We present, experimentally and numerically, the observation of Fermi-Pasta-Ulam recurrence induced by breather solitons in a high-Q SiN microresonator. Breather solitons can be excited by increasing the pump power at a relatively small pump phase detuning in microresonators. Out of phase power evolution is observed for groups of comb lines around the center of the spectrum compared to groups of lines in the spectral wings. The evolution of the power spectrum is not symmetric with respect to the spectrum center. Numerical simulations based on the generalized Lugitato-Lefever equation are in good agreement with the experimental results and unveil the role of stimulated Raman scattering in the symmetry breaking of the power spectrum evolution. Our results show that optical microresonators can be exploited as a powerful platform for the exploration of soliton dynamics.

DOI: 10.1103/PhysRevLett.117.163901

The Fermi-Pasta-Ulam (FPU) recurrence was first raised by Fermi and his colleagues in the 1950s [1]. In a numerical simulation of string oscillation with nonlinear coupling between different modes to test thermalization theory, they found that at a certain point the energy will return to the fundamentally excited mode, rather than distributing homogeneously among different modes. This discovery triggered the rigorous investigation on plasma physics by Zubusky and Kruskal [2], which led to the discovery of solitons. Solitons and their related theory have revolutionized the research in diverse arenas, including fluid dynamics [3], optics [4,5], and Bose-Einstein condensation [6,7].

In optics, the FPU recurrence was first demonstrated based on the modulation instability (MI) in optical fibers [8]. As a feature of the FPU recurrence, the powers of the pump mode and the signal mode in MI evolve periodically with a phase delay of $\pi$. The collision between solitons in fibers also facilitated the observation of FPU recurrence in an active cavity [9]. Furthermore, optical breathers, e.g., the Akhmediev breather (AB) in the nonlinear Schrödinger equation (NLSE) [10–12], are an important manifestation of FPU recurrence. Since collisions between breathers and solitons can result in optical rogue waves [13–15], studying FPU recurrence and the control of the transition between solitons and breathers may contribute to the understanding of optical rogue waves.

Recently, maturity in the fabrication of high-Q microresonators [16] has fueled rapid progress on Kerr frequency comb generation [17–22]. In the frequency domain, microresonator-based frequency comb synthesis has promising applications in optical clock [23], optical arbitrary waveform generation [24], microwave photonics [25,26], etc. In the time domain, microresonators provide a new and important approach for realizing optical solitons [21,27–30]. Unlike mode-locked lasers, passive microresonators have no active gain or saturable absorber, freeing them from the influence of the complex gain dynamics. Hence, soliton generation in microresonators can exhibit excellent predictability. Moreover, the bandwidth and peak power of the soliton can be controlled by varying the pump phase detuning [21,28,31]. The ability to accurately predict and control soliton dynamics in microresonators accurately will make microresonators a versatile test bed for the study of fundamental soliton physics, including the FPU recurrence. Moreover, breather solitons, which can exhibit FPU recurrence, have been widely predicted in microresonators [32–37], but they still lack rigorous experimental investigation, to our knowledge.

In this Letter, we present the observation of FPU recurrence induced by breather solitons in a silicon-nitride (SiN) microresonator. By controlling the pump condition, we can excite the breather soliton in the microresonator and show that the power evolution for the comb lines at the center and the wing is out of phase. We also observe that the spectral breathing is not symmetric with respect to the spectrum center and identify that stimulated Raman scattering (SRS) is responsible for the symmetry breaking. Both the recurrence and the symmetry breaking are well described by numerical simulations based on the generalized Lugitato-Lefever equation (LLE), including the Raman effect [36–40]. The observation of FPU recurrence in microresonators will improve our understanding of nonlinear systems and breather theory. Furthermore, it also gives more insight into the different operating regimes of...
Kerr frequency combs and adds to the understanding of soliton mode locking in microresonators.

The experimental scheme is shown in Fig. 1(a). An on-chip SiN microresonator is used for the generation of the Kerr frequency comb and the breather soliton. When the microresonator is pumped by a continuous-wave laser, the power enhancement inside the cavity initiates parametric oscillation and frequency comb generation under moderate pump power. In our experiments, we use an anomalous dispersion microresonator, whose dimensions are 800 × 2000 nm with a radius of 100 μm, to generate the Kerr frequency comb. A notch filter (1550 nm, 4 nm bandwidth) is used to suppress the strong pump line by over 35 dB. Figure 1(a) also illustrates the operating regimes of Kerr frequency combs and the experimental method to excite the breather soliton. The breather soliton regime is close to the soliton regime and breather solitons are generated at relatively small pump phase detuning and high pump power [31,33]. Therefore, we have three steps for generating the breather soliton: (I) tune the laser to generate the soliton, (II) tune the pump laser backward several picometers to lower the excitation threshold of breather solitons (see Fig. S1 in the Supplemental Material [41]), and (III) increase the pump power to excite the breather soliton.

For phase (I), stable solitons can be generated by scanning the laser across the cavity resonance from blue side to red side [21]. To overcome the transient instability in soliton generation in SiN microresonators, the laser is tuned backward after crossing the cavity resonance [29,44]. This backward tuning also gives access to a single soliton. At a pump power of ~300 mW (in the bus waveguide), when pumped around 1551.28 nm, a stable single soliton is generated in the microresonator. The comb has a well-defined sech² spectrum [Fig. 1(b)] and low intensity noise [Fig. 1(c)]. There are some spectral jumps on the optical spectrum, which can be attributed to the mode interaction; however, they will not change the soliton property significantly [28,29,45], qualitatively different from the multi-phase-step combs in Ref. [46].

Soliton behavior in microresonators is governed by the LLE [38,47]. For SiN microresonators, SRS is important in determining the property of solitons [29,36,39,40]. Hence, we use the generalized LLE, with SRS included, to describe the soliton generation,

\[
\frac{\partial}{\partial t} \left( \tau_0 + \frac{\alpha + \theta}{2} + i\delta_0 + \frac{\beta_2 L}{2} \frac{\partial^2}{\partial \tau^2} \right) E - i(1 - f_R)\gamma |E|^2 E - if_R L \left( E \int_{-\infty}^{\tau} h_R(\tau - \tau')|E|^2 d\tau' \right) - \sqrt{\theta} E_{in} = 0, \tag{1}
\]

where \(E\) is the envelope of the intracavity field, \(\tau_0\) is the round-trip time (4.5 ps), \(L\) is the length of the cavity, \(t\) and \(\tau\) are the slow and fast time, respectively, \(\alpha\) and \(\theta\) are the intrinsic loss and the external coupling coefficient, respectively, \(\beta_2\) is the group velocity dispersion, \(\gamma\) is the nonlinear coefficient, \(\delta_0\) is the pump phase detuning, \(|E_{in}|^2\) is the pump power, and \(h_R(\tau)\) is the Raman response function. In simulations, the Raman effect is calculated in the frequency domain, with a Lorentzian gain spectrum [48], whose peak is centered at −14.3 THz and bandwidth is 2.12 THz. When choosing \(\alpha = 0.0024\), \(\theta = 0.0004\), \(\beta_2 = -81 \text{ ps}^2/\text{km}\), \(\gamma = 0.9 \text{ W/m}\), and \(f_R = 0.13\) and setting the pump condition at 220 mW and having \(\delta_0 = 0.022\), a stable soliton is generated whose spectrum is shown by the red line in Fig. 1(b), in close agreement with the experiments. The difference in the amplitude of the pump line results from the strong directly transmitted pump, superimposed on the output comb. A closer agreement can be reached if we include a small third order dispersion (TOD). However, to rule out the role of the TOD in the symmetry breaking of the spectral breathing
After the generation of stable solitons, we follow the road map shown in Fig. 1(a) to generate the breather soliton. By tuning the laser backward several picometers further and increasing the pump power to \( \sim 430 \) mW, the breather soliton can be excited (see Sec. III of the Supplemental Material [41] for the transition dynamics from stable solitons to breather solitons). The breather soliton state is identified by the sharp peak in the rf spectrum [Fig. 1(e)]. Note that the breathing frequency is nearly 4 times the linewidth of the pumped resonance (100 MHz). From our measurements, the modulation depth of the converted comb lines, defined as \( (P_{\text{max}} - P_{\text{min}})/(P_{\text{max}} + P_{\text{min}}) \), with \( P_{\text{max(min)}} \) being the maximum (minimum) average power, is \( \sim 50\% \). Similar narrow rf peaks were observed in normal dispersion microresonators and interpreted as a dark breather pulse [22]. Narrow rf peaks have also been reported recently in anomalous dispersion Si and SiN microresonators [49]. The spectrum of the breather solitons becomes sharper at the top of the spectrum compared to the soliton spectrum. In simulations, breather solitons can be generated by decreasing \( \delta_0 = 0.014 \) and increasing the pump power to 360 mW. The averaged spectrum (averaging over a slow time \( \tau \)) of the simulated breather soliton is shown by the red line in Fig. 1(d), which reproduces the sharp top of the experimental spectrum. The breather soliton retains a Raman induced frequency shift, implying that the breather soliton remains as a pulse, as chaotic waveforms do not exhibit the frequency shift [39]. The autocorrelation trace also provides evidence of pulse-like behavior (see Sec. 4 of the Supplemental Material [41] for further temporal details and a discussion of temporal breathing). Furthermore, the excitation process is reversible; i.e., we can return to the soliton state from the breather soliton state by manually decreasing the pump power.

To test the FPU recurrence induced by breather solitons, we use a pulse shaper [50] to select out some specific comb lines to record the fast evolution of the breathing spectrum. The pulse shaper has a transmission bandwidth ranging from 1530 to 1600 nm, with the ability to programmably select out specific comb lines. For synchronization between different spectral slices, a portion of the output comb is used as a reference signal to trigger the oscilloscope [PD1 in Fig. 1(a)]. We use the pulse shaper to select out either nine comb lines around the center of the spectrum (\( \sim 1560 \) nm, 9 nm to the red of the pump) or the remaining 31 comb lines (but not the pump line) within the passband of the pulse shaper in the short and long wavelength wings.

The recorded traces for the comb lines around the center and the comb lines in the wings are depicted in Fig. 2(a). The power change of the comb lines around the center is nearly out of phase with the comb lines in the wings, a signature of FPU recurrence. Because of the low power of a single comb line after the pulse shaper and its fast breathing rate (\( < 1 \mu \text{W}, > 350 \text{ MHz} \)), the recorded trace shows some distortions. However, the breathing exhibits good periodicity [see Fig. 1(e)], allowing numerical filtering of the signal. Here, we record the traces over 4 \( \mu \text{s} \), corresponding to more than 1000 breathing cycles; the rf spectrum computed from the recorded trace for the wing is shown in the inset of Fig. 2(a). The strongest rf tone is selected by a 20 MHz bandpass filter (BPF) is used to select the strongest rf tone. (b) Reconstructed comb line power evolution after numerical filtering. The blue (orange) shaded regions illustrate the time slots where the power flows toward the center (wing). Center (blue lines), comb lines within 1553–1569 nm; wing (orange lines), comb lines within 1530–1550 nm and 1569–1600 nm.

![FIG. 2. (a) The recorded fast evolution of the comb lines around the center and in the wings of the spectrum. (Inset) The rf spectrum of the power evolution measured over 4 \( \mu \text{s} \) for comb lines in the wings. A 20 MHz bandpass filter (BPF) is used to select the strongest rf tone. (b) Reconstructed comb line power evolution after numerical filtering. The blue (orange) shaded regions illustrate the time slots where the power flows toward the center (wing). Center (blue lines), comb lines within 1553–1569 nm; wing (orange lines), comb lines within 1530–1550 nm and 1569–1600 nm.](image-url)
with respect to the spectrum center is also in agreement with Fig. 3. As shown in Fig. 4(b), the comb lines at the center and in the wing show out of phase evolution and FPU recurrence, similar to the experiment. However, the comb lines far away from the center (beyond the bandwidth of our commercial pulse shaper) breathes with the phase delay of $2\pi$, i.e., the same phase. This is verified by recording and numerically filtering the evolution recorded for comb lines at the long and short wavelengths selected using a homebuilt pulse shaper; see Fig. 4(c). Furthermore, the simulation also shows the mode-interaction induced spectral jumps in Fig. 1(d) have negligible influence on the breathing dynamics (see Sec. 6 in the Supplemental Material [41]).

To further unveil what causes the asymmetric breathing for the breather solitons, we turn off the SRS term in the simulation. The breather soliton can still be excited under the same pump condition. However, the breathing dynamics in Fig. 4(d) are symmetric with respect to the center of the spectrum (coinciding with the 1551 nm pump, as there is no SRS induced soliton frequency shift). The comparison with Fig. 4(a) reveals that SRS is responsible for the symmetry breaking in the breathing dynamics observed in Fig. 3. SRS is generally significant for SiN microresonators [29,39]. However, in fluoride microresonators, SRS is much weaker [21]; hence, symmetric breathing of the solitons can be expected.

For the breather in the microresonator, one significant difference from ABs is that the energy in the wing of the spectrum can return to a group of several modes around the center [see Fig. 2 and Fig. 4(b)], while energy returns to the single pump for ABs. This is because the breather in microresonators remains a pulse during evolution, while ABs fully recover to be a continuous wave in FPU recurrence. This difference shows how the soliton dynamics in the framework of the LLE are distinct from those in the NLSE and illustrate how the dissipative effects and SRS break the integrability of the system and affect the breather behavior.

In conclusion, we observe breather solitons and FPU recurrence in an on-chip SiN microresonator. Breather solitons can be excited at high pump power and small detuning. By selecting out two groups of comb lines around the center and in the wing, we find that the energy returns to the center and flows out from the center periodically. Furthermore, we show that SRS breaks the symmetry of the spectral breathing. Our results show how the dissipative effects and SRS affect the breather properties and can contribute to the understanding of breathers and the operation of Kerr frequency combs. Furthermore, the observation of FPU recurrence in microresonators shows that on-chip microresonators can be used as a powerful platform to explore soliton physics.
