Time-Domain Orthogonal Finite-Element Reduction-Recovery Method for Electromagnetics-Based Analysis of Large-Scale Integrated Circuit and Package Problems

Duo Chen and Dan Jiao, Senior Member, IEEE

Abstract—A time-domain orthogonal finite-element reduction-recovery method is developed to overcome the large problem sizes encountered in the simulation of large-scale integrated-circuit and package problems. In this method, a set of orthogonal prism vector basis functions is developed. Based on this set of bases, an arbitrary 3-D multilayered system such as a combined package and die is reduced to a single-layer system with negligible computational cost. More importantly, the reduced single-layer system is diagonal and, hence, can be solved readily. From the solution of the reduced system, the solution of the other unknowns is recovered in linear complexity. The method entails no theoretical approximation. It applies to any arbitrarily shaped multilayer structure involving inhomogeneous materials or any structure that can be geometrically modeled by triangular prism elements. In addition, it permits nonlinear device modeling and broadband simulation within one run. Numerical and experimental results have demonstrated its accuracy and high capacity in simulating on-chip, package, and die-package interface problems.

Index Terms—Die–package cosimulation, electromagnetic simulation, finite-element methods, large scale, on-chip, package, time domain.

I. INTRODUCTION

THE SCALING of supply voltages and the increased level of integration have conspired to make the analysis and design of microelectronic systems increasingly challenging. The impact of noise due to signal switching, die–package interaction, power management techniques, substrate coupling, etc., can be seen at all levels of a power delivery network, from chip to package to motherboard to the voltage regulator module. Prevailing circuit-based signal-integrity paradigms are reaching their limits of predictive accuracy when applied to the combined die–package problem. Thus, there is a critical need for the electromagnetics-based cosimulation of the die and package to control the global electrical interaction and optimize performance as an integrated system.

The cosimulation of the die and package results in numerical problems of ultra-large scale, requiring billions of parameters to describe them accurately. In order to address the large problem size, electromagnetic solutions have to scale favorably. In recent years, researchers have been developing electromagnetics-based computer-aided-design technologies amenable for integrated-circuit (IC) and packaging problems as can be seen from [1]–[19].

In [11] and [12], a time-domain layered finite-element reduction-recovery (LAFe-RR) method was developed for solving large-scale IC problems. This method can reduce the system matrix of size \( O(N) \) rigorously to that of size \( O(M) \) for any multilayered structure, with \( N \) being the number of unknowns in the entire 3-D structure and \( M \) being the number of unknowns in a single layer. Furthermore, the reduction from \( O(N) \) to \( O(M) \) is achieved without any computational cost via analytical means, and hence, the CPU and memory overheads are minimal. Moreover, the reduction preserves the sparsity of the original matrix, thus enabling an efficient computation of the reduced matrix. The solution of the \( O(M) \) parameters generated by this method is the same as that of the \( O(M) \) parameters in the original \( O(N) \) equation. The method has been successfully applied to solve large-scale IC problems.

The remaining computational task in the LAFe-RR method is the solution of the reduced system. Although the sparsity is preserved in the reduction process, if the reduced system is large, solving it could be still challenging.

In this paper, an orthogonal finite-element reduction-recovery (OrFe-RR) method was developed to advance the LAFe-RR method to the level of simulating a combined die–package system. In this method, a set of orthogonal prism vector basis functions is developed. These basis functions are complete. In addition, they enforce the tangential continuity of the electric field and the normal continuity of the electric flux across material interfaces. The advantage of this set of bases is three-fold. First, an arbitrary 3-D multilayered system such as a combined package and die can be reduced to a single-layer system with negligible computational cost. Second, the reduced single-layer system is diagonal and, hence, can be solved readily. Third, the solution of the unknowns in other layers...
The remaining of this paper is organized as follows. In Section II, the orthogonal prism vector basis functions developed in this work are presented. In Section III, the time-domain OrFE-RR method is detailed. In Section IV, numerical and experimental results are given to demonstrate the accuracy and high capacity of the proposed method, and Section V relates to our conclusions.

II. ORTHOGONAL PRISM VECTOR BASIS FUNCTIONS

Based on our knowledge in 2-D orthogonal vector bases in a triangular element [20] and 3-D orthogonal vector bases in a tetrahedral element [21], the 3-D orthogonal vector bases in a prism element are developed as follows.

In each prism element, we construct fifteen vector bases from $N_1$ to $N_{15}$ as shown in Fig. 1. The degrees of freedom associated with bases $N_i (i = 1, 2, 3, \ldots, 6)$ are assigned on the upper and lower planes. Each of these bases is purely tangential to edge $i$ at the midpoint of edge $i$. They ensure the tangential field continuity across the element interface. They are given by

$$\mathbf{N}_i = \zeta \mathbf{Z}_i, \quad i = 1, 2, 3$$

$$\mathbf{N}_i = (1 - \zeta) \mathbf{Z}_{i-3}, \quad i = 4, 5, 6$$

(1)

in which $\zeta$ is 0 on the lower plane and 1 on the upper plane, and vector bases $\mathbf{Z}_i$ are

$$\mathbf{Z}_i = \left[ \mathbf{W}^i - \sum_{m=1}^{3} \frac{\langle \mathbf{W}^i, \mathbf{B}^m \rangle}{\langle \mathbf{B}^m, \mathbf{B}^m \rangle} \mathbf{B}^m \right], \quad i = 1, 2, 3$$

(2)

where $\mathbf{W}^i_e (i = 1, 2, 3)$ are the normalized edge basis functions in element $e$ given by [22, pp. 276–279]

$$\mathbf{W}^i_1 = l^i_1 (\xi_1 \nabla \xi_2 - \xi_2 \nabla \xi_1)$$

$$\mathbf{W}^i_2 = l^i_2 (\xi_2 \nabla \xi_3 - \xi_3 \nabla \xi_2)$$

$$\mathbf{W}^i_3 = l^i_3 (\xi_3 \nabla \xi_1 - \xi_1 \nabla \xi_3)$$

(3)

in which $l^i_e (i = 1, 2, 3)$ is the length of edge $i$ in element $e$, and $\xi_i (i = 1, 2, 3)$ are the area coordinates [22, pp. 95–97], and $\mathbf{B}^i_e (i = 1, 2, 3)$ are the supplemental vector basis functions given by

$$\mathbf{B}_1^i = \xi_1 \xi_2 \hat{n}_1 \quad \mathbf{B}_2^i = \xi_2 \xi_3 \hat{n}_2 \quad \mathbf{B}_3^i = \xi_3 \xi_1 \hat{n}_3$$

(4)

in which $\hat{n}_i$ denotes the unit vector that is normal to edge $i$.

The degrees of freedom associated with bases $N_i (i = 7, 8, 9)$ are assigned along the vertical edges of a prism element. They also guarantee the tangential field continuity across the element interface. These bases are given by

$$\begin{align*}
N_7 &= \xi_1 \nabla \zeta \\
N_8 &= \xi_2 \nabla \zeta \\
N_9 &= \xi_3 \nabla \zeta.
\end{align*}$$

(5)

From (1) and (2), it can be seen that the normal components of bases $N_i (i = 1, 2, 3, \ldots, 6)$ vanish at the midpoints of the element edges on the upper and lower triangular elements shown in Fig. 1. Hence, they form an incomplete set of bases, i.e., they cannot be used to represent fields that have nonvanishing normal components at the midpoints of the element edges. To make them complete, bases $N_i (i = 10, 11, 12, \ldots, 15)$ are constructed to be complementary to bases $N_i (i = 1, 2, 3, \ldots, 6)$. They supplement the normal components of the electric fields. In addition, they are associated with each individual element, i.e., not shared by elements, hence allowing for the normal discontinuity of $\mathbf{E}$ and thereby ensuring the normal continuity of the electric flux across element interfaces in the variational process of a finite-element procedure. These bases are given by

$$\begin{align*}
N_i &= \zeta \mathbf{B}^i_{-9}, \quad i = 10, 11, 12 \\
N_i &= (1 - \zeta) \mathbf{B}^i_{-12}, \quad i = 13, 14, 15.
\end{align*}$$

(6)

Defining a numerical integration on the upper and lower planes as

$$\langle \mathbf{N}_i^e, \mathbf{N}_j^e \rangle_S = \sum_{l=1}^{3} \alpha_l \mathbf{N}_i^e (m_l) \cdot \mathbf{N}_j^e (m_l)$$

(7)

where $m_l$ denotes the midpoint of edge $l$ and $\alpha_l$ is the coefficient chosen such that the numerical integration is at least second-order accurate (generally chosen as 1/3 in our implementation), we obtain

$$\begin{align*}
\langle \mathbf{N}_i^e, \mathbf{N}_j^e \rangle_V &= 0, \quad i = 1, 2, 3, 10, 11, 12; j = 1, 2, 3, 10, 11, 12; i \neq j \\
\langle \mathbf{N}_i^e, \mathbf{N}_j^e \rangle_V &= 0, \quad i = 4, 5, 6, 13, 14, 15; j = 4, 5, 6, 13, 14, 15; i \neq j \\
\langle \mathbf{N}_i^e, \mathbf{N}_j^e \rangle_V &= 0, \quad i = 1, 2, 3, 10, 11, 12; j = 4, 5, 6, 13, 14, 15; j \neq i + 3
\end{align*}$$

(8)

i.e., basis functions $N_i (i = 1, 2, 3, 10, 11, 12)$ are orthogonal to each other, $N_i (i = 4, 5, 6, 13, 14, 15)$ are orthogonal to each other, and these two sets are also mutually orthogonal to each other. In addition, because the bases on the lower and upper planes are perpendicular to the vector bases along the vertical edges, we have

$$\begin{align*}
\langle \mathbf{N}_i^e, \mathbf{N}_j^e \rangle_V &= 0, \quad i = 1, 2, 3, 10, 11, 12; j = 7 - 9 \\
\langle \mathbf{N}_i^e, \mathbf{N}_j^e \rangle_V &= 0, \quad i = 4, 5, 6, 13, 14, 15; j = 7 - 9
\end{align*}$$

(9)

i.e., basis functions $N_i (i = 1, 2, 3, 10, 11, 12)$ and $N_i (i = 4, 5, 6, 13, 14, 15)$ are orthogonal to basis functions $N_i (i = 7, 8, 9)$.  

Fig. 1. Illustration of the orthogonal prism vector basis functions.
III. TIME-DOMAIN ORFE-RR METHOD

In this section, first, a time-domain finite-element framework is outlined. The proposed OrFE-RR method is then detailed, which includes the reduction from a 3-D layered system to a single-layer one that is diagonal in negligible computational cost, the recovery of other unknowns in linear complexity, and the performance analysis.

A. Time-Domain Finite-Element Framework

Compared with other time-domain computational electromagnetic methods such as finite-difference time-domain-based methods and time-domain integral-equation-based methods, a time-domain finite-element method (TDFEM) [23] deals with sparse matrices as well as possessing increased capability in handling irregular geometries and arbitrary inhomogeneity. In this section, we outline the basic numerical scheme of the TDFEM.

The electric field \(\textbf{E}\) inside an IC and package problem satisfies the second-order vector wave equation

\[
\nabla \times \left(\mu_r^{-1} \nabla \times \textbf{E}(\mathbf{r}, t)\right) + \mu_0 \varepsilon \partial_t^2 \textbf{E}(\mathbf{r}, t) + \mu_0 \sigma \partial_t \textbf{E}(\mathbf{r}, t) = -\mu_0 \partial_t \textbf{J}(\mathbf{r}, t)
\]

subject to certain boundary conditions. In (10), \(\mu_r\) is the relative permeability, \(\mu_0\) is the free-space permeability, \(\varepsilon\) is the permitivity, and \(\sigma\) is the conductivity. The time-domain finite-element solution of (10) results in the following system of ordinary differential equations:

\[
\mathbf{T} \frac{d^2 \mathbf{u}}{dt^2} + (\mathbf{R} + \mathbf{Q} \frac{du}{dt}) + \mathbf{S} \mathbf{u} + \mathbf{f} = \mathbf{0} \tag{11}
\]

in which \(\mathbf{T}, \mathbf{R}, \mathbf{Q},\) and \(\mathbf{S}\) are square matrices, \(\mathbf{u}\) is the unknown field vector, and \(\mathbf{f}\) is the excitation vector. The elements of the matrices \(\mathbf{T}, \mathbf{R},\) and \(\mathbf{S}\) are given by

\[
T_{ij} = \mu_0 \varepsilon \langle \mathbf{N}_i, \mathbf{N}_j \rangle_V \\
R_{ij} = \mu_0 \sigma \langle \mathbf{N}_i, \mathbf{N}_j \rangle_V \\
S_{ij} = \mu_r^{-1} \nabla \times \mathbf{N}_i \cdot \nabla \times \mathbf{N}_j \rangle_V \tag{12}
\]

in which \(\mathbf{N}_i\) and \(\mathbf{N}_j\) are the vector basis functions used to expand unknown fields, and \(\langle \cdot , \cdot \rangle_V\) denotes volume integration. Matrix \(\mathbf{Q}\) is related to the absorbing boundary condition. If the first-order absorbing boundary condition is used to truncate the computational domain, the elements of \(\mathbf{Q}\) are given by

\[
Q_{ij} = \frac{1}{c} \left\langle \hat{n} \times \mathbf{N}_i, \hat{n} \times \mathbf{N}_j \right \rangle_S \tag{13}
\]

where \(c\) is the speed of light, \(\hat{n}\) represents a unit vector normal to the truncation boundary \(S\) and pointing outward, and \(\left\langle \cdot , \cdot \right \rangle_S\) denotes surface integration.

Adopting a central difference scheme to approximate the first- and second-order time derivatives in (11), we obtain

\[
\tilde{T} u^{n+1} = \left(2T - \Delta t^2 S\right) u^n + \left[0.5 \Delta t (R + Q) - T\right] u^{n-1} - \Delta t^2 f^n \tag{14}
\]

in which

\[
\tilde{T} = T + 0.5 \Delta t (R + Q) \tag{15}
\]

and \(\Delta t\) represents the time step. Obviously, \(u^{n+1}\) (the field value at the \((n+1)\)th time step) can be solved in a time marching fashion from the solution of \(u\) at previous time steps.

Matrix \(\mathbf{T}\) can be very large for realistic on-chip and package problems, which constitutes a computational challenge. This challenge can be overcome by the time-domain OrFE-RR method described in the following section.

B. OrFE-RR Method

We discretize the computational domain into layers of prism elements as shown in Fig. 2(a). Conductors are also discretized in order to capture the internal fields accurately. In each element, the electric field is expanded into orthogonal vector basis functions described in Section II. The unknowns are ordered layer by layer. In each layer, the unknowns are divided into surface and volume ones. As shown in Fig. 2(a), the unknowns associated with the horizontal edges are surface unknowns, and the unknowns associated with the vertical edges are volume unknowns. The unknowns are then ordered from \(S_1\) to \(V_1\) to \(S_2\) to \(V_2\) and so on, resulting in a 3-D layered system matrix shown in Fig. 2(b). In this matrix, all the \(D_l\) and \(A_l\) matrices are diagonal due to the orthogonality of the vector basis functions as shown in (8). Since the surface vector bases \(\mathbf{N}_i(i = 1, 6, 10, 15)\) are perpendicular to volume vector bases \(\mathbf{N}_i(i = 7, 9)\), as can be seen from Fig. 1, and \(\mathbf{T}\) in (15) solely comprises matrices formed by the inner product of \(\mathbf{N}_i\) and \(\mathbf{N}_j\), all the Q matrices in Fig. 2(b) vanish.

1) Reduction From a 3-D Layered System to a Single-Layer One That Is Diagonal in Negligible Computational Cost: Since all the Q matrices vanish, the 3-D layered system is naturally decomposed into a 2-D layered system formed by surface unknowns only, as shown in Fig. 3(a), and \(L\) decoupled matrices formed by volume unknowns in each layer only, as shown in Fig. 3(b). This step certainly is free of any CPU and memory cost. As a result, the matrix equation (14) is naturally decomposed into

\[
\mathbf{P}_S x_S = b_S, \quad \mathbf{P}_{V_l} x_{V_l} = b_{V_l}, \quad l = 1, 2, \ldots, L \tag{16}
\]

in which \(\mathbf{P}_S\) is the 2-D layered system shown in Fig. 3(a), \(\mathbf{P}_{V_l}\) is the volume-unknown-based system in layer \(l\) shown in Fig. 3(b), and \(x_S\) and \(x_V\) represent the surface and volume unknowns, respectively.
there is no need to perform matrix factorization and matrix-vector multiplication since $D_i$ and $\Lambda_i$ are diagonal.

The single-layer system can be further reduced to a single-interface system shown in Fig. 5, where

$$D_i' = D_i - \Lambda_i D_i^{-1} \Lambda_i$$

$$D_i'' = D_i' - \Lambda_i D_i'^{-1} \Lambda_i$$

$$b_{i,j}' = b_{i,j} - \Lambda_i b_{i,j-1}'$$

$$b_{i,j}'' = b_{i,j} - \Lambda_i b_{i,j-1}''$$

$$\begin{bmatrix} D_i \\ - \Lambda_i \end{bmatrix} \begin{bmatrix} x_{i,j} \\ x_{i,j+1} \end{bmatrix} = \begin{bmatrix} b_{i,j}' \\ b_{i,j+1}' \end{bmatrix}$$

Fig. 5. Reduced single-interface system.

Again, the operations in (19) and (20) only involve diagonal matrices, the cost of which is negligible. In addition, the reduced single-interface system is also diagonal and, hence, can be solved readily.

2) Recovery of Other Unknowns in Linear Complexity: Once the unknowns in the reduced system shown in Fig. 5 is known, the surface unknowns in other layers can be recovered from

$$x_{S,l} = D_l^{-1} [b_{S,l} - \Lambda_l x_{S,l+1}]$$

$$x_{S,l+1} = D_l^{-1} [b_{S,l+1}' - \Lambda_l x_{S,l}]$$

$$x_{S,l+1} = D_l^{-1} [b_{S,l+1}' - \Lambda_l x_{S,l}]$$

Clearly, the aforementioned operations have linear complexity due to diagonal matrices $D_i$ and $\Lambda_i$.

The volume unknowns are recovered layer by layer from

$$x_{V,l} = P_{V,l}^{-1} b_{V,l}$$

in which $P_{V,l}$ is assembled from

$$P_{V,l,ij} = h_l (\mu_0 e_l^t + 0.5 \Delta t \mu_0 \sigma_l^t) \langle \xi_i, \xi_j \rangle \Omega_l$$

$$l = 1, 2, \ldots, L$$

$P_{V,l}$ is a sparse matrix, the dimension of which is approximately half of the number of unknowns in a single layer. If the size of the single-layer system is small, $P_{V,l}$ can be readily solved. However, if the size of the single-layer system is large, solving $P_{V,l}$ can be a numerical challenge. In the following, we present an algorithm of solving $P_{V,l}$ in linear complexity.

Without loss of generality, assuming that the volume unknowns are assigned along the $z$-direction, Fig. 6(a) shows an $x$-$y$ cross-sectional view of these volume unknowns, in which each dot denotes a volume unknown. If the unknowns are ordered from line 1 to line 2 to line 3, and to line $N_z$, a $P_{V,l}$ matrix having the pattern shown in Fig. 6(b) will be generated. It is a block tridiagonal matrix. More importantly, each diagonal block is a tridiagonal matrix. The off-diagonal blocks are very sparse. For example, for the mesh shown in Fig. 6(a), each row has only two nonzero elements (or even less); one is the diagonal one, and the other is the super- or subdiagonal one.

To fully explore the structure of $P_{V,l}$ to expedite its solution, we split $P_{V,l}$ as the following:

$$P_{V,l} = P - L - U$$

where $P$ is the block diagonal matrix, $-L$ is the strict lower triangular part, and $-U$ is the strict upper triangular part. The matrix patterns of $P$, $L$, and $U$ are shown in Fig. 6(c). $L$ and $U$ are sparse matrices. For the mesh shown in Fig. 6(a), $L$ and $U$ are bidiagonal matrices.

The matrix $P$ serves as an effective preconditioner of $P_{V,l}$. It was shown by numerical experiments that, with $P$, the iterative process of solving (22) converges in a few iterations for the realistic on-chip and package examples we have tested.
By using $P$ as the preconditioner, (22) is solved iteratively as
\[ P x^{(k+1)} = (L + U)x^{(k)} + b_{V1}, \quad k \geq 0 \quad (25) \]
with $k$ being the iteration number. When (25) converges, $x^{(k+1)} = x^{(k)}$, and hence, $(P-L-U)x^{(k+1)} = b_{V1}$. From (24), it can be seen that $x^{(k+1)}$ is the solution of (22). In the Appendix, we give a proof to show that the iteration in (25) converges for any right-hand side $b_{V1}$ and any initial vector $x^{(0)}$.

Since $P_{V1}$ is a block tridiagonal matrix, (25) can be simplified to
\[ P_{ii}x_{i}^{(k+1)} = L_{i,i-1}x_{i-1}^{(k)} + U_{i,i+1}x_{i+1}^{(k)} + d_{i}, \quad 1 \leq i \leq N_{x} \quad (26) \]
in which $i$ denotes the line index and $P_{ii}$ denotes the $i$th diagonal block of $P$, which is formed by volume unknowns on line $i$. Since $P_{ii}$ is a tridiagonal matrix, as shown in [15], its inverse can be stored efficiently in two sequences $\{u_{j}\}$ and $\{v_{j}\}$, $j = 1, 2, \ldots, m$, with $m$ being the dimension of $P_{ii}$. Meanwhile, $P_{ii}^{-1}b$ can be performed in linear complexity [15].

3) **Performance Analysis:** The numerical procedure of the proposed OrFE-RR method can be summarized as follows.

Step 1) Reduce the original 3-D layered system matrix to a single-interface system (shown in Fig. 5) that is diagonal.

Step 2) Precalculate the inverse of $P_{ii}$ in (26). Beginning of the time marching.

Step 3) Solve the reduced system shown in Fig. 5 and obtain the solution of a single surface.

Step 4) Recover solutions of surface unknowns in all other layers using (21) and recover solutions of volume unknowns in all layers using (22).

Step 5) Construct the new right-hand side of (14) for the next time step. Go back to Step 3).

End of the time marching.

The computational cost of each step is analyzed as follows.

Step 1) The cost is negligible due to orthogonal prism vector basis functions that render $D_{i}$ and $\Lambda_{i}(l = 1, 2, \ldots, L)$ diagonal.

Step 2) Both memory and CPU costs are linear because $P_{ii}$ is a tridiagonal matrix. Assuming that the number of unknowns along a single line in Fig. 6(a) is $m$, the memory and CPU cost of calculating and storing $P_{ii}^{-1}$ is $O(m)$.

Step 3) The cost is negligible since the reduced system is diagonal.

Step 4) Both memory and CPU costs are linear.

Step 5) The cost is a few sparse matrix-vector multiplications, which has a linear complexity.

Overall, in the proposed OrFE-RR method, the reduction from a 3-D layered system to a single-layer one costs negligible computational resources; the reduced system is diagonal, and hence, its solution time is minimized; the complexity of recovery scales linearly with the number of unknowns to be recovered. The method applies to any arbitrarily shaped multilayer structure embedded in aninhomogeneous media. The time step permitted by this method is the same as that permitted by the conventional TDFEM schemes.

**IV. Numerical Results**

To validate the accuracy of the proposed time-domain OrFE-RR method, we first simulated a parallel-plate waveguide, the analytical solution of which is known. According to typical geometrical dimensions of on-chip problems, the waveguide width (along the $y$-direction) was set as 1 $\mu$m, the waveguide height (along the $x$-direction) was set as 0.1 $\mu$m, and the waveguide length (along the $z$-direction) was set as 3.5 $\mu$m. The structure was divided into 35 layers along the length. An incident transverse electric magnetic plane wave was launched at the near end of the waveguide (at $z = 0$). An exact absorbing boundary condition is placed at both the near and far ends of the waveguide to absorb the outgoing wave. The excitation was a time derivative of a Gaussian pulse $E_{inc}(t) = \hat{E}2t\exp(-t^{2}/\tau^{2})$, in which $\tau = 3.0 \times 10^{-13}$ s. The structure was discretized into triangular prism elements, resulting in 8067 unknowns. The time step was chosen as $0.7 \times 10^{-16}$ s. In total, 20000 time steps were simulated. The electric field at 1.7 $\mu$m was sampled. As can be seen from Fig. 7(a), the result obtained from the proposed OrFE-RR method shows an excellent agreement with the analytical solution. Fig. 7(b) and (c) shows the electric fields sampled at $z = 0.1, 1.7$, and 3.5 $\mu$m.
The waveforms and time delay obtained by the proposed method were compared with those simulated by a conventional TDFEM solver. The results are on top of each other.

With the accuracy validated, a test-chip interconnect structure with a length of 100 μm was simulated. The test-chip interconnect structure was fabricated using conventional silicon processing technology [14]. It comprised three metal layers and thirteen inhomogeneous dielectric stacks. The structure was divided into ten layers along its length, resulting in 30,973 unknowns. A current source was placed at the near end. The far end was left open. The time step used in this simulation is $1.2 \times 10^{-16}$ s. Fig. 8 shows the time-domain waveforms of the voltages sampled at the near and far ends of one wire in the interconnect structure. Fig. 9 shows the frequency-domain S-parameters obtained from the proposed method in comparison with the measured data. Excellent agreement is observed.

Next, a test-chip interconnect structure of 2000-μm length was simulated. The structure was discretized into 127,093 unknowns. The time step was chosen as $1.2 \times 10^{-16}$ s. The input current and the voltage waveforms sampled at the near and far ends of one wire in the interconnect structure are shown in Fig. 10, which demonstrates a clear inductance effect. The simulated S-parameters in comparison with the measured data are shown in Fig. 11. Again, excellent agreement is observed.

After demonstrating the accuracy of the proposed method, we tested its performance in comparison with the conventional TDFEM that employs a state-of-the-art multifrontal-based sparse matrix solver, UMFPACK [24]. The on-chip interconnect structure of 2000-μm length was chosen as the testing example. The meshing on the $xy$ plane was fixed while the number of layers along the length ($z$-direction) was varied to generate approximately 20,000 to 30 million unknowns. Fig. 12 shows the CPU and memory cost as a function of the number of unknowns. Obviously, the proposed method outperforms the conventional method in both CPU time and memory consumption. More importantly, the proposed method scales favorably with the number of unknowns. Since the cost of the reduction in the proposed method is negligible, the computation is solely spent on recovering $N$ unknowns of interest, which clearly shows a linear complexity as can be seen from Fig. 12. To be specific, Fig. 12(a) and (b) shows the CPU cost and memory...
Fig. 9. $S$-parameters of a 100-μm-long test-chip interconnect simulated by the proposed OrFE-RR method.

Fig. 10. Simulation of a test-chip interconnect of 2000-μm length. (a) Input current. (b) Voltages sampled at the near and far ends of one wire in the interconnect structure.
consumption in factorization, respectively. The conventional method has to factorize the entire system matrix \( \mathbf{T} \) in (15), whereas the proposed method only needs to invert \( \mathbf{P}_{ii}^{-1} \) in (26), which has a 1-D size and is tridiagonal. Fig. 12(c) shows the matrix solving time. The conventional method has to perform backward–forward substitutions of a matrix that has a 3-D size, whereas the proposed method deals with the multiplication of \( \mathbf{P}_{ii}^{-1} \) with a vector, which has a 1-D size, and, moreover, can be done in linear complexity.

In Fig. 12, the complexity curve of the conventional TDFEM solver was not drawn to the end because, when the number of layers exceeded 100, yielding more than \( 1.5 \times 10^5 \) unknowns, the conventional solver based on [24] failed to factorize the system matrix. In addition, from Fig. 12, it can be seen that, even if the number of unknowns is in the range that the conventional solver is applicable, the complexity is not linear.

The convergence performance of the iterative solution of (22) is shown in Fig. 13. Clearly, the proposed method only requires a few iterations to achieve good accuracy when recovering volume unknowns.

Next, we tested the capability of the OrFE-RR method in modeling irregular geometry. A real package structure (provided by Intel Corporation) was simulated. The structure involved a bottom ground plane with via holes, a center via layer consisting of both power and ground vias, and a top power plane with via holes, occupying an area of \( 2500 \times 2500 \) \( \mu m \). A bottom negative supply voltage (VSS) via was excited by a current source. An unstructured mesh was used to capture the irregular geometry of the vias and holes. The voltage maps of the positive supply voltage (VCC) and VSS package planes were shown in Fig. 14(a) and (b). Although it was the VSS via that was excited, the coupling to the VCC plane can be clearly seen.

We then simulated a \( 2500 \times 2500 \) \( \mu m \) combined die–package power delivery system. An illustration of this example is shown in Fig. 15. The package structure was kept the same. Three on-chip layers were added. VCC and VSS vias traversed via holes and contacted package planes. The on-chip power rails were connected through on-chip vias. A current source was launched at a VSS via from the silicon. In Fig. 16, the dynamic voltage maps of the package and on-chip layers were plotted at the 6000th time step. In this simulation, a time step of \( 2.5 \times 10^{-15} \) s was used. The CPU cost at each time step was 0.51846 s.

V. Conclusion

In this paper, a set of orthogonal prism vector basis functions have been developed. These bases are complete in representing fields. In addition, they enforce the tangential continuity of the electric field and the normal continuity of the electric flux across material interfaces. Based on this set of bases, a time-domain OrFe-RR method was developed to solve large-scale IC and package problems. This method is capable of reducing a 3-D layered system matrix to a single-layer system matrix with negligible cost, irrespective of the original problem size. In addition, the reduced single-layer system matrix is diagonal, and hence, can be solved readily. From the solution of the reduced system, the solutions of other unknowns are recovered in linear complexity. The method applies to any arbitrarily shaped multi-layer structure involving inhomogeneous materials. It entails no theoretical approximation. Numerical and experimental results have demonstrated its superior performance in simulating on-chip, package, and combined die-package problems.

APPENDIX

Define a sequence of iterations of the form

\[ x^{(k+1)} = G x^{(k)} + f \]

in which \( G \) is a square matrix. It is known that, if the spectral radius of \( G \), denoted by \( \rho(G) \), is less than 1, then \( I - G \) is nonsingular, and the iteration in (A.1) converges for any \( f \) and \( x^{(0)} \) [25].

From (25), it can be seen that \( G \) in our iteration scheme is

\[ G = P^{-1}(L + U). \]

Denoting the eigenvalues of \( G \) by \( \lambda \), we have

\[ G v = \lambda v \]

in which \( v \) denotes the eigenvector. From (A.2) and (A.3), we obtain

\[ (L + U)v = \lambda P v. \]

Taking a norm on both sides of (A.4), we obtain

\[ |\lambda| = \frac{\| (L + U)v \|}{\| P v \|} \]

in which \( \| (\cdot) \| \) denotes the norm of \( (\cdot) \). Without loss of generality, the 1-norm of a vector is used, which is

\[ \| g \|_1 = \sum_{i=1}^{m} |g_i| \]

where \( m \) is the length of vector \( g \). If \( \| (L + U)v \| \) is less than \( \| P v \| \), then the modulus of \( \lambda \) is less than 1, then \( \rho(G) < 1 \), and then the convergence of (25) is proved.

Matrices \( L \) and \( U \) are the off-diagonal blocks of \( P_{VL} \), and \( P \) is the diagonal block. From (23), the matrix elements of \( P_{VL} \) can be written as

\[ P_{VL,mn} = h_t (\mu_0 \varepsilon T + 0.5 \Delta t \mu_0 \sigma T) \langle \xi_m, \xi_n \rangle_{\Omega e} \]
Fig. 15. Illustration of the die–package power delivery example. (a) Top view from the package side (Big circles are holes; small circles are sampled via contacts). (b) Bottom view from the on-chip side.

Fig. 16. Simulation of a 2500 × 2500-μm combined die–package system. (a) Voltage map of an on-chip layer (both VSS and VCC wires are shown). (b) Voltage map of the second on-chip layer (both VSS and VCC wires are shown). (c) Voltage map of a package VCC plane. (d) Voltage map of a package VSS plane.
where

\[ \langle \xi_m, \xi_n \rangle_\Omega = \begin{cases} \frac{\Delta}{12}, & m = n \\ \frac{\Delta}{12}, & m \neq n \end{cases} \tag{A.8} \]

in which \( \Delta \) is the area of a triangular element \( e \). Hence, \( P_{Vl,mn}^e \) can be denoted by

\[ P_{Vl,mn}^e \sim \begin{cases} t, & m = n \\ t/2, & m \neq n \end{cases} \tag{A.9} \]

in which

\[ t = h_t (\mu_\sigma \varepsilon_t^2 + 0.5\Delta t\mu_0 \sigma^2) \frac{\Delta}{6}. \tag{A.10} \]

With the matrix elements of \( P_{Vl} \) known, \( \| (L + U)v \| \) and \( \| Pv \| \) can be derived. Since \( P \) is tridiagonal and symmetric, \( \| Pv \| \) can be written as

\[ \| Pv \| = \sum_{m=1}^{M} \| P_{Vl,m,m-1}v_{m-1} + P_{Vl,m,m}v_m + P_{Vl,m,m+1}v_{m+1} \|. \tag{A.11} \]

Considering an arbitrary volume unknown denoted by node \( m \) in Fig. 17, assuming that the mesh is reasonably good, and hence, the sizes of all the elements are similar, we obtain

\[ P_{Vl,m,m} \sim n_e t \tag{A.12} \]

in which \( n_e \) is the number of triangular elements that own node \( m \) as one of their vertices. In (A.12), \( P_{Vl,m,m} \) is obtained by assembling the contribution from \( n_e \) elements. Based on our unknown ordering scheme, nodes \( m - 1, m, \) and \( m + 1 \) all reside on the same line, as shown in Fig. 17. Since nodes \( m \) and \( m - 1 \) can only be simultaneously shared by two elements and so are nodes \( m \) and \( m + 1 \), \( P_{Vl,m,m-1} \) and \( P_{Vl,m,m+1} \) are assembled from two elemental contributions as

\[ P_{Vl,m,m-1} \sim t \]

\[ P_{Vl,m,m+1} \sim t. \tag{A.13} \]

Therefore, (A.11) can be written as

\[ \| Pv \| = \sum_{m=1}^{M} [(t)v_{m-1} + (n_et)v_m + (t)v_{m+1}] \|. \tag{A.14} \]

Since nodes \( m - 1 \) and \( m + 1 \) are adjacent to node \( m \), the eigenfield \( v \) at these two nodes can be estimated by \( v \) at node \( m \).

Hence

\[ \| Pv \| \sim \sum_{m=1}^{M} (n_e + 2)t \| v_m \|. \tag{A.15} \]

As shown in Fig. 17, node \( m \) not only interacts with the adjacent two nodes residing on the same line but also interacts with nodes residing on the line left to it and the line right to it. The interaction with the nodes residing on the left line is characterized by \( L \) and that with the nodes residing on the right line is characterized by \( U \). Therefore, \( L \) and \( U \) consist of matrix elements \( P_{Vl,m,n} \) in which node \( n \) resides on the adjacent lines and connects directly to node \( m \) through one edge. Assuming that the number of nodes \( n \) is \( n_p \), \( \| (L + U)v \| \) can be evaluated by

\[ \| (L + U)v \| = \sum_{m=1}^{M} \sum_{n=1}^{n_p} \sum_{n=1}^{n_p} P_{Vl,m,n}v_n = \sum_{m=1}^{M} \sum_{n=1}^{n_p} (t)v_n \|. \tag{A.16} \]

Since the \( n_p \) nodes are adjacent to node \( m \), (A.16) can be estimated as

\[ \| (L + U)v \| \sim \sum_{m=1}^{M} n_p \| v_m \|. \tag{A.17} \]

Take the mesh shown in Fig. 17 as an example. \( n_p = 4 \) (the number of circled nodes), and \( n_e = 6 \); hence, from (A.15) and (A.17), \( \| (L + U)v \| < \| Pv \| \).

There exists a general relationship between \( n_p \) and \( n_e \)

\[ n_e = 2 \left( \frac{n_p}{2} + 1 \right) = n_p + 2. \tag{A.18} \]

Hence, from (A.15) and (A.17), the following inequality always holds true:

\[ \| (L + U)v \| < \| Pv \|. \tag{A.19} \]

Therefore, from (A.5), \( \rho (G) < 1 \). Hence, the iteration in (25) converges for any \( b_{Vl} \) and any initial vector \( x^{(0)} \).

ACKNOWLEDGMENT

The authors would like to thank Dr. M. J. Kobrinsky and Dr. S. Chakravarty of Intel Corporation for providing the measured data and Dr. W. Shi of Intel Corporation for providing the package structures.
