{-}B}(t_1)]/(t_2 - t_1). \quad (1)$$

This test highlighted the need for more-reliable frequency

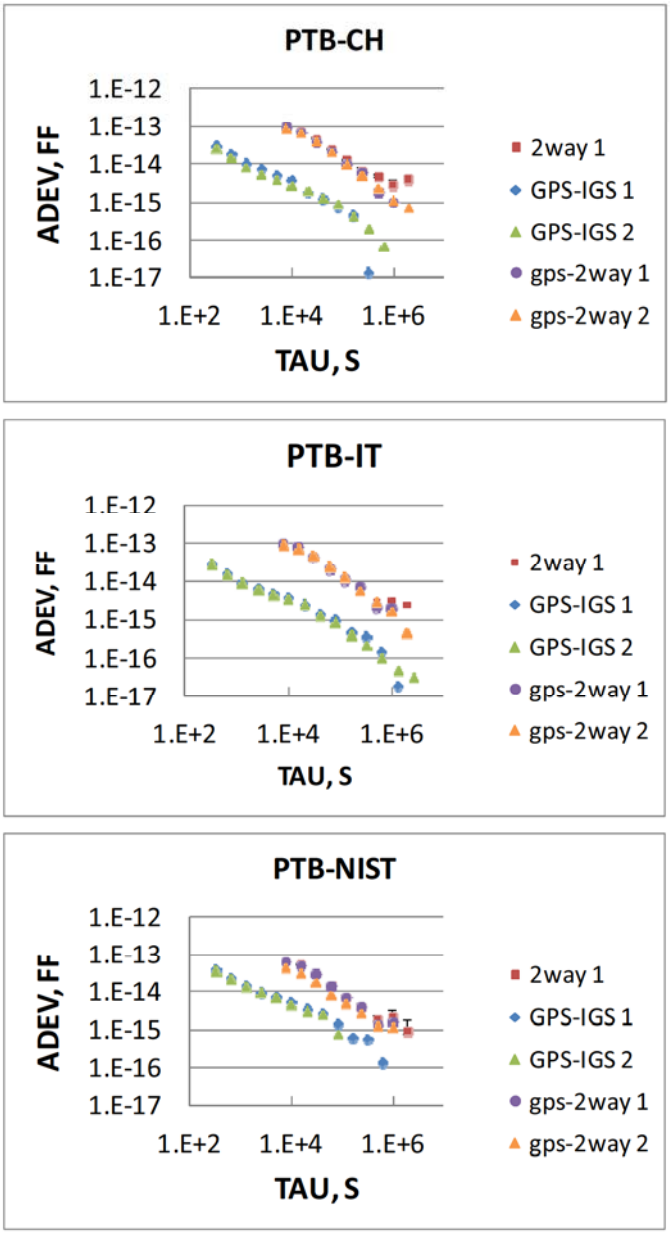

Figure 6. Frequency stability of the Fig. 4 subtraction of solutions: USNO GPSCPTT - IGS Segment 1, Segment 2; USNO GPSCPTT - TWSTT Segment 1 and Segment 2. Time stability of clock pair obtained from non-subtracted TWSTT measurements shown in red. GPS-IGS 1 outliers are likely caused by small sample sizes at large averaging times.

uncertainty values at averaging times of 10-20 d. As Fig. 6 shows, these averaging times meet or exceed the maximum for which Allan deviation values can be computed from the measurements under study. Therefore, in assigning error bars for a given averaging time, we generally used an ADEV from a smaller averaging time. Because the ADEV values (Fig. 6) decrease with averaging time, this led to conservative uncertainty estimates. Table 2 shows the uncertainties chosen

TABLE II. CHARACTERISTICS OF FREQUENCY COMPARISONS COMPUTED USING USNO GPSCPTT, TWSTT AND BIPM CIRCULAR T

Link	Dates (MJD)	Averaging Time (d)	Frequency Uncertainty (10^{-15}) (ADEV tau, d, in braces)		
			TWSTT	***GPSCPTT***	***Circ T***
PTB-IT	55399-409	10	2.4 (5)	N/A	3.5
	55569-89	20	1.8 (11)	0.054 (14)	2.3
PTB-NIST	55354-64	10	1.5 (5)	1	8.3
	55404-09	5	1.5 (5)	1	16
	55574-89	15	1.4 (5)	1	5.5
	55634-44	10	1.4 (5)	1	5.8

for each frequency comparison.

Fig. 7 shows the computed frequencies and error bars. As Fig. 7a shows, the *Circular T* values have large uncertainties, and therefore both GPSCPTT and TWSTT values agree with them. Fig. 7b shows only the GPSCPTT and TWSTT values. In all cases, the two values agree, but in some cases, a good fraction of the error bars is needed to reach agreement. This indicates that the uncertainty estimates were appropriate, that (1) is not an optimal frequency computation technique given the noise types present in the data, or some combination of both.

V. DISCUSSION

[7] indicates that frequency values obtained from TWSTT using the endpoint method (1) may be improved by using end points created by averaging 24 h of TWSTT measurements. More-detailed inspection of the ADEV, Modified Allan

deviation (MDEV), and time deviation (TDEV) values of our TWSTT measurements would confirm this true or false in our case. It may also be more appropriate to use MDEV rather than ADEV as a frequency uncertainty estimator if flicker PM noise is present [8].

Day-boundary discontinuities were not removed or otherwise mitigated when computing frequencies from the GPSCPTT values. The frequency uncertainty caused by these is thought to average out after approximately 8 d [9]; it is therefore possible that these degraded some of the GPSCPTT frequency computations. While the additional uncertainty caused by day-boundary discontinuities is not reflected in the USNO GPS – IGS difference, it is reflected in the USNO GPS – TWSTT difference, and therefore would have been incorrectly assigned to the TWSTT uncertainty. Nonetheless, the oversized uncertainty of the TWSTT values would have compensated the undersized uncertainty of the GPSCPTT values, allowing the error bars to meet in Fig. 7 regardless.

The computational methods of [9, 10] circumvent the added frequency uncertainty associated with day-boundary discontinuities. However, [9] would require modification of processing algorithms, and [10] yields biased frequency values when days of data are missing (as was true in this case). Therefore, neither was attempted here.

VI. Conclusions

The time stability of USNO GPSCPTT estimates lies between tens and a few hundreds of ps, based on comparisons with TWSTT and IGS rapid combined values. This time stability remains nearly constant as averaging time increases, indicating that better frequency-estimation uncertainty can be achieved by averaging over longer periods.

The frequency stability of USNO GPSCPTT estimates is between 10^{-15} and 10^{-14} at an averaging time of 1 d based on comparisons made as above. Subtraction of USNO and IGS GPSCPTT estimates along the PTB-CH and PTB-IT links indicates that 10^{-16} stability may be achieved in 10 d.

An attempt was made to compute frequency values from TWSTT and GPSCPTT data in a manner similar to that which might be used in a primary frequency standard comparison. This indicated that (a) more study is needed to obtain reliable frequency uncertainty estimates at averaging times typical of fountain evaluations (15-25 d), (b) refinement is needed in the frequency computation techniques used (by us) and (c) a reduction of the uncertainty associated with the processing of GPSCPTT data would likely be needed as well.

Acknowledgment

The IGS provided the raw GPS measurements and a priori orbit/clock values used in USNO GPSCPTT data analysis. Constructive comments were contributed by Mr. Nick Stamatakos and the USNO editorial board.

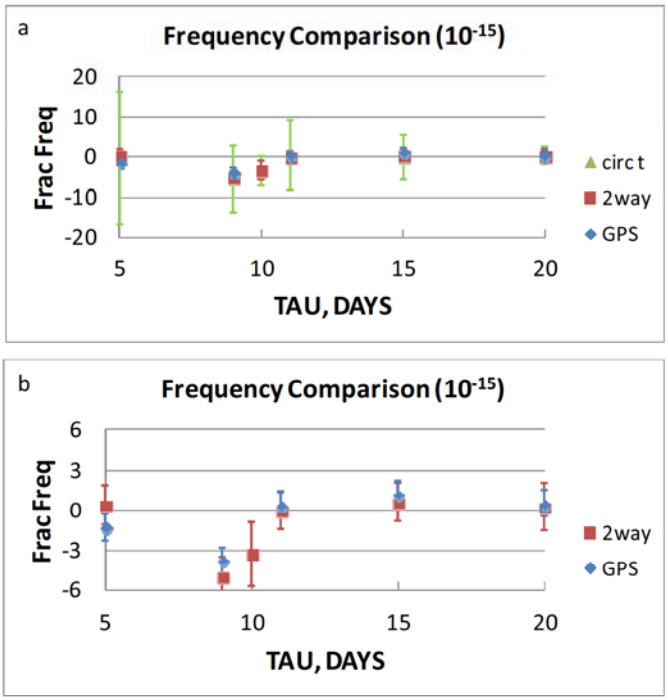

Figure 7. Fractional frequency of PTB-IT and PTB-NIST clock values as estimated using *BIPM Circular T*, TWSTT, and USNO GPSCPTT. Values with 10-day averaging times were plotted at tau = 9, 10 and 11 days for better visibility.

analysis centers use a variety of software and models in creating their results. We use the difference between USNO and IGS GPSCPTT values to create a lower bound for USNO GPSCPTT uncertainty estimates.

III. RESULTS

Fig. 1 shows the time differences for the three clock pairs as measured using TWSTT and GPSCPTT. Each set of measurements was divided into two segments, 55287 – 55470 (Segment 1) and 55474 – 55651 (Segment 2), due to hardware outages/discontinuities. A mean value was removed from each segment to compensate uncalibrated hardware delays. Despite the fact that GPSCPTT provides 288 measurements per day and TWSTT only 12, the GPSCPTT results have lower short-term noise. The GPSCPTT and TWSTT values agree well long-term.

Figs. 2-3 show the frequency and time stability of the clock differences shown in Fig. 1. The stability values include both clock and measurement noise. Stability values were computed independently for Segments 1 and 2.

Figs. 2-3 show that for each clock pair, the two GPS segments have similar stability as do the two TWSTT segments. Fig. 2 shows that the frequency stability of the TWSTT measurements is worse than that of GPSCPTT in short-term, with the frequency stabilities of the two measurement sets coming together at about 3-10 d. Fig. 3 shows a similar result for the time stability of the two techniques, with the time-stability values of the two measurement sets becoming similar at 1-3 d. The per-measurement noise of the GPSCPTT measurements is around 10 ps, whereas that for TWSTT is a few hundred picoseconds.

Fig. 4 shows the subtracted values GPSCPTT-TWSTT and GPSCPTT-IGS. The GPSCPTT-TWSTT differences have a point-to-point noise of +/- 2 ns along with some long-term variations. The GPSCPTT-IGS values of Fig. 4 are miniscule in comparison, with a jitter level well under 100 ps.

Fig. 5 shows the time stability of the subtracted values, along with Segment 1 TWSTT time stability of the non-subtracted values for reference. The GPSCPTT-IGS time stability remains below 10 ps out to averaging time (tau) =4800 s, then rises to tens of picoseconds as tau increases, and then remains at that level (with some variations) as tau further increases. The GPSCPTT-TWSTT differences have a time stability of a few hundred ps which generally remains constant (minus a few variations) for all averaging times. Fig. 5 shows that the TWSTT values must be averaged for 32 – 64 hours to access the time stability of the clock pairs.

Fig. 6 shows the frequency stability of the subtracted values, which in both subtraction pairs trends downward with increased averaging time (a consequence of time stability that remains constant as averaging time increases). The GPSCPTT-IGS frequency stability values remain nearly an order of magnitude better than the GPSCPTT-TWSTT values

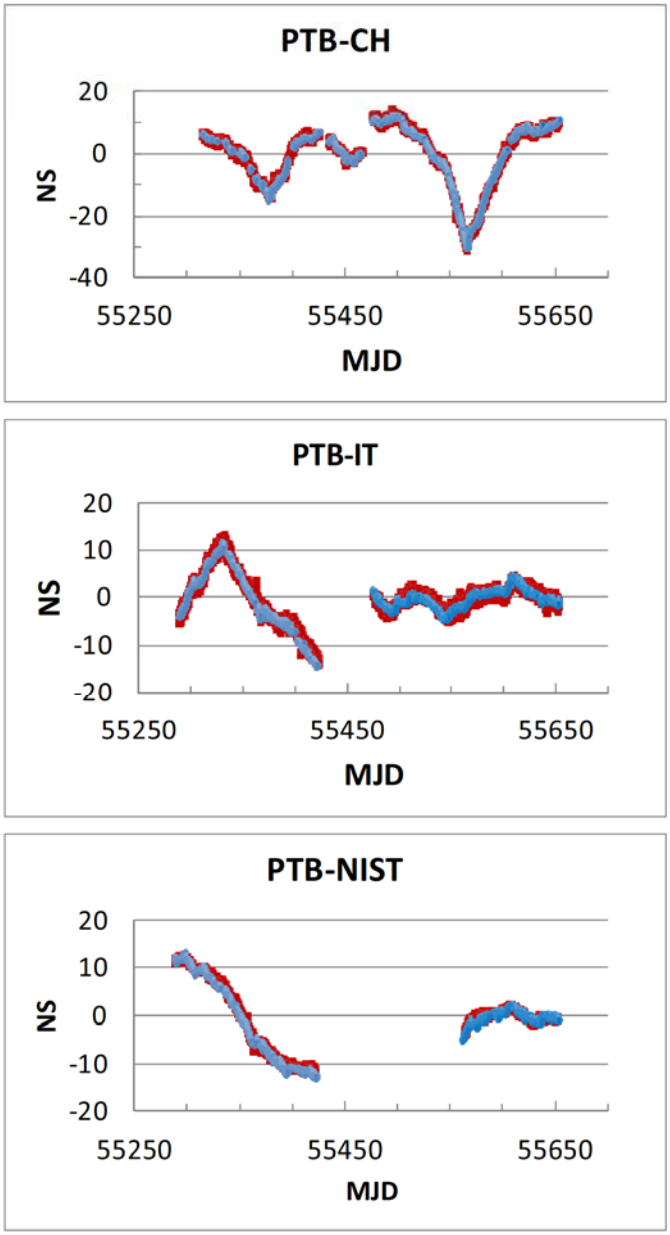

Figure 1. Time differences between clock pairs measured using TWSTT and USNO GPSCPTT. A (different) mean was removed from the two TWSTT and two GPSCPTT segments (55287 – 55470; 55474 – 55651) of each clock pair. Day-boundary discontinuities were not removed.

for averaging times past 10 d. The GPSCPTT-IGS values have a stability of $1 \cdot 10^{-15}$ or better at tau = 1 d, which decreases to $1 \cdot 10^{-16}$ at 8-10 d, except possibly along the the PTB-NIST link. The GPSCPTT-TWSTT differences have a frequency stability of about $1 \cdot 10^{-14}$ at 1 d. Along the PTB-NIST link, it is unclear whether the combined TWSTT-GPSCPTT link noise ever averages down enough to access the frequency stability of the PTB-NIST clock pair.

PPP using NRCan Ultra Rapid products (EMU): near real-time comparison and monitoring of time scales generated in time and frequency laboratories

***Abstract*— The Precise Point Positioning (PPP) time-transfer technique requires the availability of precise estimates of GNSS satellite orbits and clock offsets. Several such products are available from the International GNSS Service (IGS), each having their own characteristics: robustness, update rate, latency and satellite clock offset time interval. The most frequently updated IGS products are the Ultra Rapid products, which are generated four times a day with a latency of three hours. Natural Resources Canada (NRCan) contributes its own Ultra Rapid GPS product to the IGS for combination. However, the underlying processes running at NRCan generate products much more frequently - 24 times a day - with a latency of 90 minutes, offering an opportunity for more timely time-transfer results when used in PPP. INRIM and NRCan hereby assess the potential of using the PPP with the NRCan Ultra Rapid GPS products to serve as a short latency time-transfer tool. A specific experiment has been set up, where the NRCan Ultra Rapid GPS products, as well as all currently available IGS products, are used in PPP time transfer between selected IGS stations collocated in timing laboratories. Results and relative merits are compared in light of their respective delivery and frequency stability characteristic, in view of designing an automated near real-time monitoring system to assist timing laboratories in operational maintenance of frequency standards and time scales dissemination to external users.**

I. INTRODUCTION

The PPP time-transfer technique [1] requires the availability of precise estimates of GNSS satellite orbits and clock offsets. Several such products are available from the IGS [2], each having their own characteristics in terms of robustness, update rate, latency and satellite clock offset time interval. The most frequently updated IGS products are the Ultra Rapid products, which are generated four times a day with a latency of three hours. NRCan contributes its own Ultra Rapid product to the IGS for combination. Moreover, the underlying processes running at NRCan generate these products much more frequently, 24 times a day, with a latency of 90 minutes. When used in PPP processing, the reduced latency of Ultra Rapid products and their quality, as will be shown later, offer an opportunity for more timely time-transfer results.

Hence two objectives were sought undertaking this work: 1) assess the potential of using Ultra Rapid products in PPP to serve as a short latency time-transfer tool; and 2) prototype an automated near real-time monitoring system.

II. EXPERIMENT

In order to evaluate the time transfer capabilities of the NRCan PPP and NRCan Ultra Rapid products as a monitoring tool to assist timing laboratories in their operational maintenance of frequency standards and time scales dissemination to external users, a specific experiment has been set up.

A. Precise satellite orbit and clock products

As indicated in Table I, a list of external products have been taken into account, namely the NRCan Ultra Rapid (EMU), the IGS Ultra Rapid (IGU) and the IGS Rapid (IGR) products.

978-1-61284-110-6/11/$26.00 ©2011 IEEE

1) NRCan Ultra Rapid products (EMU)

The EMU products are generated hourly with a delay of 90 minutes after the last observation. They consist of a SP3 format orbit/clock file at 15 minutes interval for all satellites in the GPS constellation, covering a total of 48 hours, the first 24 hours being estimated from observations and the last 24 hours being an extrapolation of the orbital elements and clocks. Also included is a RINEX clock format file at 30 seconds interval for all satellites in the GPS constellation for the 24 hours estimated portion only. The EMU products generation process was described in [3].

2) IGS Ultra Rapid products (IGU)

The IGU products are generated 4 times a day with a delay of 3 hours after the last observation as a combination of up to seven individual Analysis Center solutions, including the NRCan EMU products. The IGU products also consist of a SP3 format orbit/clock file at 15 minutes interval for all satellites in the GPS constellation, covering a total of 48 hours, the first 24 hours being estimated from observations and the last 24 hours being an extrapolation of the orbital elements and clocks. However there are no associated RINEX clock format files, so the satellite clock interval is restricted to 15 minutes.

TABLE I. PRECISE SATELLITE PRODUCTS

Label	Description	Update Interval	Delay[a]	Clock Interval	Time Reference
IGR	IGS Rapid	24 hr	17 hr	300s	Timescale IGRT
IGU	IGS Ultra Rapid	6 hr	3 hr	900s	Piecewise alignment
EMU	NRCan Ultra Rapid	1 hr	1.5 hr	30s	

a. after last observation

TABLE II. IGS STATIONS SELECTED

WSRT	Westerbork, Netherlands	AOA SNR-12 ACT	HM

a. HM: Hydrogen Maser; Cs: Cesium Frequency standard

3) IGS Rapid product (IGR)

The IGR products are generated daily with a delay of 17-18 hours after the last observation as a combination of up to eight individual Analysis Center solutions. The IGR products consist of a SP3 format orbit/clock file at 15 minutes interval for all satellites in the GPS constellation and a RINEX clock format file at 300 seconds interval for all satellites in the GPS constellation. All clock estimates are referred to the IGRT timescale [4].

Fig. 1 shows the median satellite orbit and clock RMS differences of EMU and IGU with respect to IGS Rapid products. It can be seen that the orbit and clock quality are comparable at the levels of 2-4cm and 80-100ps respectively. It can also be seen how the prediction degrades, especially for the clocks.

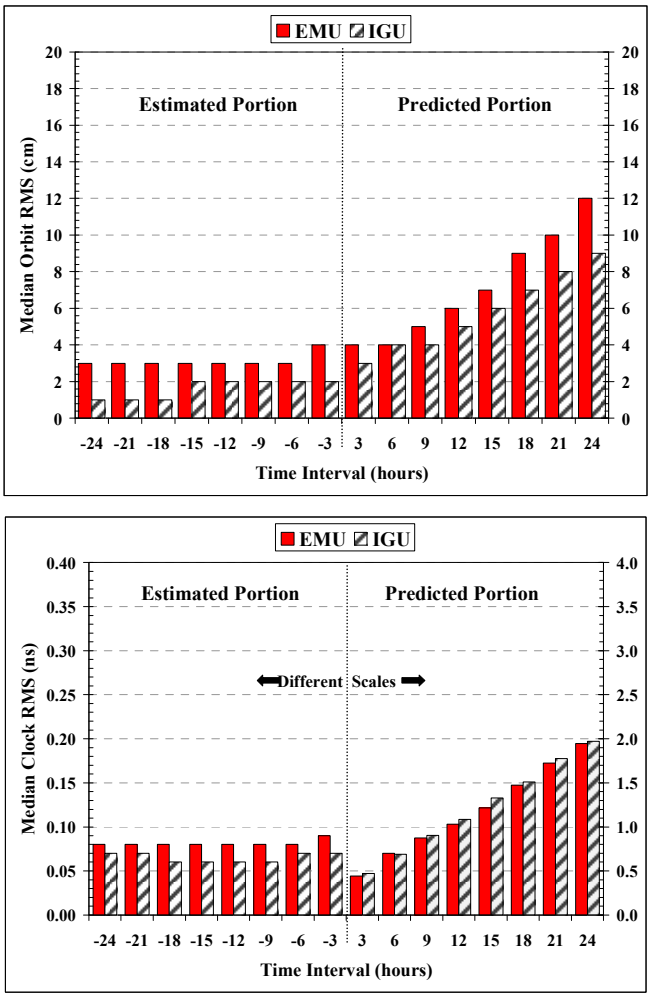

Figure 1. Median satellite 3-D position (top) and clock(bottom) RMS of EMU and IGU vs IGR.

B. IGS stations selected

As indicated in Table II, a set of 12 IGS stations, mostly co-located in time and frequency laboratories, have been selected and considered. Their daily and hourly RINEX 30 seconds observation files have been automatically retrieved and processed by means of the NRCan PPP algorithm.

C. Automated processing

In order to have an automated operational process, procedures able to periodically retrieve the required PPP input, namely the RINEX station observation files and the products described above, were developed and operated on an NRCan computer. Three independent automated processes are regularly scheduled:

- a process gathering the hourly/daily RINEX observation files for the selected 12 stations, running three times per hour, namely 10, 30 and 50 minutes after the hour;
- a process gathering the orbit and clock products (EMU, IGU and IGR), running every 10 minutes, namely 0, 10, 20, 30, 40 and 50 minutes after the hour;
- a process checking the presence of specific instances of each product within their availability window, running every 10 minutes, namely 5, 15, 25, 35, 45 and 55 minutes after the hour; this process triggers PPP processing whenever a specific product instance is detected.

As soon as a specific product instance is available, the PPP processing for the 12 selected stations is scheduled using the available data and specified products. For each of the product types, the multiday product selection is as follows:

- the EMU products for each of the initial 5 days, plus the latest EMU product, covering the hours of the additional day (1, 2, 3, … , 24 hours);
- the IGU products for each of the initial 5 days, plus the latest IGU product covering the hours of the additional day (6, 12, 18 and 24 hours);
- only those data files containing the full 6 days are processed with the corresponding IGR products.

The station RINEX data files are concatenated to span the previous 5 days and the first n hours of current day corresponding to the current product instance time span (estimated portion only in the case of Ultra Rapid products). This process provides multiple RINEX data file for each station per day, each file n hours longer than the previous and the last file covering the full 6 days.

The NRCan PPP version considered for this experiment is Version 1.5, Release 06010, characterized by the following new features:

- 2003 IERS tide model;
- Global Pressure & Temperature (GPT) model [5] for hydrostatic troposphere delay;
- Kouba's simplified yaw/attitude model [6];
- adaptive widelane & narrowlane thresholds for cycle clip detection;
- kinematic antenna orientation tracking;
- station clock constraints;
- GLONASS-only and GPS+GLONASS processing.

The multi-day solutions were generated using dual-frequency pseudorange and carrier-phase with a 10° elevation mask and exercising the adaptive widelane and narrowlane cycle slip detection. One static position was estimated for the whole multiday period with earth tides and ocean loading applied. Hydrostatic tropospheric delays were modeled with Hopfield using pressure and temperature from the GPT model and 50% relative humidity. The wet troposphere delay component was estimated with 0.05m/√hr process noise as well as North and East hydrostatic delay gradients. Finally the station clocks were estimated at the interval of the satellite clock products, without constraints. Note the EMU 30 second RINEX satellite clock files were decimated to 300 seconds to speed-up the processing. No GLONASS observations or products were used herein.

The NRCan PPP station clock estimates related to each product are respectively labeled PPP(IGU) at 900 seconds interval, and PPP(IGR) and PPP(EMU), at 300 seconds interval.

III. RESULTS

The three automated processes were operated continuously over 6 weeks, namely for the MJD 55399-55441 period (2010 July 22 – 2010 September 2; GPS Week 1593(day 4) – 1599(day 4)), yielding 8844 PPP(EMU) solutions, 1483 PPP(IGU) solutions and 450 PPP(IGR) solutions. All solutions were automatically graphed and posted on a private WWW page.

Over the experiment period there were many missed hourly RINEX observations files but no product outages. The delay in obtaining monitoring results was 1h40-2h00 for PPP(EMU) solutions, 3h20 to 3h40 for PPP(IGU) solutions and 17hours to 18 hours for PPP(IGR) solutions. There were two problems in PPP solutions where receiver tracking malfunctions were misidentified for 1ms jumps in data, causing the resulting clock phase graphs to be unreadable.

A. Effect of clock product time reference

The top two panels of Fig. 2 shows PPP(EMU) results for two single stations, USN3 and AMC2. The rough alignment of the time reference of the Ultra Rapid clock products to GPS

time is quite clear, the clock phase and frequency jumps being readily apparent. For a meaningful clock monitoring application the single station PPP clock results will need to be differenced between stations to remove the discontinuous time reference, as shown in the bottom panel of Fig. 2.

B. Monitoring results

For visual appreciation of the consistency of the monitoring results, Fig 3 shows examples of all 6-day PPP(EMU) solutions ending on Sundays and Wednesdays at 0h00 for all baselines between USN3, AMC2 and BRUS stations. Each solution thus overlaps by 3 or 4 days with the previous one. The PPP(IGU) solutions are similar but at 900 seconds interval rather than 300 seconds.

The AMC2-BRUS and USN3-BRUS baselines show a slow frequency drift followed by a correction in the later part of August 2010.

TABLE III. IGR-EMU DOUBLE DIFFERENCE STATISTICS

Baseline	Bias (ns)	SDev[a] (ns)	RMS (ns)	Max(|Δφ|) (ns)	Max(|Δf|) 10^{-15}
USN3-AMC2	0.037	0.063	0.073	0.285	1.66
USN3-BRUS	-0.075	0.109	0.132	0.522	1.87
USN3-IENG	0.017	0.111	0.112	0.331	3.32

TABLE IV. IGR-IGU DOUBLE DIFFERENCE STATISTICS

Baseline	Bias (ns)	SDev[a] (ns)	RMS (ns)	Max(|Δφ|) (ns)	Max(|Δf|) 10^{-15}
USN3-AMC2	-0.017	0.075	0.077	0.240	1.16
USN3-BRUS	-0.074	0.159	0.175	0.503	2.33
USN3-IENG	-0.040	0.136	0.142	0.441	2.06
USN3-NRC1	-0.005	0.066	0.066	0.442	1.52
USN3-NRL1	0.004	0.092	0.092	0.520	2.71
USN3-PTBB	-0.135	0.138	0.193	0.509	1.82
USN3-SFER	-0.133	0.179	0.223	1.542	2.70
USN3-SPT0	-0.028	0.141	0.144	1.037	2.83
USN3-SYDN	-0.140	0.200	0.244	3.035	4.68

a. standard deviation about mean bias

C. Quality of PPP(EMU) and PPP(IGU)

The PPP(EMU) and PPP(IGU) baseline solutions involving USN3 were differenced with the corresponding PPP(IGR) solutions for all 6-day solutions ending on Sundays and Wednesdays 0h00 during the experiment campaign. The mean bias, standard deviation about mean bias, RMS and maximum absolute value of the double differences are reported in Table III and IV and examples are given in Fig. 4.

Most baselines show biases of less than 100ps and standard deviations of less than 150ps. In Fig. 4 some baselines show signs of frequency biases. The frequency bias was estimated for each solution by differencing the first and last double difference clock phases and their maximum absolute value is reported in Table III and IV. In most cases the frequency bias does not exceed few parts in 10^{15}.

IV. CONCLUSION

NRCan PPP estimates generated using the NRCan and IGS Ultra Rapid products show a good agreement with respect to those obtained using IGS Rapid products. The level of performance is very promising, especially taking into account the reduced latency of the station clock product of about 2 hours when using NRCan products. The monitoring process can detect nanosecond level clock phase jumps and few parts in 10^{15} clock frequency changes. Although the processing is demanding in terms of computation time and robustness, it was possible to effectively automate the whole process, from data collection to plotting of the stations clock differences. Use of several products is recommended, as was done herein, to cover for potential product outages. The station clock differences obtained using Ultra Rapid and Rapid products could be posted in an dedicated webpage to provide the timing community timely information, helping in maintaining an objective level of "quality of service" for the time and frequency laboratories.

ACKNOWLEDGMENT

The authors thank the many institutions and individuals, including NMI, for their efforts in voluntarily contributing data and products to the IGS [2]. Precise single station GNSS application such as the Precise Point Positioning would not exist without them.

Abstract — **The GNSS reception chains (timing receiver + antenna + antenna cable) are used to perform time comparisons of remote atomic clocks. This time transfer system represents the basis of the time laboratories contributions for the realization of the Temps Atomique International (TAI). The calibration of these chains are necessary to ensure accuracy and long term stability of time links used in TAI but also in precise time station (PTS) dedicated to GALILEO.**

Currently, the most widely used approach to determine the electrical-delay of these devices is the differential method developed by the BIPM (Bureau des Poids et Mesures). Another solution is the absolute calibration of each reception chain element in using artificial signals. This method was first defined and put into operation by NRL (Naval Research Laboratory) and the University of Colorado. In 2005, CNES (Centre National d'Etudes Spatiales) decided to develop this technique with a similar approach.

This paper will compare the results of NRL and CNES absolute calibrations performed on two different time transfer systems. First of all, it will describe the calibration method used by each laboratory and the differences which characterize them. An uncertainty budget will be presented for the results of both calibration techniques. Then, both time transfer systems, composed of different receivers and antennas models, will be described briefly. Finally, the absolute calibrations results performed using the NRL and the CNES methods will be compared..

I. INTRODUCTION

The construction and the diffusion of the time scales rely on the utilization of navigation and telecommunication satellites system. Thanks to this ease of access and use, the GNSS (Global Navigation Satellites System) time and frequency transfer is the most used tool to compare remote clocks. The present GNSS reception chains (multi-channel, multi-frequency receiver + cable + antenna) and the evolution of data treatment techniques (P3 or PPP methods) allowed remote comparison of clocks with a statistical uncertainty of a few nanoseconds [1, 2]. Currently, the global uncertainty of these measurements is dominated by the systematic uncertainty of the reception chain calibration. This measurement is ensured by the BIPM (Bureau International des Poids et Mesures) in using the differential calibration [3]. One GNSS system is designated as the reference and is in constant circulation among time laboratories. A relative calibration is performed between this reception chain and the laboratory GNSS equipment where both are referenced to the same clock. With this method, the electrical delay of the GNSS implement is determined with an uncertainty of about 2.5 ns for P1 or P2 (k=1).

Another method, the absolute calibration, using artificial signals showed it is possible to calibrate the reception chain with an uncertainty budget inferior to 1 ns (k=1) [4,5].

This paper proposes a comparison of absolute calibrations performed at NRL (Naval Research Laboratory) and at CNES (France space agency) with two different GNSS reception chains. The first part is dedicated to the receiver calibration method when the second part describes the antenna calibration method. In both cases, the general principle of methods and the differences characterizing the approaches used by CNES and NRL will be presented. Finally, a calibrations comparison of the different reception chains performed at CNES and NRL will be discussed in the last part.

II. RECEIVER CALIBRATION

The absolute calibration method was first defined and put into operations by NRL [6] and the University of Colorado [4]. Since 2005, CNES is developing this method with a similar approach [5,7].

A. *Principle*

The approach of the receivers calibration consists in an artificial reception free of delays, effects and noises upstream at the output of antenna: atmospheric delays (troposphere and ionosphere), multipath effects or antenna delay. These conditions can be only conducted with a GNSS Signal Simulator (GSS) (Figure 1). The GSS allows to simulate the signals emitted by the GNSS satellites in real conditions. It is able to produce the GNSS signal but also all the noises resulting of natural reception (signal propagation or clock error,…).

The absolute calibration needs a emitted signal without noises. The simulator generates only the navigation message

and two carrier frequencies: L1 modulated by the C/A and P codes and L2 modulated by P code.

The power of the radiofrequency (RF) signal is -70 dBm and must be adjusted to correspond to the reception level acceptable by the receiver (-110 dBm generally). It provides also a 1PPS (1 Pulse Per Second) signal which lets the receivers to be synchronized with the simulator.

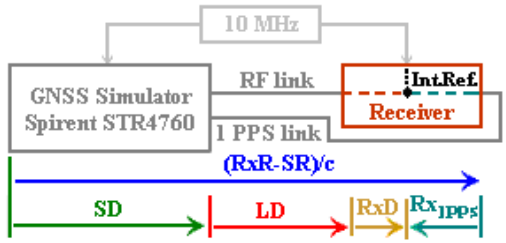

Figure 1. Schematic of receiver absolute calibration

The internal electrical time delay of the receiver is calculated thanks to (1):

$$RxD = \frac{RxR - SR}{c} - LD - SD + Rx_{1PPS} \qquad (1)$$

where:
- *RxD:* Receiver delay [ns]
- *RxR-SR:* Difference between the receiver and simulator pseudo-ranges [m]
- *c:* Light celerity (299 792 458 $m.s^{-1}$)
- *LD:* 1PPS and RF links delays difference (LD_{RF}-LD_{1PPS})
- *SD:* Simulator delay [ns]
- Rx_{1PPS}: Time delay between the receiver internal reference and the external 1 PPS [ns]

During the calibration measurement, due to their temperature sensitivity, the receivers and the simulator are located in a room regulated in temperature.

B. Main differences between both techniques

There are several hardware differences between the CNES and the NRL calibration benches. The NRL receiver calibration bench is equipped with a GPS signal simulator Spirent GSS8000. The reference signals are generated by a Symmetricom 5071A clock. At CNES, the simulator used is a Spirent STR4760 and a MASER EFOS supplies the reference signals. The oscilloscope used by CNES and NRL is the same model: a fast digital Tektronix DPO7000.

At NRL, the calibrations are performed in room where the temperature is equal to 297 ± 3 K (24°C). The temperature regulation of the CNES laboratory is of 293 ± 1 K (20°C).

Three points differentiate the CNES and NRL methods used to calibrate the time receivers:

- *The simulator calibration method*

One of principal differences between the NRL and CNES absolute methods is the way to calibrate the simulator. The internal delay of the simulator corresponds to the delay between the beginning of the PRN C/A code and the internal 1 PPS synchronized with the GPS time. In amplifying a single channel C/A code, the time difference between the rising 1PPS and the code transition can be measured with an oscilloscope.

The NRL method consists in determining the time difference by direct reading (Tick-to-Code) with an oscilloscope. With this approach, the measurement uncertainty is about 0.2 ns [4]. The CNES method is based on the same measurement but where a post-treatment is added. The technique used is the correlation which looks like a standard GPS signal acquisition. It consists of determining the code offset versus the PPS generated by the simulator and the residual carrier phase offset. This method improves upon the simulator calibration because the time delay is estimated over more than one code transition [5]. The measurement uncertainty is the integration time of the correlation which is equivalent to the oscilloscope resolution. The oscilloscope used has a resolution of 0.1 ns which will be therefore the uncertainty of the correlation.

The CNES uses a specific function of the GSS software : the "Single Channel" setting. This program generates one signal C/A on one channel without the navigation message. for To calibrate the simulator, the NRL uses a scenario of a geostationary satellite because for the Spirent simulator models 7700 and higher the "single channel utility" gives incorrect results. It works fine on the 2760 and 4760. It was checked that both methods give the same results on a STR4760 simulator.

- *The pseudo-ranges of the simulated constellation*

The NRL constructs the pseudo-ranges of the simulated constellation from the navigation files generated by the receiver. The CNES uses the pseudo-ranges directly supplied by the simulator. The calibrations comparison give the same results in using both treatments with the GSS8000..

- *The utilization of the RF and 1 PPS links*

At CNES, the links used for the simulator and the receiver calibration are not the same. Two different cables are used to transmit the 1 PPS signal between the simulator and the oscilloscope (simulator calibration) and between the simulator and the receiver (receiver calibration). Two RF links are also used. During the receiver calibration (RxD), the RF link is composed of a cable, attenuators and a bloc DC to obtain a acceptable power level for the receivers. For the simulator calibration (SD), the RF link is different, consisting of a cable, an isolator and an amplifier to visualise the signal with an oscilloscope. The RF and the 1 PPS links of the NRL absolute calibration bench are the same for the simulator and the receiver calibration. The RF link is made up of a cable, an amplifier, variable attenuators and a DC block.

C. Uncertainty budget of the receiver calibration

- CNES typical uncertainty budget

The uncertainty of the receiver delay is the quadratic sum of the measurement uncertainty of the simulator calibration, the RF and 1 PPS links, the pseudo-ranges difference and the

parameter Rx_{1PPS}. The uncertainty varies according to the receiver kind [8]. This difference is due to the calculation and the measurement technique of the Rx_{1PPS} parameter which is defined by each manufacturer.

TABLE I. UNCERTAINTY BUDGET OF DIFFERENT RECEIVERS ABSOLUTE CALIBRATION

Uncertainty source	Receivers calibration uncertainty [ps] (k=1)	
	Septentrio	*Dicom*
SD (Simulator STR4760)	351	351
LD_{RF} (RF link)	36	36
LD_{HF} (1 PPS link)	25	25
RxR-SR	135	161
Rx_{1PPS}	184	-
U(receiver)	**421**	**389**
Expanded U (Rx)	**842**	**778**

The simulator uncertainty takes into account the uncertainties of RF and 1 PPS links measurement, the correlation uncertainty (oscilloscope resolution), the pseudo-ranges error and interchannel bias (provided by the constructor). The RF link delay is measured through a VNA (Vector Network Analyzer). The 1 PPS link delay is determined with a Time Counter Interval in employing the double weight method. For the Septentrio receiver, the Rx_{1PPS} is measured with a time interval counter. It is not necessary to determine the Rx_{1PPS} value for the Dicom receiver because the output data are automatically corrected of this bias at each GPS acquisition.

- NRL typical uncertainty budget

The uncertainty of the receiver delay is the quadratic sum of the measurement uncertainty of the Tick-to-Phase, the Tick-to-Code, the delays of RF pads, in the connectors, in the DC block and the simulator accuracy [4].

TABLE II. ERROR ESTIMATE OF THE RECEIVER ABSOLUTE CALIBRATION

Uncertainty source	Error estimate [ps] (k=1)
Tick-to-Code	200
Delay in Rf pads	100
Delay in the connectors	100
Delay in the DC block	100
Simulator accuracy	1000
U(receiver)	**1000**
Expanded U (Rx)	**2000**

III. ANTENNA CALIBRATION

A. *Principle*

The antenna calibration consists of estimating the time-delay due to the signal propagation through the antenna. It will be therefore necessary to determine the input and output ports of the signal in the device. An antenna allows the transition of the electromagnetic wave between a guided environment (cable) and a free environment (air). One of the access ports will be defined by the connector (antenna/cable). The other port is defined by the position of the phase center which is the interface point between the guided environment and the free space.

Antennas used in GNSS reception chain for the time transfer are active (included an internal amplifier) and have a Right-Hand Circular Polarization (RHCP). The amplifier does not allow the reciprocal signal crossing through the antenna. To calibrate this kind of equipment, it is necessary to use the method in transmission presented in Figure 2. This experiment is performed in an anechoic chamber in order to limit the multi-path effect. The measurement of the transmission delay between both ports of a VNA gives access to the value of the antenna group delay. The signal supplied by the VNA is transmitted by a passive antenna to the receiving antenna (element to calibrate). The receiving antenna sends then the signal to the second port of the VNA.

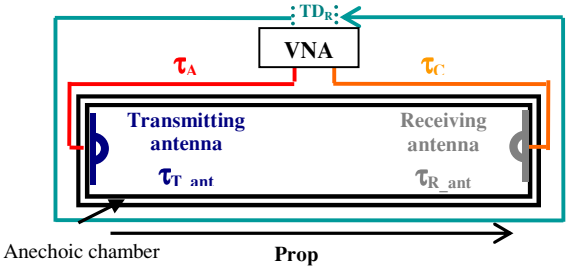

Figure 2. Schematic of a GNSS antenna absolute calibration

In using the method in transmission, the group delay of the receiving antenna is defined by the following equation (2):

$$\tau_{R\_ant} = TD_R - \tau_A - \tau_{T\_ant} - Prop - \tau_C \qquad (2)$$

where:

- $\tau_{R\text{-}ant}$: Electrical delay of the receiving antenna [s]
- TD_R: Total time delay of the transmission measurement [s]
- τ_X: Electrical delay of the cable X [ns]
- $\tau_{T\text{-}ant}$: Electrical delay of the transmitting antenna [s]
- *Prop:* Delay due to the signal propagation in the air [s]

B. *Main differences between both techniques*

There are also hardware differences between the NRL and CNES antenna calibration benches. The VNA used by CNES is a Wiltron 37200A. The transmitting antenna is a GPS antenna 704-X. The anechoic chamber is covered of *Eccosorb CV* absorbents that the rejection rate at 1.5 GHz is of 10 dB.
And another hand, the NRL uses a Broadband Dual Polarized transmitting antenna, a TECOM antenna (1-4 GHz). The NRL VNA is a Agilent 8722ES. The reference of the anechoic chamber absorbents is not known.

The principal difference between the NRL and CNES approaches to determine the internal delay of a GNSS antenna is the calibration of the transmitting antenna.

- *The transmitting antenna calibration*

To perform the antenna calibration with the method in transmission, the delay of the transmitting antenna must be known; thus it must be calibrated. Two methods are available to calibrate a passive antenna: the method in transmission (with two identical antennas or with the three-cornered hat method) or the method in reflection.

CNES uses a GPS antenna with a right circular polarization. To calibrate this antenna, it is necessary to use a measurement in transmission. With both identical antennas, the group delay of the antenna is defined by the following equation (4):

$$\tau_{T\_ant} = (TD_R - \tau_A - Prop - \tau_C)/2 \quad (4)$$

where:
- τ_{T_ant}: Electrical delay of the transmitting antenna [s]
- TD_R: Total time delay of the reflection measurement [s]
- τ_X: Electrical delay of the cable X [s]
- *Prop*: Delay due to the signal crossing in the air [s]

The NRL uses a bipolarized antenna that can be calibrated with the method in reflection. During this measurement, the signal supplied by the VNA and emitted by the antenna is reflected by an element placed downstream to the output port at a known distance.

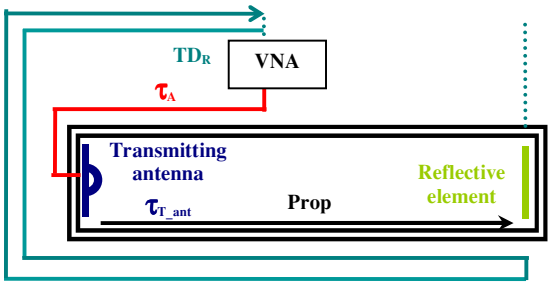

Figure 3. Antenna calibration with the method in refection

In using the method in reflection, the group delay of the transmitting antenna is defined by the following equation (5):

$$\tau_{T\text{-}ant} = (TD_R/2) - \tau_A - Prop \quad (5)$$

where:
- τ_{T_ant}: Electrical delay of the transmitting antenna [s]
- TD_R: Total time delay of the reflection measurement [s]
- τ_A: Electrical delay of the cable A [s]
- *Prop:* Delay due to the signal crossing in the air [s]

C. *Uncertainty budget of the antenna calibration*

- CNES typical uncertainty budget

The CNES antenna calibration uncertainty in using the method in transmission is composed of the measurement uncertainty of the total delay, the RF links, the distance between both phase centers and the uncertainty calibration of the transmitting antenna..

TABLE III. TYPICAL UNCERTAINTY OF THE ANTENNAS ABSOLUTE CALIBRATION

Source uncertainty	**Antenna calibration uncertainty [ps] (k=1)**		
	Novatel 702-GG	***Ashtech Choke-ring***	***Leica Choke ring 3D***
TD_T	301	308	309
τ_A/τ_C	36	36	36
Prop	210	210	210
$\tau_{T\text{-ant}}$	267	267	267
U(Antenna)	**456**	**461**	**461**
Expanded U (Ant)	**912**	**922**	**922**

The total delay uncertainty corresponds to the instrument measurement noise, the VNA. The propagation error takes into account the variations of the phase centers and the measurement error of the distance between both antennas. The time delay of the transmitting antenna was determined with the method in transmission with two identical antennas.

- NRL typical uncertainty budget

The NRL uncertainty estimation of the antenna calibration takes into account the errors due to the cable A, the anechoic chamber, the cable C and the total delay measurement. The total uncertainty of the antenna calibration is the quadratic sum of these error sources. [4].

TABLE IV. ERROR ESTIMATE OF ANTENNAS ABSOLUTE CALIBRATION

Source uncertainty	**Error estimate [ps] (k=1)**
CableA /Chamber	100
Cable C	100
Tota delay	100
U(Antenna)	**200**
Expanded U (Ant)	**400**

IV. RESULTS COMPARISON

The Figure 4 presents the results of the receivers absolute calibration in using the NRL and the CNES methods. This comparison was performed for a Dicom GTR50 receiver and a Septentrio PolaRx receiver.

The NRL measurement will be taken as the comparison reference for all the graphs presented in this section.

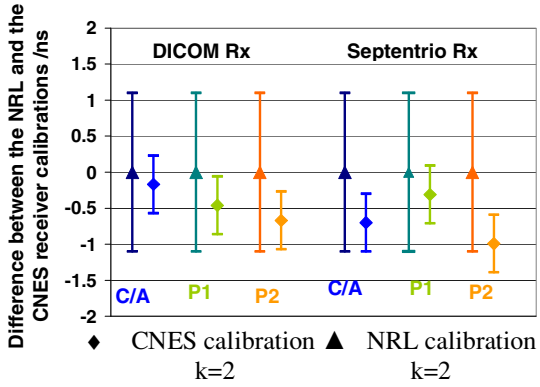

Figure 4. Comparaison between CNES and NRL receiver calibration

The results of the CNES and NRL receiver calibrations are of the same order of magnitude although all the CNES measurements are inferior to the NRL measurements. This difference could arise from the simulator thermal sensitivity. The CNES measurement points and their uncertainties are enclosed in the NRL error bars except for the Septentrio receiver P2 point. Only one measurement of the Septentrio receiver calibration was performed at NRL. It is therefore impossible to confirm the truthfulness of this value.

The figure 5 presents the results of the antennas absolute calibration with the NRL and the CNES method. These calibrations are performed with two types of antennas:

- A Novatel 702-GG antennas
- An Ashtech Choke-ring

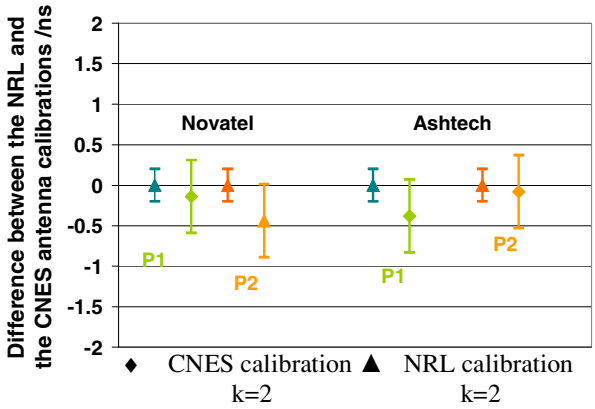

Figure 5. Comparaison between CNES and NRL antenna calibration

The antenna calibration results are in the same order of magnitude. There is an overlap of the CNES and NRL uncertainty bars but not a complete lapping for all measurements. The reproducibility is not also excellent than for the receiver calibration. The explanation can be arisen from the NRL and CNES measurement environments. At NRL the anechoic chamber is aging and the absorbents performance deteriorate. Moreover, the absorbents rejection rate of the CNES anechoic chamber is not very high. The replacement of the absorbents at CNES and at NRL could perhaps allow to obtain a better compatibility between the measurements.

V. CALIBRATION OF THE COMPLETE RECEPTION CHAIN

Thanks to the calibration of the antennas and the receivers, it is possible to determine the electrical delay and the uncertainty measurement of the entire reception chains.

Two reception chains will be composed with the calibrated elements :

Chain 1 : Dicom GTR50 receiver + Novatel 702-GG antenna

Chain 2 : Septentrio PolaRx2 receiver + Ashtech Z12-T antenna

The figure 6 presents the delay difference of these reception chains for the L1 frequency code C/A and code P and for the L2 frequency.

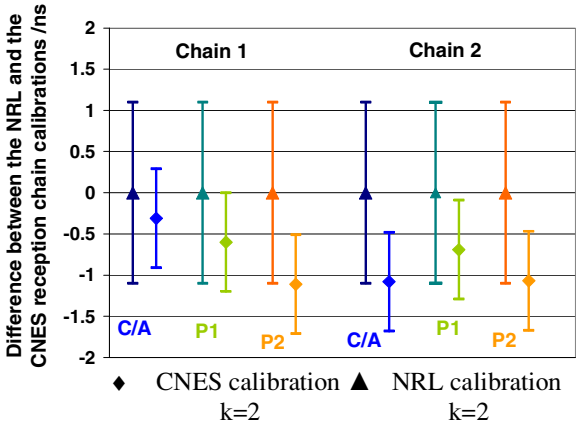

Figure 6. Comparaison between CNES and NRL reception chain calibration

The results of the reception chain calibrations performed at CNES and at NRL are of the same order of magnitude even if the error bars do not completely overlap. The difference between the NRL and CNES reception chain calibrations is inferior to 1 ns even if the measurement environments are not identical. These close results allow to validate the absolute methods put in operations at NRL and CNES and to prove the reproducibility of this technique.

The table IV presents the uncertainty of the reception chains for the L1 frequency code C/A and code P and for the L2. The value for a iono-free utilization is also presented.

Because the ionosphere delay is frequency dependent, one can compute P3, the ionosphere-free linear combination of P1 and P2. Knowing the absolute delay for the P1 and P2 pseudorange codes, the ionosphere-free delay is calculated as follows :

$$RxD_{(P3)} = \frac{f_1^2}{f_1^2 \quad f_2 2^2} RxD_{(P1)} \quad \frac{f_2^2}{f_1^2 \quad f_2^2} RxD_{(P2)} \qquad (6)$$

As P1 = 1.575420 GHz et P2 = 1.22760 GHz, the following approximate equation is used :

$$RxD_{(P3)} = 2.5457 * RxD_{(P1)} - 1.5457 * RxD_{(P2)} \quad (7)$$

The P3 uncertainty is calculated in the same manner :

$$u(P3) = \sqrt{(2.5457 * u(P1))^2 + (1.5457 * u(P2))^2} \quad (8)$$

This formula gives a result three times superior to the P1 or P2 uncertainty but does not take into account any correlations between the L1 and L2 uncertainties.

The global uncertainty presented in the table V is the quadratic sum of the uncertainty of the receiver and the antenna.

TABLE V. UNCERTAINTY COMPARISON OF THE NRL AND CNES ABSOLUTE CALIBRATION OF GNSS RECEPTION CHAINS

Chains	**Calibration method**	**Uncertainty Calibration [ns] (k=1)**	
		C/A/P1/P2	***P3***
Chain 1	NRL	1.03	3.07
	CNES	0.60	1.78
Chain 2	NRL	1.03	3.07
	CNES	0.65	1.93

The uncertainty for the reception chains is about 0.6 ns with the CNES method and 1 ns for the NRL method for the C/A, the P1 or the P2 code. For the iono-free combination, the CNES uncertainty is slightly inferior to 2 ns when it is estimated to 3 ns for the NRL method.

VI. CONCLUSION

It's the first time that a comparison of the absolute calibration results is performed. Two reception chains are used for this comparison : The first is composed of a Dicom GTR50 receiver and a 702-GG Novatel antenna and the second is constituted a Septentrio PolaRx2 receiver and a Ashtech Choke-ring antenna.

The CNES uncertainty of the receiver and antenna calibrations is the same order of magnitude included between 0.39 ns to 0.46 ns. The NRL uncertainty is dominated by the receiver calibration uncertainty estimated to 1 ns when the antenna uncertainty estimation is of 0.2 ns. The uncertainty for the complete reception chain is of 0.6 ns with the CNES method and 1 ns for the NRL method for the P1 or P2 code. For the iono-free combination, the CNES uncertainty is slightly inferior to 2 ns when it is of 3 ns at NRL.

The comparison between the CNES and NRL results shows a good compatibility for the receiver and the antenna calibrations. The results of the NRL and CNES reception chain calibration are close with a maximum difference of 1 ns even if the measurement environment are not similar. This comparison allows therefore to validate the absolute methods put in operation at NRL and at CNES in proving the reproducibility of this technique.

***Abstract*— The calibration uncertainty (u_B) is the dominant part in the total uncertainty budget of the *UTC* generation [1,3]. There are two calibration strategies: (a) Receiver calibration and (b) Time link calibration. The state-of-the-art [1,4,5] of the u_B is of order 5 ns for GNSS time transfer based on the strategy (a) and is 1 ns for TWSTFT based on the strategy (b) in which the absolute offset is canceled. In the *BIPM Circular T*, the uncertainty in *UTC-UTC*(k) is obtained from the uncertainties in the links [3]. To reduce the uncertainty in *UTC-UTC(k)*, it is optimal to use the calibration strategy (b). Earlier investigations gave theoretical and practical proofs [6-12]. Based on these studies, we propose the BIPM calibration scheme using a calibration system composed of three GNSS geodesic receivers: one is stationary at BIPM and the other two travel between the laboratories. We describe the set-up of the system, the schedule, the uncertainty u_B and aging of the u_B. The u_B is expected to be better than 2 ns for even very long inter-continental *UTC* baselines.**

I. INTRODUCTION

The recently used PPP technique greatly improves the precise time transfer and is comparable to the impact of the introduction of TW links 10 years ago. Both have produced significant progress and trigged the studies in new methods for the accurate *UTC* time links. One of the important issues is the calibration. There are two basic concepts:

a) *Receiver*-calibration
b) *Link*-calibration

As discussed in [3], time link calibration uncertainty u_B is the dominant part in the uncertainty of *UTC-UTC*(*k*) published in Section 1 of *BIPM Circular T* [1]. The so far TW calibration is based on the (b) concept, i.e., the time link calibration, and that is why the u_B of TW link reaches 1 ns [4]. While the GNSS receiver calibration [5] using the concept (a) still remains at 5 ns. However for the computation of *UTC-UTC*(k), the calibration concept (b) is required. It is potentially easy to reduce the u_B.

Since 2007, studies of the GNSS link calibration have been conducted based on the concept (b). TW links have already been used to calibrate GPS PPP [6] and MC links. The GPS MC link BEV-PTB [7] is the first calibration using the concept (b); at the moment of the calibration (Sep. 2008), its u_B was 3 ns. It was and is still the lowest value reached for the GNSS calibration in the *BIPM Circular T* [1]. A study [8], see also section IV, proved that we can convert the link calibration to the absolute receiver calibration if at least one of the receivers in the network is absolutely calibrated. [8, 9, 12] generalized the link calibration to all the *UTC* time link calibrations and estimated the reachable u_B. [10, 11] proposed a link calibration scheme using a traveling GPS receiver and realized the link calibrations on the baselines ROA-PTB and CH-PTB. The u_B declared is less than 2 ns.

All these studies and exercises gave encouraging results. Based on these studies and towards a standardization of the *UTC* time transfer calibrations, this paper proposes a new BIPM calibration scheme that will be tested in a pilot experiment to strength the Asia-Europe time links. The goal of the pilot experiment is to reach the expected uncertainties in the *UTC* time links:

$u_A \leq 0.3$ ns
$u_B \leq 2$ ns

If this pilot experiment is successful, we will consider using the BIPM scheme to calibrate more *UTC* time links, and in particular, the inter-continental TW and GNSS baselines.

In the following sections, we first define the 'total delay', then the set-up of the 'total delay calibration', the schedule of the calibration tour, named **BIPM scheme,** and finally the uncertainty estimation and conclusion.

II. THE BIPM CALIBRATIN SCHEME

The typical values of time transfer uncertainty are u_A(TW)=0.5 ns, u_A(PPP)=0.3 ns and u_B(TW)=1.0 when using the TW portable station. However the u_B(TW)=1.0 ns has never been realized between Asia-Europe. The present value is 5 ns. The ratio between u_A and u_B is 1:10. Clearly, the major difficulty to improve the quality of Asia-Europe time transfer is the calibration.

When a real TW link calibration is not available, we apply in the *UTC* computation a *link* calibration correction by an alignment operation, e.g., we align a TW link to the corresponding GPS link. This calibration correction is the "total delay of the link" which is the key concept in the BIPM scheme. Therefore the so called new scheme, in term of the

link calibration, has always being practiced in *UTC* computation. The so far BIPM GNSS links are *receiver* calibrated in general while in the new scheme the GNSS links are *link* calibrated.

The following notations are used in the paper:

- **$Dly_{R/i}$**: the total delay of a *receiver* system at Lab(*i*), *i* = BIPM, PTB, Lab(*k*), …
- **$Dly_{L/ij}$**: the total delay of a time *link* system which is the difference of Dly_{Ri} and Dly_{Rj}
- **Ref_i**: the reference receiver at Lab(*i*), *i* = BIPM, PTB, Lab(*k*), …
- **Std_B**: the BIPM traveling standard equipment consisting of N ≥2 GNSS receivers
- **$UTCP_i$**: the *UTC* point at Lab(*i*), *i* = BIPM, PTB, Lab(*k*), … cf. Figures 1 and 4
- **$CLBP_i$**: the calibration point at Lab(*i*). *i* = BIPM, PTB, Lab(*k*), … The $Dly_{R/i}$ is the total delay between this point and the phase center of the antenna at laboratory *i*, cf. Figures 1 and 4
- **Δ**=$CLBP_i$–$UTCP_i$ is the cable delay between the *UTC* point and the calibration point. This is the only measure of the delay that should be made and supplied to BIPM by the Lab(*i*). Δ is considered as known in the following discussion.

III. THE DEFINITION OF THE TOTAL DELAY

The total delay of a *link* is the difference of the total delays of two GNSS receivers at the ends of a baseline. It is defined with the help of the total delay of the *receivers*.

A. The total delay of a GNSS receiver

The total delay of a GNSS receiver (Dly_R) at Lab(*k*) is the total electronic delay between the phase center of the antenna and the $UTCP_k$. It is the sum of all the delays of the cables plus the pieces of equipment, which include the receiver, the splitter(s), the frequency distributor(s), the amplifier(s), the phase micro stepper(s) … and the cables between the antenna and the receiver as well as the cables between all the laboratory equipments, including the **Δ**, on the path of the satellite signal from the antenna to the $UTCP_k$ (Figures 1, 4). If the $CLBP_i$ and $UTCP_i$ are not the same, the delay between them is the Δ which should be measured by the Lab(*k*).

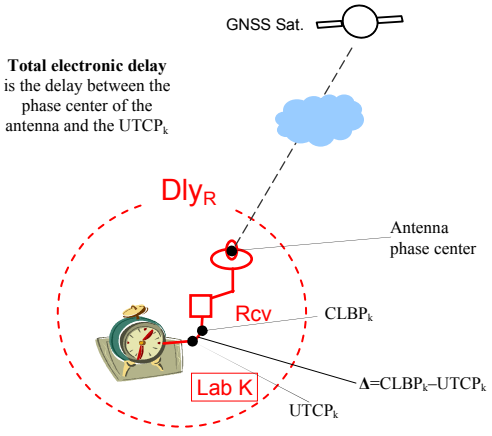

Figure 1. The total delay of a GNSS *receiver* (Dly_R) at Lab(*k*)

In the present BIPM calibrations of C/A receivers, some components, e.g. BIPM antenna cable etc., are measured separately by BIPM and the Lab(*k*). But this practice is not necessary and may introduce errors. Table I shows the discrepancies of the BIPM antenna cable delay and its uncertainties (SD) measured by 18 laboratories. If we take into account only the results accompanied with the uncertainties, the minimum delay is 183.0 ns ±0.5 ns and the maximum is 186.2 ns ±0.01 ns. The difference is 3.2 ns, largely over the given uncertainties. If we also consider those results that are not accompanied by the uncertainty, the difference reaches 6.6 ns. The standard deviation is 1.6 ns. This is only a simple cable, so that it is clear that discrepancies in the delays for other complex parts of the equipment could be worse. All these errors will go to the final error budget of the calibration. It is wiser to avoid all these non necessary measurements by defining and using the *total delay*. However, the laboratories could optionally measure all the components of the all delays. This information would be helpful in case of doubt.

TABLE I. THE DELAYS OF THE BIPM CABLE C101 MEASURED BY 18 DIFFERENT *UTC* LABORATORIES

Cable C101:

Laboratory	Delay /ns	SD /ns	Measurement method	Date (YYMM)
BIPM	184.34	0.4	Double Weight Pulse method	0105
OP	184.6	0.3	Dual weighing method	0112
IEN	185.6	0.1	Pulse method	0202

B. The total delay of a time link

The total delay of a receiver (Dly_R) as defined above is not measurable with only the BIPM scheme. The Dly_R serves in this section only to define the Dly_L, the total delay of a time *link* between Lab(*i*) and Lab(*j*) in the BIPM scheme:

$$Dly_L(i\text{-}j)=Dly_R(i)-Dly_R(j)$$

for a *UTC* link with *j*=PTB, it becomes:

$$Dly_L(k\text{-PTB})=Dly_R(k)-Dly_R(\text{PTB})$$

The total delay of a link Dly_L is the CALR in the case of a TW link. However, the methods to obtain them are quite different. Figure 2 illustrates the configuration of the geometry of the Dly_L which is directly measurable in the BIPM scheme. By default, the total delay in the following sections is always that of the time *link* Dly_L.

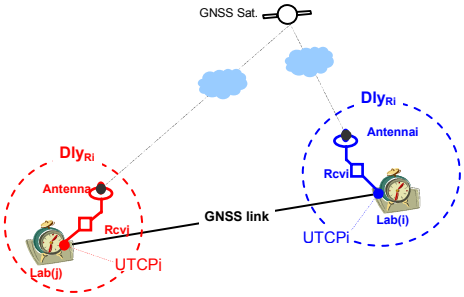

Figure 2. The total delay of the *link* Lab(*i*)-Lab(*j*): Dly_L (i-j)=Dly_R(i)-Dly_R(j)

C. *The BIPM scheme and the computation of a Dly_L*

For performing a *link* calibration with the BIPM scheme, the travelling receiver Std_B does not need to be calibrated and, furthermore, long-term stability of Std_B is not a critical issue. The only requisite is that the Std_B must be stable during the calibration tour. This is in fact a usual requisite for any calibration.

Let us first state that measurement noise (assumed white noise) is not a limiting factor in our calibration scheme, as in any calibration scheme: because hundreds of measurements are taken each day, the measurement noise averages out below 0.1 ns and therefore will not be further considered. On the other hand, the total uncertainty of the calibration depends highly on the instability of the travelling Std_B over the duration of the calibration trip. In order to limit the disturbance of this instability, a multi-receiver system and a rigorous schedule are used in the BIPM scheme. These measures can greatly reduce the impact of jumps in the Std_B reference during the calibration tour because we can know exactly, by the comparison between the traveling and the stationary receivers, the closure measurement at BIPM and the side by side set-up at Lab(k), where andwhen a jump occurred, as well as its size.

Compared with the present BIPM calibration, the new scheme is characterized by:

- the key point is the stability of the BIPM standard which is composed of N+1 GNSS receivers, one of them staying at BIPM (in fact, there are more than one GNSS receivers operational at BIPM and all of them can back up the fixed reference) and a traveling standard composed of N other receivers (N≥2). For the pilot experiment, the BIPM standard consists of three GPS receivers: a reference receiver Ref_B stays at BIPM plus a traveling standard with two GPS receivers: Std_{B1} and Std_{B2} (Figure 5);
- the clock result of a GPS PPP solution is associated with the phase center variation of the antenna which will be determined with a cm level of accuracy by PPP. The laboratories can put the antennas of the Std_B anywhere suitablebut trying to avoid the multi-paths' effect. Therefore, the Std_B ensemble must be of geodetic receivers;
- the common point of the two traveling receivers of the Std_B is a splitter sharing a cable leading to the calibration point (CLBP), cf. Fig. 5. All the calibrations are made with the CLBP as reference;
- the $CLBP_k$ of Lab(*k*) is referred to $UTCP_k$. The Lab(*k*) needs only to measure the delay $\Delta=CLBP_i-UTCP_i$;

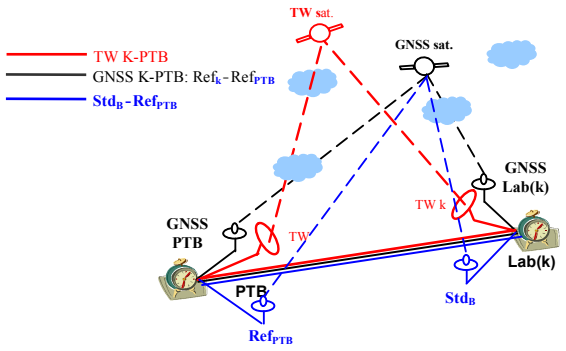

Figure 3. The side-by-side common-clock short-baseline set-up and the total delay Std_B-Ref_k: $Dly_L(Std_B\text{-}Ref_k)=Dly_R(Std_B)\text{-}Dly_R(Ref_k)$

- the calibration result is the total delay of a link Dly_L. We calibrate the total delay of all the time links on the route of the traveling Std_B between PTB and Lab(*k*). The link(s) to calibrate can be of any types: GPS, GLN and TW (Figure 3);
- since the goal is to calibrate links for *UTC*, PTB should always be included. The scheme may be simplified without PTB only if experiences prove the long-term stability of the Ref_{PTB} and the Std_B. But this needs time.

The BIPM scheme has four steps. Fig. 3 is the set-up of step 3.

1) start the measurements at the BIPM;
2) visit the PTB;
3) visit successively Lab(*k*), k=1, 2, 3, …;
4) close the measurements at the BIPM.

IV. Discussion

The basic idea of this section was proposed for the first time in [8]. We generalize the principle to adapt it to the new BIPM scheme. We first prove that the BIPM *link* calibration can be converted to the GNSS *relative receiver* calibration and then that this *relative* calibration can be transferred into the *absolute* calibration. For a time link network, if one of the receivers is *absolutely* calibrated, this *absolute* scale can be transferred to all the other receivers.

We then discuss some characters of the BIPM scheme.

A. *Convert a link calibration to a GNSS* receiver *calibration*

We recall first that the BIPM scheme is not an *absolute receiver* calibration. We are interested in the *link* calibration that affects the *UTC*-*UTC*(*k*) and also in an arbitrary time *link* UTC(*k*)-UTC(*j*). In the following discussion, the "*receiver calibration correction*" stands for the delay correction to be added to the RefGps value (the raw receiver recordings in the CGGTTS data files).

We take an arbitrary *UTC* baseline Lab_k-PTB. Suppose the *receiver* delay correction of the GNSS *receivers* is X_p for PTB and X_k for Lab_k; $Link_k$ is the non calibrated GNSS *link* between Lab_k and PTB; $Link_K$ is the *receiver* calibrated *link*; $Link_B$ is the calibrated *link* by carrying out the BIPM scheme. We can compute the calibration value of the GNSS receiver at Lab_k by two steps: first the *link* correction between Lab_k and PTB and then the *receiver* correction at Lab_k, as follows:

$$Link_K = [RefGps(Lab_k)+X_k] - [RefGps(PTB)+X_p] \quad (4.1)$$

By the definition of the total delay of the link, we have $C_k=X_k-X_p$. Introducing it in equation (4.1):

$$\begin{aligned} Link_K &= [RefGps(Lab_k) + C_k + X_p] - [RefGps(PTB) + X_p] \\ &= RefGps(Lab_k) - RefGps(PTB) + C_k = Link_k + C_k = Link_B \end{aligned} \quad (4.2)$$

Above the C_k can be obtained through the BIPM scheme and X_p can be given through earlier calibration (although we do not need it here). The *receiver* calibration correction, i.e. the total delay of the GNSS receiver at Lab_k can be computed with the simple relation: $X_k = C_k+X_p$. The fact that the *receiver* delay at PTB X_p is cancelled in equation (4.2)

confirms that we do not need it to calibrate any receivers and C_k can be considered as the receiver calibration correction because X_p can be set to any value e.g. X_p=0.

Now we should prove that such obtained *receiver* calibration correction is correct not only for the *UTC* link between Lab_k and PTB but also correct for any link between a pair of *UTC* labs. To be general, we take arbitrarily two labs: Lab_k and Lab_j. From the definition of $Link_k$ and the equation (4.2), we have:

$$C_k = X_k - X_p = Link_B - Link_k \quad (4.3)$$

$$Link_K = Link_k + C_k = [RefGps(Lab_k) + C_k] - RefGps(PTB) \quad (4.4)$$

where C_k is the calibration delay correction applied to the Lab_k *receiver*. As for the *receiver* of PTB, calibrated or not is not important to obtain the calibrated $link_K$ (X_p is canceled). Similar as equation (4.3), the *receiver* delay corrections:

$$C_k = X_k - X_p = Link_B(Lab_k - PTB) - Link_k(Lab_k - PTB) \quad (4.5)$$

$$C_j = X_j - X_p = Link_B(Lab_j - PTB) - Link_k(Lab_j - PTB) \quad (4.6)$$

By subtracting equation (4.6) away fromequation (4.5):

$$C_k - C_j = X_k - X_j = Link_B(Lab_k - Lab_j) - Link_k(Lab_k - Lab_j) \quad (4.7)$$

$$Link_B(Lab_k - Lab_j) = Link_k(Lab_k - Lab_j) + C_k - C_j \quad (4.8)$$

Similar as the equation (4.1), the calibrated GNSS link equals:

$$Link_K(Lab_k - Lab_j) = [RefGps(Lab_k) + C_k] - [RefGps(Lab_j) + C_j] \quad (4.9)$$

In the equation (4.9), C_k and C_j are the GNSS *receiver calibration corrections*. Introducing equations (4.6) and (4.7) into (4.9), we have the GNSS link with the traditional *receiver* calibrations X_k and X_j:

$$Link_K(Lab_k - Lab_j) = [RefGps(Lab_k) + X_k - X_p] - [RefGps(Lab_j) + X_j - X_p]$$
$$= [RefGps(Lab_k) + X_k] - [RefGps(Lab_j) + X_j] \quad (4.10)$$

Again, X_p the *receiver* calibration correction for PTB GNSS receiver is cancelled in the arbitrary link. Equations (4.8) and (4.9 or 4.10) give the same result (within their uncertainties) but with completely different calibration set-ups.

From the equations (4.8) to (4.9) and then (4.10), we transfer the *link* calibration obtained through $Link_B$ (the new BIPM scheme) to the *receiver* calibration (the traditional calibration scheme). The *link* calibration corrections differ from the *receiver* delay corrections by a common constant: X_p. However, it is important to understand that:

1. it is not necessary to know the value of X_p in the BIPM calibration scheme for the *UTC* time transfer;
2. if we know one of the X_k or X_j, we can compute the X_p. It is easy to prove this by exchanging the positions of Lab_k and PTB in equation (4.1), i.e. the X_p of the PTB can be determined at *any* Lab_k

Equation (4.10) is that of the traditional BIPM calibration. As mentioned in the introduction, one of its disadvantages is that the uncertainty is poor: u_B = 5 ns. Equations (4.2) and (4.8) use the new BIPM scheme calibration and its u_B is well reduced, potentially less than 2 ns [10,11]. Furthermore the BIPM scheme allows *simultaneous* multi GNSS receiver calibration between the *UTC* laboratories that operate GPS, GLN and TW facilities. *Simultaneous* measurement is impossible for the traditional calibration (eq. 4.10). Possible biases due to, for example, the long-term variations of the internal reference of Std_B receiver and the geodesic hypothesis etc., are not avoidable.

B. Convert a relative *receiver calibration to* absolute *one*

To identify the difference between the BIPM scheme and the absolute calibration, we name the BIPM-scheme obtained receiver calibration correction the "*relative* receiver calibration". An *absolute* calibration is to determine the sum of the absolute delays of the antenna, the receiver, all the equipment and the cables on the way of the GNSS signal passing through, which is *absolutely* measurable. The direct output of BIPM scheme is defined with respect to the standard receiver Std_B. In the relation (4.2), we assume that in $link_K$ the total delay of the GNSS receiver at PTB is *absolutely* calibrated. The absolute delay is $X_{p/A}$. Let us set, $X_{p/A} = X_p + X_o$, X_o here is the difference between the *receiver* calibration and the *absolute* calibration. Therefore, we have at the Lab_k

$$X_k = C_k + X_p = C_k + X_{p/A} - X_o, \quad (4.11)$$

$$X_{k/A} = X_k + X_o = C_k + X_{p/A} \quad (4.12)$$

Therefore, to convert the BIPM scheme total delay C_k to the *total absolute delay* $X_{k/A}$, it is as easy as to add a constant: $X_{p/A}$. Again for the *UTC* generation, we compute the *UTC*-*UTC*(k) and do not need the *absolute* delay. However, the *total absolute delay* is indispensable for the Section 5 where the differences of the *UTC* and GNSS system reference time are given.

It is interesting to point out that:

1) in the *UTC* network, if any of the receivers is *absolutely* calibrated (not necessarily that of PTB), its *absolute* scale can be transferred to all the other receivers;

2) if there are *more than one* receiver *absolutely* calibrated in the BIPM scheme, the redundant calibrations can improve the calibration by a least square adjustment, cf. [17] for details.

C. The BIPM scheme is a unified one-for-all calibration

By Figure 3, the set-up of the BIPM scheme at Lab(*k*) serves to calibrate all kinds of *UTC* time *links* between the Lab(*k*) and PTB: TW and all type of GNSS (C/A, P3 or PPP). This is the so-called unification of all the *UTC* time links by the unique BIPM standard [12].

Advantages of the unified approach are:

1. the calibration results will be affected only by the short-term instability of the Std_B;
2. calibration of the TW links, in particular of the very long inter-continental TW links, is possible;

3. improvement of the calibration uncertainty u_B for most *UTC* time links, and consequently reduction of the uncertainty of [*UTC* – *UTC*(*k*)] in the *Circular T* from 5 to 2 ns, see below V;
4. simplified organization of *UTC* calibration campaigns;
5. simplified monitoring of these calibrations.

D. The BIPM scheme is more accurate and less manpower, time and money consuming

In the traditional BIPM differential calibrations of GNSS equipment, different BIPM standard receivers travel for different GNSS receivers calibrations: GPS C/A code receivers, GPS P3 code receivers and GLONASS receivers. TW calibration is separately. Many of them have never been achieved. During the calibrations, the visited laboratories have to determine the position of the BIPM antennas and to measure all the delays of cables and equipment on the path of the satellite signal. These increase the total uncertainty and the labors.

The new BIPM scheme allows the calibration of all types of links on a baseline; the laboratories measure and supply only the delay Δ between UTCP(*k*) and CLBP(*k*). This saves time, manpower and reduces the measurement uncertainties.

Generally speaking, if the uncertainty of a *receiver* calibration is *u*, the total uncertainty in *UTC*-*UTC*(*k*) is $u_B \approx \sqrt{2} \times u$. However, for a link calibration, we have $u_B \leq u$.

E. Comparison between the new and the old BIPM schemes

We summarize the features of the new BIPM scheme vs. the traditional ones.

- The new scheme calibrates links while current schemes calibrate receiving equipment. Through link calibration, all existing techniques between a pair of laboratories can be calibrated at the same time.
- Two receiving systems travel in the new scheme, providing redundancy and cross-checking. As the equipment is organized in a unique container and as the visited lab should only provide a frequency and a 1PPS and only measures the delay of the 1PPS, the operations are simpler and the risk of mistake is minimized.
- The receivers provide phase and code measurements allowing the precise positioning of antennas with PPP. This is not the case in the present C/A calibrations.
- Finally the link calibration uncertainty u_B is expected to be 2 ns or below (see next section) while, in the present scheme, the combination of the uncertainties of the two receiver calibrations provides a link uncertainty u_B = 5 ns.

V. THE UNCERTAINTY

The proposal in this section was originally raised in [12]. We generalize it to the new BIPM calibration scheme.

*A. The u_B of a UTC link Lab(*k*)-PTB*

The calibration uncertainty for the link Lab(*k*)-PTB can be estimated by:

$$u_B^2(k\text{-PTB}) = [u_A^2(k\text{-PTB}) + u_A^2(\text{Std}_B) + \boldsymbol{c}^2(\text{Std}_B)]/N \qquad (5.1)$$

N is the number of BIPM traveling receivers; $\boldsymbol{c}$ is the conventional short-term-link-instability of the Std_B for a typical calibration tour that consists of 4 occupations of 4 steps: BIPM➔PTB➔Lab(*k*)➔BIPM. If we set $\boldsymbol{c}$ = 2 ns (as is shown to be achievable by Esteban et al [10]) and N=1, the u_B of the calibrations are: u_B(GNSS P) ≈ 2.23 ns (for u_A = 0.7); u_B(GNSS C/A) ≈ 2.60 ns (for u_A = 2.0) and u_B(TW) ≈ 2.17 ns (for u_A = 0.5). The above estimations are conservative as in fact N=2 so that the value of u_B obtained by equation (5.1) may be reduced, e.g. to about 1.6 ns for the GNSS P3 code calibration [17].

B. Aging of the u_B

The above estimation is valid only at the moment of the calibration without taking into account of the evolution of u_B with time. It is logic that without re-calibration or an independent check, the maximum life of a "*free running*" u_B is limited, saying about 10 years, e.g., for each of the techniques u_B(>10 year) = 10 ns. A "free running" u_B increases with time. For the purpose of automatic computation, it is useful to design an analytical model for u_B evolution. For example, a model based on a random walk phase noise or on a flicker phase noise (or on a combination of both) could be used. In the following, examples are shown for a random walk model, although the resulting values are probably overly pessimistic for the long-term:

$$u_B^2(T - T_0)_{\text{k-PTB}} = u_B^2(T_0)_{\text{k-PTB}} + (T - T_0) \times u_{A^2\text{k-PTB}} \qquad (5.2)$$

Here T-T_0 is the time since the calibration in months and u_A is the random walk part of the 1-month Type A uncertainty of the link taken to be: u_A(GNSS C/A code) ≈ 0.7 ns; u_A(GNSS P codes) ≈ 0.5 ns and u_A(TW) ≈ 0.3 ns. The values of u_B for different calibration ages calculated on the basis of the above hypothesis are presented in Table III. The unit is ns.

TABLE II. EVOLUTION OF U_B INCREASING WITH TIME AS A RANDOM WALK PROCESS

Link	$u_B(T_0)$ /ns	u_A /ns	u_B(1yr) /ns	u_B(3yr) /ns	u_B(5yr) /ns	u_B(10yr) /ns	u_B(>10yr) /ns
TW	1.0	0.3	1.4	2.1	2.5	3.4	10
GNSS P	2.0	0.5	2.6	3.6	4.4	5.8	10
GNSS C/A	3.0	0.7	3.9	5.2	6.2	8.2	10

VI. THE EXPERIMENT SET-UP

Figure 4 illustrates the general set-up up of the BIPM calibration scheme at the Lab(*k*). Here the 'time transfer equipment' represents one or all the time transfer techniques: TW, GLN and GPS C/A, P3 and PPP. The configuration between the pulse distributor driven by the master clock and the receivers of Lab(*k*) as well as the BIPM traveling standard is demonstrated. The BIPM traveling Std_B is installed in the BIPM calibration station (Figure 5), composed of two GPS geodesic receivers driven by the same master clock as the receivers at Lab(*k*). The pulse passes first through the CLBP_k of the distributor then through the BIPM receiver cables goes to the BIPM splitter in the station where it is separated into two signals going to the two BIPM individual standard receivers, Std(1) and Std(2). The delay of the ensemble of the BIPM Std from the antennas to the CLBP_k is same at all the

Labs and will be canceled in the time links. The difference of the links of the Std_B-PTB and that of the Lab(*k*)-PTB is nothing but the *link* calibration correction.

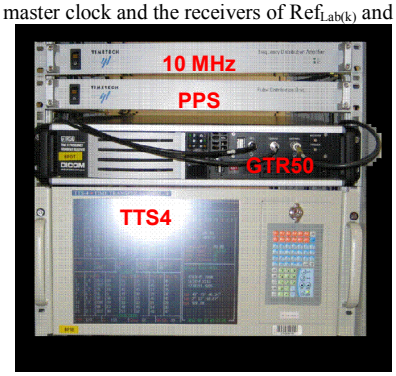

Figure 5. *The BIPM calibration station Std_B*

VII. SUMMARY

We have studied a new calibration approach based on the *link* calibration concept, and named it "the BIPM calibration scheme". We developed a set of calibration equations and computer programs that have been installed in the *UTC/TAI* software package Tsoft. Preparation of the equipment and organization are ongoing. A pilot study has been lunched during the CCTF TW Working Group meeting in Sept. 2010 in Beijing and will plan to perform the first measurements in laboratories in 2011.

TW and GPS PPP are the best performing techniques in *UTC* time transfer. Each has advantages and is indispensable. However, since last year, two phenomena arose: the quality of TW is degrading and that of the PPP has improved. Replacing the degraded TW links by PPP does not seem a good solution; we propose therefore 1) combination of the two techniques to improve the u_A; 2) differential of the two techniques to improve the u_B. In particular, we aim at strengthening the Asia-Europe very long baselines for *UTC* time transfers. This is the goal of the pilot experiment. To do it, we need:

- Combination TW and PPP: TW+PPP
- Application of the TW indirect links composed of two direct ones
- PPP assisted calibration: the BIPM scheme of calibration TW-PPP
- The expected uncertainties: $u_B \leq 2$ ns and $u_A \leq 0.3$ ns

The methods applied in this paper could be extended to the whole *UTC* time transfer worldwide network through coordination with the Regional Metrology Organizations for supporting. A significant improvement of the global uncertainty is expected.

***Abstract*—Reviewing calibration results over the history since early 1980's among several labs shows very mixed results. The best stabilities of GPS receivers, as given by calibrations, are of the order of a few nanoseconds or better over a year, though many results are quite a bit worse. Absolute calibrations show similar potential, though there are problems. We conclude that more calibrations and standard methods are needed.**

I. INTRODUCTION

The purpose of this paper is to evaluate the status of GPS receiver delay calibrations, for a subset of receivers that support the generation of international atomic time (TAI). We first discuss historical and current methods for calibrating receivers. Then we look at the history of differential receiver calibrations in order to estimate receiver stabilities for the receivers in use at the time. Our last consideration of differential calibrations is to compute closures of calibration values by use of the most recent available data. These data give a measure of consistency of differential calibrations for use in current receivers. Finally, we discuss the history, use and potential for absolute calibrations.

GPS data are used in various ways for comparing clocks for generating TAI. All of these comparison methods are differential. We use the data to determine the difference between UTC(lab) among the labs that contribute to TAI. The delays through receivers need to be calibrated differentially in order to reference the data to a laboratory's UTC measurement plane. The best way to do this is with the use of a portable GPS receiver as a calibration system. The method is to do a series of common-clock, short-baseline calibrations between a travelling receiver and the primary receivers of different labs.

For example, to calibrate the differential delay between laboratory A (lab A in the following) and laboratory B (lab B), we could start with a portable system at lab A. To achieve a common-clock short-baseline calibration, one connects the travelling receiver to the same clock signals as the primary receiver, measuring the delay in the reference signal from the lab's UTC reference plane. We will discuss the details of a common-clock short-baseline calibration later. In principle, one collects data from the same satellites, measured against the same clock in two receivers with separate antennas, positioned near each other. With proper calibration of reference signals and coordinates, the difference in the measurements should be due only to the difference in the receiver systems, mainly the delays in the antennas, antenna cables and receivers. Evaluating these data allows us to determine the difference in the delays between each pair of systems. The sequence, in practice, would be to first measure the travelling receiver against the primary system at lab A, which we denote Trav-SysA (1). The travelling system is then brought to lab B, where we measure Trav-SysB. We then bring the travelling system back to lab A, where we determine a closure measurement of Trav-SysA (2). This closure gives a measure of any systematic shift in the delay of Trav during the trip. Typically, we then conclude that the difference in primary receivers is:

SysB – SysA= (Trav-SysA(1) + Trav-SysA(2))/2 - (Travs-SysB).

The actual value of SysB-SysA must be accompanied by the uncertainty of this measurement. We will discuss methods used for determining this in later sections.

There are many laboratories that contribute GPS data in support of generating TAI. There are also several different types of receivers, several different formats for the data, and several different methods for processing these data. In all cases, the differential receiver delays are crucial for

determining the values for UTC(lab A) – UTC(lab B). These delay values cannot be determined remotely. Either differential measurements must be made *in situ* against another receiver, or an absolute calibration of the receiver system must be done, which requires interrupting service. Differential calibrations appear to be the most accurate and convenient method of measuring these relative delays, though an absolute calibration is required for the total delay of one receiver system. Campaigns of calibrations have been done historically, and seem to be required at ongoing intervals to maintain accurate time transfer. We discuss in this paper the status of current differential and absolute calibrations, various hardware and software methods for performing calibrations, and possibilities for the way forward to best use GPS receivers and data in support of TAI.

II. Measurement Techniques for Calibration

GPS receivers for timing from 1980 on used a 1 pps signal as a reference. GPS time was measured against this 1 pps usually by use of a time-interval counter. Calibration involved measuring this reference 1 pps against the reference plane for time of the lab [1]. With the advent of receivers that used a 5 MHz or 10 MHz frequency signal as the reference signal, calibration became more complicated. Receivers measure GPS signals against a zero-crossing of the 5/10 MHz. This zero-crossing is determined by a 1 pps signal. So, in addition to knowing the offset of the 1 pps from the reference plane, the so-called tic-to-phase needs to be measured. Complicating this, some receivers lock an internal oscillator to the external frequency, and use that for a reference. Determining the internal reference point may be somewhat ambiguous. The internal reference point may be more than the next internal zero-crossing from the reference 1pps, or indeed may precede it, since the processing is usually digital. In addition, there are tic-to phase zones where the reference point may slip forward or backward a cycle. These forbidden zones may not be near to the value when the measured external tic-to-phase is close to zero. Figure 1 gives a block diagram illustration of the aspects involved with calibrating a frequency-reference receiver.

Some receivers can have a 1 pps out that is derived directly from the internal frequency reference with a fixed delay from the lock point. In that case, it may be possible to use that signal to eliminate any ambiguity for the reference zero-crossing in the receiver.

Thus we see that there are several measurement techniques possible for calibration. In addition, the question of biases in time-interval counters has been considered [2]. One recommendation has been to use a travelling time-interval counter along with the travelling receiver to minimize uncertainties due to counter error.

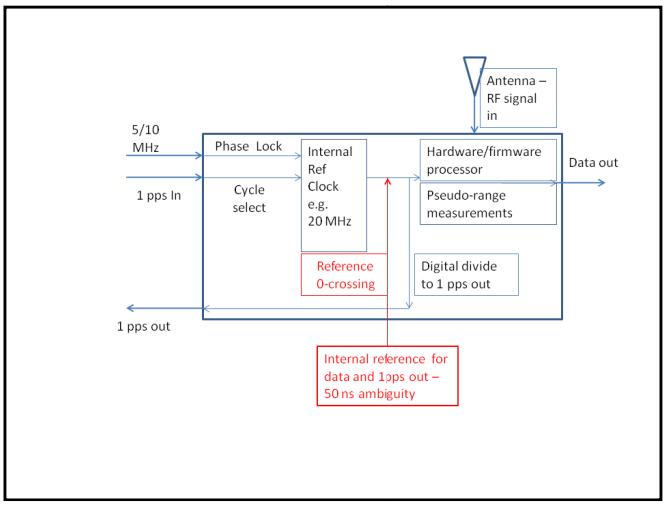

Figure 1. Block diagram of the timing functions in a modern GPS or GNSS receiver that measures the received pseudo-range against an internal oscillator, which in turn is locked to an external frequency reference. This illustrates the difficulty in unambiguously finding the the reference point.

III. Processing Calibration Data

Historically, there have been two different frequencies that have delays through the receiver, L1 and L2, with C/A and P codes modulated on these frequencies, P code not being originally intended for civilian use. While these are the frequencies of most interest to the timing community historically, a new frequency specifically designed for civilian use, L5, is appearing in the new GPS constellation, as well as a version of the C/A code on L2 called L2C. There will also be other constellations of interest. The Russian system, GLONASS, has been available for some time. Though less used for various reasons, GLONASS may become more used for TAI generation as it is modernized. There are also the European system, Galileo, and the Chinese system, Compass or Beidou 2, which are being developed.

There are several formats that data can be taken in and several methods for processing these data. The CGGTTS format [3] provides 13 minute averages every 16 minutes, with all delays from the satellite removed and the times of the on-board satellite clock adjusted for GPS time. For a short-baseline common-clock comparison, as a minimum, pseudo-range data must be adjusted for the range delay, the delay of the signal from the GPS satellites to the receivers. If exact common-view computations are done this is enough. However, the CGGTTS format uses only the C/A code for the main data, the Reference-GPS data. If there are P code on L2 carrier (P2) data, measured ionosphere values are a deterministic combination of both P2 and C/A code data. It is possible to use the combination of Reference-GPS and measured ionosphere data types to compute the differential delays for both the C/A code and the P2 code.

The format called RINEX (for Receiver INdependent EXchange format) [4] has been developed to provide detailed data for flexible processing options. RINEX data are instantaneous pseudo-range data, and are typically recorded every second to every 30 seconds. This format can store data

for all codes from all constellations. It is managed and updated by the International GNSS Service (IGS), and version 3 should provide flexible capability. However, it requires more storage space and processing than the CGGTTS data, which are already pre-processed. Minimal processing for common-clock short-baseline calibrations would be software that corrects only for the range delay from the satellites to the receivers, then differences these data between receivers matching exact common-view data, i.e. exactly matching satellites and transmission times between receiver data. This processing gives the differential calibration for the maximal density of data, with the minimum of extraneous processing.

In the timing community, it is most common to use either of two software systems for processing RINEX data. The P3 software reads RINEX files and outputs a CGGTTS format using either the C/A or P codes on L1 (C1 or P1) and the C/A or P2 codes on L2 (C2 or P2). The P3 data type is the ionosphere-free combination of P1 or C1 and P2 (C2 is available on a very limited number of satellites at this time). This format can, in principal, be used for differencing any of these codes individually, with 13 minute averages every 16 minutes. In practice, the usual output from the software allows for using the P3 combination and the value of the measured ionosphere to derive calibration values. Alternatively, one can use Precise-Point Positioning (PPP) [5,6] software to estimate the value of local clock against IGS system time at both locations for every reference time in the RINEX files. This uses carrier-phase smoothing of the code measurements, fixed local coordinates, and IGS post-processed estimates of satellite orbits to give an optimal estimate of the receiver's reference clock. While the PPP software produces perhaps the most precise estimates of user clock against system time, using it to compute differences for a local calibration introduces terms that do not cancel between receivers, due to the smoothing and averaging techniques.

Thus there are various processing methods for computing calibrations, with trade-offs for convenience, complexity, and accuracy.

A. OP-NIST

Table I and Figure 2 give the values for differential calibrations between OP and NIST since 1983 [1]. The values denoted d are differential time corrections to be added to [UTC(NIST)-UTC(OP)], and u(d) are estimated uncertainties for the periods of comparisons. All calibrations are of NBS10 at NIST compared to NBS51 at OP except for the November 2009 calibration. The NBS10 vs. OP NBS51 calibrations were all C/A code only comparisons. The November 2009 calibration compared the new primary receiver at NIST, NISTn1, with TTR01 and OPMT at OP. NISTn1 is a Novatel OEM4-G2* used at NIST for providing both CGGTTS and RINEX format data to the BIPM and IGS. This provides the backup link to the NIST TWSTFT link. OPMT, an Ashtech Z12-T*, provides the RINEX files to the BIPM that are used for the NRCan PPP computation or for the CGGTTS TAIP3 files. There is no endorsement or critique either implied or intended. This is the source for the backup link to TWSTFT for the link OP-PTB in the TAI network. The NISTn1 vs. OPMT comparison included codes on L1 and L2, yielding a P3 comparison. The best stabilities seem to be on the order of a few ns or better over a year. There are some larger variations that are unexplained, and an apparent walk of almost 10 nanoseconds over 20 years.

* Note that we include product names and model numbers only for reference. No endorsement or critique is implied.

IV. Calibration History

A. OP-PTB

We present first, in Table II and Figure 3, the calibrations from the BIPM website [7] for C/A receiver calibrations between OP and PTB.

TABLE I. Some past calibrations between NIST and OP

OP Receiver	NBS51-NBS10		TTR01-NISTn1		OPMT-NISTn1	
Date	d/ns	u(d)/ns	d/ns	u(d)/ns	d/ns	u(d)/ns
July 1983	0.0	2.0				
September 1986	0.7	2.0				
October 1986	-1.4	2.0				
January 1988	-3.8	3.0				
April 1988	0.6	3.0				
March 1995	-3.7	1.0				
May 1996	-3.0	1.5				
May 2002	-5.0	3.0				
July 2003	-5.6	1.9				
December 2003	-4.6	3.0				
December 2005	-8.7	3.0				
November 2009			-9.4	0.8	-7.3	0.8

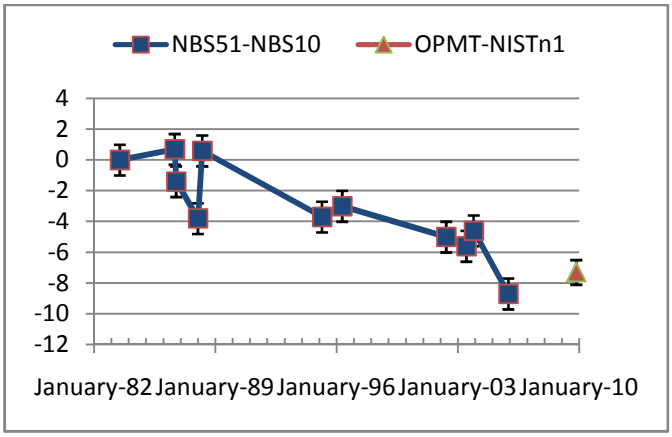

Figure 2. NIST-OP calibration values from Table 1.

TABLE II. DIFFERENTIAL TIME CORRECTIONS D TO BE ADDED TO [UTC(PTB) – UTC(OP)], AND U(D) ARE ESTIMATED UNCERTAINTIES FOR THE PERIODS OF COMPARISONS.

Date	d / ns	u(d) / ns	
October 1986	9.4	2.0	
October 1994	4.0	2.0	
July 1997	2.0	3.0	
November 1997	4.0	2.0	
March 1998	–6.0	2.0	
June 1998	5.0	3.0	
March 2002	–1.0	3.0	
June 2003	–4.7	3.0	
August 2003	0.1	3.0	
June 2004	0.1	3.0	
July 2004	0.6	3.0	TTR5 – TTS2
September 2006	–4.2	3.0	TTR5,TTR6 – TTS3
November 2009	10.3	3.0	
November 2009	4.8	3.0	

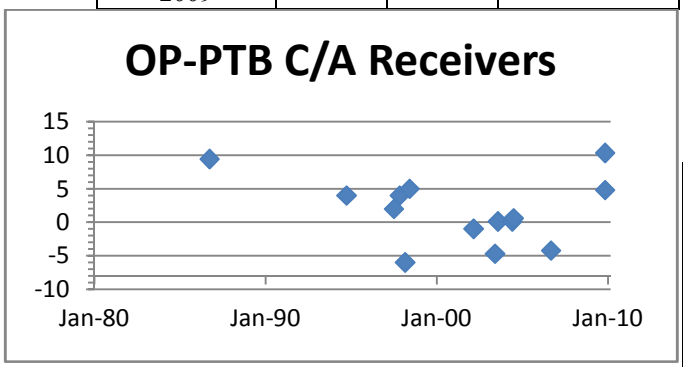

Figure 3. Plot of the data in Table II for the link OP-PTB. The receivers at OP were an NBS TTR5, then an AOA TTR6. At PTB the Code receivers were an NBS TTR5, then an AOS TTS2, followed by an AOS TTS3.

Apparent variations in calibration repeatabilities may be due to using different receivers. The best stabilities seem to be on the order of a few ns or better over a year. Next, we consider the OP-PTB GPS TAIP3 calibration link. Table III, and Figure 4 provide the P3 OP-PTB link calibration results for a direct comparison with other GPS C/A calibration results. All calibration data were computed by the BIPM during calibration campaigns, except the last line, which was released in the frame of the Galileo Fidelity activities from OP and CNES calibration campaigns [8]. Since receiver calibration values are implemented in respective receivers here, contrary to the previous C/A receiver calibrations, it is appropriate to only compare the change in values between these results and other tables. For some periods we see very little change between calibrations. For others there are 5-6 ns over a year or less, though the uncertainties are comparable in magnitude.

Finally in this section, we study the uncertainty budget consistency between GPS and TWSTFT on the OP-PTB link. Here we present an assessment of the uncertainty budget consistency between GPS and TWSTFT on the OP – PTB link. We have built daily averaged differences between UTC(OP) – UTC(PTB) as obtained from TAIP3 GPS CV and by TWSTFT. Figure 5 shows the results over two years, from February 2009 to February 2011, some outliers having been averaged out. The vertical lines materialize some events having potentially affected the measurements, like reference clock changes or a satellite transponder change. The horizontal lines are the plus or minus one sigma limits around 0, obtained from the quadratic sum of the uncertainties claimed for both techniques on the OP-PTB link. Over the whole period, the GPS TAIP3 combined uncertainty was estimated at 3.3 ns (1 σ). The TWSTFT combined uncertainty at 1 σ was estimated to be 1.1 ns until April 2009, 1.2 ns from May to November 2010, and 1.3 ns afterwards. The resulting uncertainty on the difference between both techniques is about 3.5 ns (1 σ). Over the last two years, the results obtained on the OP-PTB link are consistent with the statistics of the respective uncertainty budgets, despite major events like either reference clock changes for both techniques or a satellite change for TWSTFT, which require each time local measurements of new delays. There remains an average bias of about 2.0 ns over the period, which is probably due to some delays not properly taken into account. This calls for a better understanding and new measurements of both equipment chains.

TABLE III. . DIFFERENTIAL TIME CORRECTION D TO BE ADDED TO [UTC(PTB) – UTC(OP)] WHEN MEASURED BY GPS TAIP3 COMMON-VIEWS, U(D) BEING THE ESTIMATED TOAL UNCERTAINTIES

Date	d / ns	u(d) / ns
2002-07	10.8	5.0
2003-05	10.8	5.0
2004-08	15.0	5.0
2006-04	13.3	5.0
2008-04	13.7	5.0
2008-11	7.7	3.2

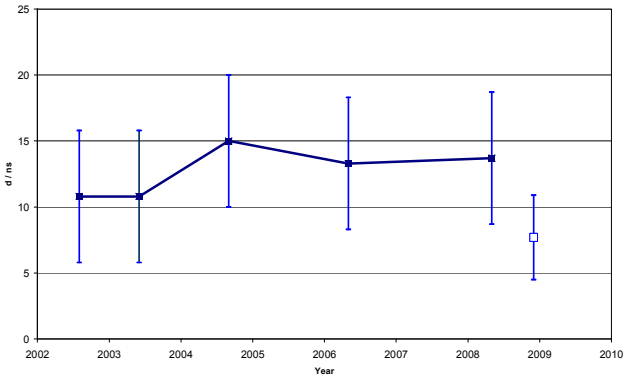

Figure 4. Plot of the data in Table III for the link UTC(PTB) – UTC(OP) by GPS TAIP3. The OP GPS receiver is OPMT. The PTB receiver is PTBB. The last point is kept separated from the others as it is the only one not measured by the BIPM.

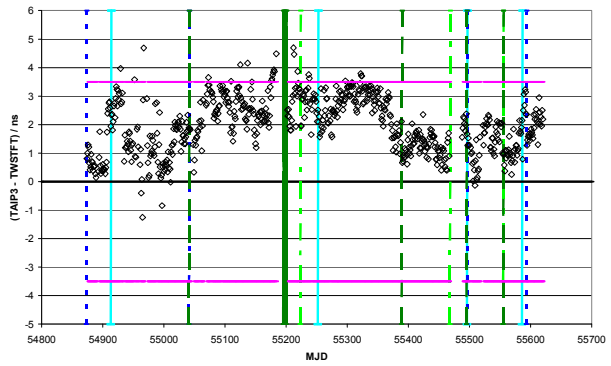

Figure 5. Daily averaged differences between UTC(PTB) - UTC(OP) by GPS TAIP3 CV and UTC(PTB) - UTC(OP) by TWSTFT.

TABLE IV. USNO – NIST CALIBRATIONS

Date	d/ns USNO C/A receivers - NBS10	u(d)/ns	d/ns USNO P3 receiver - NISTn1	u(d)/ns
Sep-86	25.3	2		
Sep-94	-9	3		
Dec-94	-7.6	1		
May-07	-7.5	2		
Aug-10			-6.2	2
Apr-11			-0.5	1

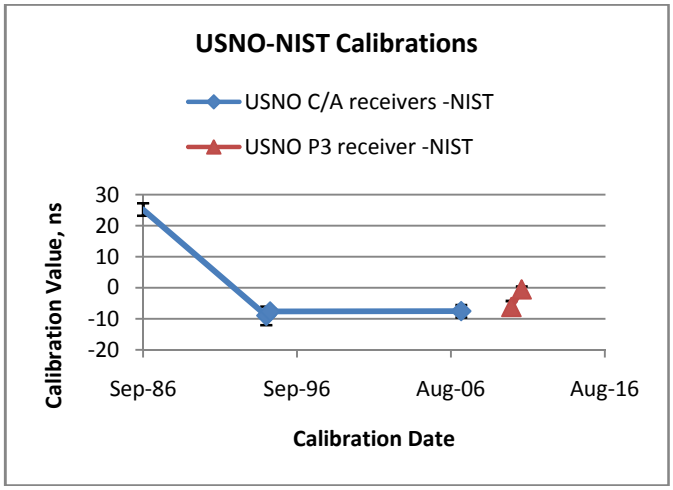

Figure 6. USNO-NIST calibration values from Table III.

B. *USNO-NIST*

Calibrations between USNO and NIST are presented in Table IV and Figure 6. These data come from the BIPM website files [7], except for the most recent calibrations of August 2010 and April 2011. These latter two use the two-frequency receivers at both labs, and are not yet finalized.

C. *USNO-OP*

Data for calibrations between USNO and OP from the BIPM website are presented in Table V and Figure 7. Given that a 14 ns step was introduced in 1997, the data are separated into calibration results before and after this event. The most recent results, from 2003 to 2007, show variations at about 2 ns per year, except for the large variation from 9 ns in 2002 to 2.4 ns in 2003. Given the good values over several years, this suggests the possibility of missing information regarding the large change over the earlier periods.

TABLE V. USNO-OP CALIBRATION VALUES FROM THE BIPM WEBSITE. A 14 NS STEP WAS INTRODUCED IN FEBRUARY OF 1997.

Date	d/ns before +14 ns	u(d)/ns	d/ns after +14 ns	u(d)/ns
Dec-84	32	10		
Oct-86	25.3	2		
Apr-87	15.6	5		
Jun-91	-14			
Jun-94	-13	2		
Sep-94	-9	1		
Dec-94	-7.6	1		
Mar-95	-20	2		
Jan-96	-14	2		
Apr-02			9	3
Dec-03			2.4	3
Jan-06			-4.5	3
Mar-07			-2.3	3

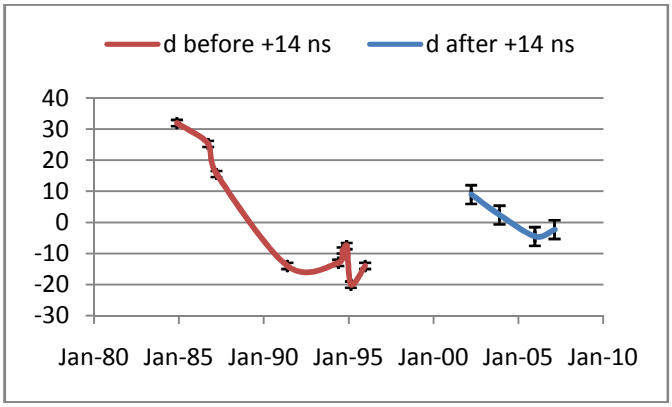

Figure 7. USNO-OP calibration data from Table V.

V. CLOSURE CALCULATIONS

We take some of the most recent calibrations and compute the total around closed loops. Clearly, the results should be 0. Note that the symbol +/- or σ in the Table VI indicates the total uncertainty for the given calibration.

C/A code, L1 frequency receivers:

OP-NIST (TTR6-OEM4)=	9.4 +/- 0.8, 2009/11
PTB-OP (TTR5,6-TTS3)=	-4.8 +/- 3.0, 2009/11
USNO MOT1-PT05=	2.3 +/- 1.2, 2010/06
NIST-USNO MOT3=	-7.5 +/- 2.0, 2007/05
Sum=	-0.6 +/- 3.9 ns

C/A code, L1 frequency receivers:

OP-NIST (TTR6-OEM4)=	9.4 +/- 0.8, 2009/11
USNO-OP=	-2.3 +/- 3.0, 2007/03
NIST-USNO MOT3=	-7.5 +/- 2.0, 2007/05
Sum=	+0.4 +/- 3.7ns

TABLE VI. CLOSURE FOR 2-FREQUENCY RECEIVERS

Labs	C1/P1 mean	C1/P1 σ	P2 mean	P2 σ	P3 mean	P3 σ	Year/ month
OPMT-NIST	-7.3	0.8	-7.2	0.9	-7.5	2.5	2009/11
PTBB-OPMT	3.3	1.0	0.4	1.4	7.7	3.3	2008/11
USN3-PTBB	…	…	…	…	-0.4	0.7	2010/06
NIST-USN3	13.1	2.0	17.6	2.0	6.2	6.0	2010/08
closure					6.0	7.3	

We see that each of the closures agree with a sum of 0 within the uncertainty. However, there is a large variation in the uncertainties for the calibrations.

VI. ABSOLUTE CALIBRATIONS

For supporting TAI, only differential calibrations are required; absolute calibrations are not necessary. Nevertheless, without any absolute calibrations, the entire TAI network could walk off. Also, it is convenient to have absolute calibrations, as this can be accomplished at a single lab without reference to any other [9]. However, absolute calibrations are generally less accurate than differential. We include a history of some absolute calibrations at NIST, as they give a measure of both the accuracy and difficulties of absolute calibration as well as the stability of receiver delays over time.

The first primary GPS receiver at NIST was NBS10.

NBS10

June 1986	53 ns	NRL
April 1987	57 +/−5 ns	
Sep 1998	54.4 +/−2 ns	

A new receiver named NIST has been primary since 2006. The 2006 Differential calibration of L1 against NBS10set the delays as L1, L2=-44.7, -44.7.

2007 NRL calibration receiver+antenna required change (not implemented) of

L1 +9.4 +/−0.4, L2 +2.3 +/−3.3.

2011-April USNO calibration of only the receiver required

L1 -25.2 +/−0.3, L2 -42.9 +/−0.3.

Comparing to the receiver only values from 2007 NRL

L1 -28.5 +/−0.4, L2 -45.4 +/−3.3 ns.

There appears to be a change of +3.3 +/−0.5 ns in the L1 channel, from 2007 to 2011.

VII. CONCLUSIONS

The historical GPS receiver calibration data appear mixed in quality. Some periods indicate potential for good repeatability, perhaps a few ns/year; But other periods show calibrations vary 10's of ns over a year or less. The closures are in line with the combined uncertainties, but these uncertainties can be as large as 7.3 ns for k = 1.

These results show that standard methods for calibrations are needed. Three aspects need standardization: 1) measurement methods, 2) processing methods, and 3) methods for computing uncertainties. This seems mandatory to reach the ns uncertainty level or below.

In any cases, regular calibrations are needed, either relative calibration campaigns or absolute calibration of separate elements of a GPS receiver chain. Coordinating GPS calibrations should be the goal to better support the generation of UTC. Receivers appear capable of supporting 1-2 ns stabilities over a year. Calibration uncertainties may be achievable at the 1 ns level. Hence differential calibrations should be accomplished approximately annually. Achieving this will take collaboration on the part of many laboratories and the BIPM.
