(Received 27 September 2002; accepted 13 December 2002)

The effect of ambient gas on the expansion dynamics of the plasma generated by laser ablation of an aluminum target has been investigated using frequency doubled radiation from a Q-switched Nd:YAG laser. The diagnostic tools include fast photography of overall visible plume emission using a 2 ns gated intensified charged coupled device and space and time resolved emission spectroscopy using a 50 cm monochromator/spectrograph and photomultiplier tube. The expansion behavior of the plasma was studied with ambient air pressure ranging from 10^{-6} to 100 Torr. Free expansion, plume splitting and sharpening, hydrodynamic instability, and stagnation of the plume were observed at different pressure levels. Space and time resolved emission spectroscopic studies showed a twin peak distribution for Al and Al^+ species at farther distances illustrating plume splitting at pressures higher than 100 mTorr. Combining imaging together with time resolved emission diagnostics, a triple structure of the plume was observed. The expansion of the plume front was compared with various expansion models and found to be generally in good agreement.

I. INTRODUCTION

Laser-produced plasma is transient in nature with characteristic parameters that evolve quickly and are strongly dependent on irradiation conditions such as incident laser intensity and pulse duration, laser wavelength, irradiation spot size, ambient gas composition, and ambient pressure. The different mechanisms involved during a laser ablation process, including laser absorption, evaporation, transient gas dynamics, radiation transport, condensation, ionization, and recombination, are rather complex and require further investigation.

There are several diagnostic techniques for characterizing a laser-produced plasma including optical emission spectroscopy, mass spectroscopy, laser induced fluorescence, Langmuir probe, photothermal beam deflection, microwave and laser interferometry, and Thomson scattering. Fast photography adds another dimension to ablation diagnostics by providing two-dimensional snap shots of the three-dimensional plume propagation. This capability becomes essential for a hydrodynamic understanding of the plume propagation and reactive scattering.

The interaction of pulsed laser ablation plumes with a background gas has received increased attention recently due to its importance in laser deposition, nanoparticle formation and growth, cluster production, etc. In addition to these applications, these studies are very important for the modeling of various processes in space physics, plasma chemistry, and hydrodynamics. Compared to the expansion into a vacuum, the interaction of the plume with an ambient gas is a far more complex gas dynamic process due to the rise of several physical processes involved such as deceleration, attenuation, thermalization of the ablated species, diffusion, recombination, formation of shock waves, and clustering. Recent measurements performed over a wide range of expansion durations have described a fairly complicated gas dynamic picture of plume ambient gas interaction which is characterized by different propagation phases and is accompanied by plume oscillations arising at rather high background pressures. In low gas pressure (less than 100 mTorr), the plume expansion could be described by Monte Carlo simulation. However, for Euler modeling, all the simulated species including the neutral atoms and ions have the same velocity, whereas experimental results indicate that excited neutral particles are characterized by slower velocity in comparison with ionized atoms. In moderate or high pressures, a blast wave model is found to accurately describe the plume propagation distance during the early expansion stages, whereas a shock layer model and an empirical drag model predict the maximum plume length with considerable accuracy.

The emission spectra, electron temperature, and density are found to be significantly influenced by the ambient atmosphere. As discussed by several authors, the surrounding atmosphere also affects the crater size and the amount of sample vaporized with the laser beam. The relative enhancement of an emitted line depends on the nature of the gas, gas pressure, and the excitation energy of the electronic transition responsible for the line. The two main mechanisms invoked in the excitation are the particle collision excitation and the electron impact excitation. Although extensive experimental and theoretical work has been done, many effects of the laser beam interaction with a metallic...
surface in the presence of ambient gas are still not satisfactorily explained.35–40

In this article, we present a detailed experimental analysis of the laser ablation of aluminum by 2 ns gated photography and space and time resolved emission spectroscopy. Fast side-on views of the plume expansion are made by recording overall visible emission from the plasma plume, which enables us to obtain information on the interaction of the plasma with the ambient gas during earlier and later stages of the process. Investigations are made on the stratification and stability of the geometry and shape of the aluminum plasma at different air pressures ranging from 10⁻⁶ to 100 Torr. We report plume splitting in the fast moving component of the plasma plume. The plume splitting behavior appears only in a narrow region of pressure (around 150 mTorr). Spatially resolved time of flight (TOF) emission measurements are carried out at this pressure to infer the species local populations inside the plasma. Present results indicate that the combination of fast photography and time resolved emission spectroscopic diagnostic techniques gives much more insight into the expansion behavior of a laser-produced plasma into an ambient atmosphere. We also estimated the ion stopping distance using the popular Monte Carlo Simulation model41,42 (SRIM code) and compared with our experimental data. An adiabatic expansion model is used to describe the plume length of the laser created aluminum plasma at different ambient pressures.

II. EXPERIMENT DESCRIPTION

The schematic of the experimental setup is given in Fig. 1. Pulses from a frequency doubled Nd:YAG laser (8 ns pulse width, maximum energy 700 mJ) were used to create aluminum plasma in a stainless-steel vacuum chamber. The chamber was pumped using a high-speed turbomolecular pump and a maximum base pressure ~10⁻⁶ Torr was achieved. The aluminum target in the form of a disk was rotated about an axis parallel to the laser beam. This avoids errors due to local heating and drilling. The laser beam was attenuated by a combination of wave plate and cube beam splitter and focused onto the target surface at normal incidence using an antireflection-coated planoconvex lens. The beam energy was monitored using an energy meter (Ophir, Model 30A).

The plume imaging was accomplished using an intensified charged coupled device [(ICCD) PI MAX, Model 512 RB] placed orthogonal to the plasma expansion direction. A Nikon lens was used to image the plume region onto the camera to form a two-dimensional image of the plume intensity. The visible radiation from the plasma was recorded integrally in the wavelength range of 350–900 nm. In order to eliminate 532 nm stray photons from reaching the camera, a magenta subtractive filter was used. A programmable timing generator was used to control the delay time between the laser pulse and the imaging system with overall temporal resolution of 1 ns.

For space and time resolved spectroscopy, an optical system was used to image the plasma plume onto the entrance slit of the monochromator/spectrograph (Acton Pro, SpectraPro 500i), so as to have one-to-one correspondence with the sampled area of the plume and the image. The optical system was translated to monitor different parts of the plume. Spatial resolution provided by our optical system was better than 0.5 mm. The monochromator was equipped with three gratings: 150 g/mm, 600 g/mm, and 2400 g/mm. One of the exit ports of the spectrograph was coupled to an ICCD camera that was operated with vertical binning of the charge coupled device array to obtain spectral intensities versus wavelength. The other exit port of the monochromator was coupled to a photomultiplier tube (PMT). A diverter mirror was used for switching from PMT to ICCD or vice versa. For time resolved studies of a particular species in the plume, the specific lines are selected by tuning the grating and imaging onto the slit of the PMT. For recording the temporal profiles, the output of the PMT was directly coupled to a 1 GHz digital phosphor oscilloscope (Tektronix TDS5014, 5 GS/s maximum real-time sample rate). This setup provides delay as well as decay of emission of a constituent species within the plasma which are very important parameters related to the evolution of laser-ablated materials in a direction normal to the target surface.

III. PHYSICAL DESCRIPTION OF LASER–PLASMA EXPANSION

Since the laser intensity exceeds the ablation threshold of the target, the laser beam evaporates and ionizes material, creating a plasma plume above the material surface. Initially, the atoms, molecules, and ions undergo collisions in the high-density region near the target forming the so-called Knudsen layer, leading to a highly directional expansion perpendicular to the target. The expansion dynamics of the laser-produced plasma plume have been described elsewhere using semiquantitative models.43,44 In the initial stage, the interaction of the laser beam with the bulk target results in the evaporation of the surface layer. Following this, the interaction of the laser beam with the evaporating material leads to the formation of an isothermally expanding plasma and this persists until the termination of the laser pulse. The
vapor particles are pushed forward and in the lateral direction solely by high pressure emanating from the target surface when the ejected plume is considered transparent to the incident laser beam. Strong laser–plasma interaction creates an additional high-pressure kinetic energy region fueling a further expansion of the plume. After the termination of the laser pulse, no particles are ejected from the target surface. An adiabatic expansion of the plasma occurs when the temperatures can be related to the dimensions of the plasma. Singh and Narayan have found that the forward directed nature of the laser evaporation process results from anisotropic expansion velocities of different species, which are mainly controlled by the initial dimensions of the expanding plasma. The thermal energy is rapidly converted into kinetic energy, with the plasma attaining extremely high expansion velocities. During the initial stages of plasma expansion when the particle density is high ($\sim 10^{19}$ cm$^{-3}$), the mean-free path of the particles is short ($\sim \mu$m) and the plasma behaves as a continuum fluid. As the plasma expands, the temperature drops very rapidly within 100 ns time, however the drop is smaller at later times ($> 100$ ns) because energy is regained in the recombination of ions.

The plasma expands freely in a vacuum or low background pressures. As the background pressure increases, the plume behavior is characterized by strong interpenetration of the laser plasma and ambient low-density gas. The expansion dynamics of the plume in this pressure regime is determined by the properties of the plasma as well as the background gas. In this regime, collisional effects start to play a role. At still higher background pressures, the expansion dynamics of the plasma are fully governed by the nature and pressure of the ambient gas used. In general, an increase in background pressure results in the following effects: (i) an increase in fluorescence from all species due to enhanced collisions on the expansion front and subsequent interplume collisions, (ii) shock front formation, and (iii) slowing of the plume compared to propagation in vacuum resulting in spatial confinement of the plasma. The presence of ambient gas during expansion may also lead to reactive scattering, thermalization of the plume, enhanced condensation leading to cluster and nanoparticle formation, etc.

IV. IMAGING RESULTS AND ANALYSES

Plasma emission begins on the target surface soon after the laser photons reach the surface. Images of the time evolution of the expanding aluminum plasma were taken at different air pressures ranging from $10^{-6}$ to 100 Torr. Typical ICCD images of the expanding plume at different times after the onset of plasma are given in Figs. 2–7 at different air pressures. These images were recorded at a laser irradiance of 3 GW cm$^{-2}$. The duration of the intensification (exposure time) is 2 ns and each image is obtained from a single laser pulse. Timing jitter is less than 1 ns. All of the images given in Figs. 2–7 are normalized to the maximum intensity in that image. It should be remembered that each image represents the spectrally integrated plume in the region 350–900 nm that is due to emission from the excited states of various species. They are not necessary representative of the total flux because a part of the plume is nonluminous.

Figures 2 and 3 represent the plume expansion at $10^{-6}$ Torr and $2 \times 10^{-2}$ Torr respectively. From Figs. 2 and 3, it is clear that there is not much influence of the ambient air pressure on the expansion of the plasma when we increase air pressures from $10^{-6}$ to $2 \times 10^{-2}$ Torr. In this region, the plasma expands freely. Plasma expansion into a
vacuum environment is simply adiabatic and can be fully predicted by theoretical models and numerical gas dynamic simulations. If the particles are released and the number of collisions among them are not too high, the Knudsen layer feeds an unstable adiabatic equilibrium (UAE). The UAE may evolve in a steady adiabatic flow, which terminates due to falling density with time. The light emission from the plume very close to the target surface exists even after 1 μs.

This stationary emission region close to the target surface has been reported by others and may result from gas collisions between the plume ejecta in the high-pressure region of the initial expansion, resulting in a Knudsen layer with stopped and/or backward moving material.

When the pressure is increased to 10^-1 Torr, the plume breaks away from the target surface 70 ns after the onset of the plasma, forming a faster moving component and a slow moving/stationary component near the target surface. Coincidentally, this pressure range falls within the transition from...
collisionless to collisional interaction of the plume species with the gas. This is supported by the fact that at these pressure levels, the intensity of radiation is enhanced especially after 100 ns. Here, the plume behavior is characterized by strong interpenetration of the laser plasma and ambient low-density gas, where a contact boundary is formed between plasma and a shock wave in the gas. During interpenetration, the transfer of kinetic energy from laser plasma to the background gas takes place, and energy and momentum exchange occurs because of ion–ion Coulomb scattering, ion–neutral collisions, charge exchange interactions, etc. The emission of this component exists until 1500 ns from the beginning of the expansion process. The time evolution of the plume at a background pressure of 150 mTorr is given in Fig. 4. At early times, the plume front is spherical in nature, but as time evolves, the plume front becomes sharpened. Plume sharpening behavior suggests that higher kinetic energy particles are emitted closer to the target surface normal. It has been reported that ions of the highest ionization state dominate in the direction of maximum emission, and that their concentration falls sharply away from the normal. Along with sharpening, the faster moving component of the expanding plume front splits again into two clouds indicating plume splitting. These peculiar plume splitting and sharpening phenomena are observed only in a particular pressure range (around 150 mTorr). Several authors have reported plume splitting in a laser-produced plasma using an ion probe, TOF mass spectroscopy, optical emission spectroscopy, laser induced fluorescence, etc. On the contrary, we observed plume splitting in the faster moving component in imaging studies. Here, the fast component of the plume has penetrated into ambient gas and a part of it may be decelerated because of interaction with background gas.

As we increase the pressure from $10^{-1}$ Torr, the mutual penetration of the laser–plasma ions and the ambient gas decrease and an interface is formed. In this regime, along with deceleration, turbulence also appears in the expanding plume. The time evolution of the images of the plume at 1.3 Torr air pressure are given in Fig. 5. Here, also the fast component of the plume penetrates into the ambient gas and the instability is observed mostly in the slower component. We expect that near the contact boundary instabilities such as Rayleigh–Taylor (RT) set in the plasma. Baranov et al. addressed the instability of a laser produced expanding plasma in a background gas. According to them, due to RT instability, the expanding plume front tends to become unstable and the interface between the plasma and ambient gas becomes perturbed. The turbulence stage was enhanced at a pressure range around 1 Torr where we can see a number of intensity peaks. This turbulence appeared after 200 ns after the evolution of the plume (for a background pressure of 1.3 Torr) and the instability was manifested by the breaking up of radiation. We also confirmed that the occurrence of heated spots in the plume is not merely due to reactive processes inside the plume (e.g., formation of AlN or AlO) by introducing He and Ar as background gases. We still observe the instability during plume expansion into Ar and He background gases, but at different pressure levels.

We made an estimate of the density of the background gas where the RT instability can form in the present experimental conditions. The RT instability would grow exponentially with time, $\sim e^{\eta t}$, at a rate:

$$\eta^2 = ka \left( \frac{\rho_p - \rho_b}{\rho_p + \rho_b} \right),$$

where $\rho_p$ and $\rho_b$ are the density of the plasma and background gas respectively, $a = d\psi/dt$, with $\psi$ being the velocity of the plasma front and $k$ as a perturbation wave number. The plasma boundary is stable when $\eta^2 > 0$ ($\rho_p > \rho_b$), while the arrangement becomes unstable when $\eta^2 < 0$ ($\rho_p < \rho_b$). The instability growth occurs in the maximum acceleration region that can be derived from the derivative of momentum conservation equation

$$\frac{d}{dt} \left( M_0 + \frac{M_0}{3} \pi R^3 \rho_b \nu \right) = 0,$$

where $M_0$ is the laser–plasma mass and $R$ is the distance from the target surface. The growth of instability corresponds to maximum acceleration region and from Eq. (2),

$$R = \left( \frac{3M_0}{4\pi\rho_b} \right)^{1/3}.$$

Following Ng et al., the mass ablated in the present experimental conditions is estimated to be $1.71 \times 10^{-5}$ g. Using our experimental parameters, viz. $R = 1.3$ cm, the calculated background density is $1.87 \times 10^{-6}$ g cm$^{-3}$ which corresponds to a pressure of 1.22 Torr (considering nitrogen) which is in good agreement with the experimental observation.

As the pressure increases, plasma deceleration starts more rapidly because of confinement of plume. The plume expansion behavior at 10 and 100 Torr are given in Figs. 6 and 7, respectively. At these pressure levels, the plasma deceleration starts very early. The expansion front is slowed more rapidly and coalesces with the slower components. As the pressure of the ambient gas increases, a greater confinement of the plasma takes place and the effective length of the plume is reduced to a few millimeters. The lifetime of the plasma plume is found to be much higher in this pressure regime because of the formation of different molecules like AlO, AlN, etc. that have much higher decay time compared to neutral and ionic species.

In order to have a better understanding of the plasma expansion and evolution, we used the imaging data to create position–time plots of the luminous front at several background air pressures shown in Fig. 8. The symbols in Fig. 8 represent experimental data points and the curves represent different expansion models. At low pressures ($< 10^{-2}$ Torr), the plume front behaves linearly with time (the straight-line fit in the graph corresponds to $R \propto t$). This indicates free expansion of the plume into a vacuum. The expansion velocities of the plasmas are measured from the slopes of the displacement–time graph. The estimated expansion velocities of the plasma in this pressure region is $\sim 10^5$ cm s$^{-1}$ which is the same as the free expansion velocity. Plume expansion in the early stage ($<40$ ns) is almost linear irrespec-
tive of the background gas pressure. The plume expansion at moderate pressures is represented by a shock model given by 26,52

\[ R = \xi_0 (E_0 / \rho_0) \left( \frac{1}{\gamma} \right)^{1.75} \]  

where \( \xi_0 \) is a constant which depends on \( \gamma \), the specific heat capacity. The shock model describes the explosive release of energy \( E_0 \) through a background gas of density \( \rho_0 \). The shock model, which neglects viscosity, gives a prediction of complete propagation. As shown in Fig. 8, the plume front position with time for 1.3 Torr agrees well with the shock model.

At later stages the plume expansion is described by a drag model, which is given by

\[ R = R_0 [1 - \exp(-\beta t)] \]  

where \( R_0 \) is the stopping distance of the plume and \( \beta \) is the slowing coefficient \((R_0 \beta = v_0)\). The drag model predicts that the plume will eventually come to rest due to resistance from collisions with the background gas. The plume front position at later stages (>500 ns) is well described by the drag model (Fig. 8). The plume front position of the plasma at 150 mTorr showed a \( t^{0.445} \) dependence.

V. PLUME LENGTH

We tried to estimate the length of the plume at different ambient gas pressures using an adiabatic expansion model and the range of Al ions using a Monte Carlo simulation program. According to the adiabatic expansion model,4 the ablated species pushes the background gas species until the plasma and gas pressure equilibrate. Then, the length of the plasma is given by

\[ L = A \left( \frac{\gamma - 1}{\gamma} \right) P^{-1/3} V^{1/3} \]  

where \( A \) is the geometrical factor related to the shape of the laser spot at the target surface, \( \gamma \) is the specific heat ratio, \( E \) is the laser energy, \( P_0 \) is the ambient gas pressure, \( V \) is the initial volume of the plasma is given by \( V = V_0 \tau_{\text{laser}}^{-w} \) (where \( V_0 \) is the initial species velocity, \( \tau_{\text{laser}} \) is the laser pulse width, and \( w \) is the spot size at the target surface). The factor \( A \) depends on the expansion geometry and for a conical plume with an expansion angle \( \theta \) (circular spot),

\[ A = \left[ \frac{1}{\tan \theta} \left( \frac{3 \tan \theta}{\pi + 2 \pi \tan \theta} \right)^{1/3} \right] \]  

where \( A \) is the geometrical factor related to the shape of the laser spot at the target surface, \( \gamma \) is the specific heat ratio, \( E \) is the laser energy, \( P_0 \) is the ambient gas pressure, \( V \) is the initial volume of the plasma is given by \( V = V_0 \tau_{\text{laser}}^{-w} \) (where \( V_0 \) is the initial species velocity, \( \tau_{\text{laser}} \) is the laser pulse width, and \( w \) is the spot size at the target surface). The factor \( A \) depends on the expansion geometry and for a conical plume with an expansion angle \( \theta \) (circular spot),

\[ A = \left[ \frac{1}{\tan \theta} \left( \frac{3 \tan \theta}{\pi + 2 \pi \tan \theta} \right)^{1/3} \right] \]  

Considering experimental parameters with \( \theta = 30^\circ \), the estimated values of plume length at different pressures along with experimental maximum range of the plume are given in Fig. 9 which are in fairly good agreement with the experimentally observed plume lengths (taken from ICCD images). Both the experiment and the model reveal that the ambient gas slows down the expansion of the ablation plume.

The estimate of the mean projected length of Al\(^+\) ions at different ambient pressures of air is based on the popular Monte Carlo simulation program SRIM.\(^{31,42}\) The calculated results are also given in Fig. 9. The estimated stopping distance is in good agreement with the experimentally observed value of plume length at low pressure (around 150 mTorr). The calculations did not follow experimental values at high pressures, where the plume length is found to be much higher compared to the calculated Al\(^+\) ion range. The comparison shows that the Monte Carlo simulation model is good for low pressures only.

VI. SPECTROSCOPIC RESULTS AND PLUME SPLITTING

To gain more insight, we performed space and time resolved spectral emission studies of different species in the expanding plasma in the background pressure levels de-
tion, we particularly emphasize the double peak observation at a background pressure of 150 mTorr. The twin-peak distribution is observed only beyond a certain distance from the target. The $R-t$ plots drawn for Al and Al$^+$ species are given in Figs. 10 and 11, respectively. It is interesting to note that the faster peak for excited Al and Al$^+$ species propagates without much attenuation. The estimated expansion velocities of fast moving Al$^+$ and Al species are $7.6 \times 10^6$ and $6.5 \times 10^6$ cm s$^{-1}$, respectively, which correspond to a kinetic energy of 800 and 650 eV, respectively. It is expected that fast electrons and ions travel at the leading edge of the plume. The ions can scatter the ambient gas, so that the following neutral particles propagate through a more rarefied ambient medium. The faster peak moves with a velocity very close to the free expansion velocity and the slower one follows a $t^{0.445}$ dependence that exactly matches with the plume front position corresponding to 150 mTorr as given in Fig. 8.

Our measurements also show that (Figs. 11 and 12) the higher the ionization state, the greater the kinetic temperature. This is probably due to enhanced absorption of laser light by the plasma. After the laser action ceases, the charge composition of the plasma is governed by three-body recombination, which dominates over radiative and/or dielectronic ones due to the rapid drop in electron temperature as the plasma expands. The ions located at the front of the plasma acquire the largest energy during hydrodynamic acceleration and the interaction time for recombination is very much reduced. This small group of high-energy ions transports a significant fraction of absorbed energy. The ions located in the inner plume layers are accelerated much less due to hydrodynamic expansion. They remain much longer in the denser state, which is being subjected to strong recombination, which in turn enhances the emission from these regions.

The position of the plume front recorded using ICCD imaging at 150 mTorr moves much slower than the free expansion model. The slow moving component in the TOF species matches well with the plume front position recorded using ICCD imaging. However, we see almost no signal corresponding to the faster profile in the TOF species using.

FIG. 10. Intensity variation of spectral emission with time for Al species (396 nm) recorded at 18 mm from the target surface. The laser power density used was 3 GW cm$^{-2}$ and the background air pressure was 150 mTorr for these measurements. The solid lines represent the SMB fit. The faster peak is fitted with simple Maxwell–Boltzmann distribution using $T$ = 650 eV. The fitting parameters for SMB distribution for the slow peaks are $T$ = 28 eV and $T$ = 7 eV respectively.

FIG. 11. Position–time graphs for two peaks observed with time resolved emission studies of Al species at 396.1 nm. Pk1 and Pk2 represent the faster and slower component, respectively. The solid line corresponds to linear fit and the dotted curve is the fit for $R \sim t^{0.445}$. 

The expansion velocities of the kinetic peaks are strongly affected by the background gas pressure. Gas phase collisions can transform the initial temporal distributions into a very different final distribution. With increasing pressure, due to the enhanced collision with the background gas species, the slowdown process is very rapid. Thus, the ambient gas acts as a retarding media, slowing the plume development, and the bringing the ion energy closer to the energy of excited neutral atomic species in the plasma. At low pressures, the temporal profiles of the different emitting species are described by single peak distribution. But, as the pressure increases, we find that the temporal distribution of excited Al and Al$^+$ is changed to a twin peak distribution. In this section, we particularly emphasize the double peak observation in the temporal profiles of Al and Al$^+$ species at 150 mTorr pressure, where the plume splitting appeared during later stages of the plasma expansion.

The time evolution of the spectral emission profiles obtained in the present work clearly reveals that the species ejected by the Al plume exhibit twin peaks for the TOF distribution. Figure 10 shows the typical TOF profile of Al at 396.1 nm recorded at a distance 18 mm from the target surface at a background pressure of 150 mTorr. The twin-peak distribution is observed only beyond a certain distance from the target. The $R-t$ plots drawn for Al and Al$^+$ species are given in Figs. 10 and 11, respectively. It is interesting to note that the faster peak for excited Al and Al$^+$ species propagates without much attenuation. The estimated expansion velocities of fast moving Al$^+$ and Al species are $7.6 \times 10^6$ and $6.5 \times 10^6$ cm s$^{-1}$, respectively, which correspond to a kinetic energy of 800 and 650 eV, respectively. It is expected that fast electrons and ions travel at the leading edge of the plume. The ions can scatter the ambient gas, so that the following neutral particles propagate through a more rarefied ambient medium. The faster peak moves with a velocity very close to the free expansion velocity and the slower one follows a $t^{0.445}$ dependence that exactly matches with the plume front position corresponding to 150 mTorr as given in Fig. 8.

Our measurements also show that (Figs. 11 and 12) the higher the ionization state, the greater the kinetic temperature. This is probably due to enhanced absorption of laser light by the plasma. After the laser action ceases, the charge composition of the plasma is governed by three-body recombination, which dominates over radiative and/or dielectronic ones due to the rapid drop in electron temperature as the plasma expands. The ions located at the front of the plasma acquire the largest energy during hydrodynamic acceleration and the interaction time for recombination is very much reduced. This small group of high-energy ions transports a significant fraction of absorbed energy. The ions located in the inner plume layers are accelerated much less due to hydrodynamic expansion. They remain much longer in the denser state, which is being subjected to strong recombination, which in turn enhances the emission from these regions.

The position of the plume front recorded using ICCD imaging at 150 mTorr moves much slower than the free expansion model. The slow moving component in the TOF species matches well with the plume front position recorded using ICCD imaging. However, we see almost no signal corresponding to the faster profile in the TOF species using.
ICCD imaging studies. The TOF profiles indicate that the yield or concentration of the higher kinetic energy peak is rather low compared to the slow moving component, which leads us to believe that the dynamic range of the ICCD is not high enough to expose these photons.

Since we observe plume splitting with imaging studies for the low kinetic energy component in the TOF profile, we conclude that there exists a triple plume structure with one component traveling near vacuum speed and two other slower components. The estimated temporal separation at a specific spatial point (considering the image at 610 ns) in plasma between the two slow layers observed with the imaging studies is \( \sim 60 \) ns. The TOF distribution of the slow component is rather broadened and, hence, we do not clearly see the splitting of the delayed TOF distribution as observed with the imaging studies. Only through the combination of imaging and TOF spectroscopy do we determine the full plume structure.

In order to gain more insight into the kinetic properties of the plume species, a shifted Maxwell–Boltzmann (SMB) distribution is used to fit the TOF profile of Al species. The SMB fit function is given by

\[
f(v) = A v^3 \exp\left(-\frac{m(v-v_0)^2}{2kT}\right),
\]

where \( A \) is the normalization parameter, \( v \) is the velocity of the species, \( v_0 \) is the flow velocity, \( T \) is the translational temperature, and \( m \) is the mass of the species. Figure 12 gives the best curve fit for the faster and slower kinetic peaks. There is a mismatch observed with the fitted SMB distribution for the slower peak. We expect that the second peak is a convolution of TOF profiles of the same species having different velocities. So we attempted to fit two SMB distributions in the slower peak and the superposition of these two fits is in relatively good agreement with the experimentally observed TOF curve.

VII. CONCLUSIONS

The expansion dynamics of laser produced Al plasma has been studied using fast photography and space and time resolved emission diagnostic techniques. The time evolution of 2 ns gated photography employing an ICCD camera allowed a precise description of the aluminum plume evolution. The expansion behavior of the plasma at different ambient air pressures ranging from \( 10^{-6} \) to 100 Torr was studied. The results show several interesting effects.

At low ambient pressure levels \( (<10^{-2} \) Torr), the plasma expands freely. The addition of ambient gas leads to more efficient electron impact excitation and plasma recombination which enhances the emission from different species in the plasma. As pressure increases above 100 mTorr, the plume is characterized by strong interpenetration of the plasma species and background gas that leads to plume splitting and sharpening. During this stage of mutual penetration of laser plasma and ambient gas, a considerable fraction of kinetic energy was converted into heat which in turn increases the temperature of the gas and radiation. At pressure levels around 1 Torr, turbulence is observed in the decelerating plume front. A further increase in pressure resulted in the contraction of the mutual penetration zone and the plasma front becomes compressed.

It is also noted that in the earlier stage \( (<40 \) ns), plasma expansion is almost linear irrespective of the background pressure. At moderate pressures and at times \( <500 \) ns, the plasma expansion is characterized by a spherical shock wave model. For time \( >500 \) ns, the velocity of the plume is low due to numerous collisions with the background gas molecules. The drag model is a good approximation in this regime. The results obtained with TOF emission studies showed a twin-peak distribution for Al and Al\(^+\) species indicating plume splitting. Here, the faster component of the species moves with the free expansion velocity whereas the slowed component has characteristics which are strongly influenced by the pressure of the background gas.

Combining both the diagnostic tools, a triple structure of the plume is deduced. Highly energetic ions moving with the free expansion velocity are not observed with fast imaging studies, probably overlooked because of the bright plume luminescence of the slow component. The temporal evolution of the slower component follows the plume front position recorded by fast photography.

An estimate of the plume and ion range is made for different ambient gas pressures using adiabatic expansion and Monte Carlo Simulation models. The plume length estimate using the adiabatic expansion model is in good agreement with observed plume length. The calculated ion range using the Monte Carlo simulation model shows good agreement with plume length measurements at moderate pressures, but considerable deviation is found at high pressures.
